This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

A
DICTIONARY
OF
APPLIED CHEMISTRY.

SODIUM. Sym. Na. At.wt. 23·00.

Occurrence. Sodium is one of the commonest and most widely disseminated elements, constituting about 2½ p.c. of the solid crust of the earth. It occurs in nature in large quantities as chloride, constituting the mineral *rock-salt* or *halite*, of which very large deposits exist at Stassfurt in Germany, Northwich in Cheshire, Salzburg in Austria, and many other localities. As sodium nitrate or Chile saltpetre it forms deposits several feet thick in the rainless districts of northern Peru, and a double fluoride of aluminium and sodium (Na_3AlF_6) called *cryolite*, occurs in considerable quantity in Greenland. It is also found in nature, although in smaller quantity, as the sulphate *glauberite* $Na_2SO_4,7H_2O$; as the sesquicarbonate *trona*

$$Na_2CO_3,NaHCO_3,2H_2O,$$

and as *borax* or *tincal* $Na_2B_4O_7,10H_2O$, as a deposit in the beds of certain dried-up lakes. Many rock-forming minerals contain sodium, the most important being *albite*, soda-felspar $NaAlSi_3O_8$, *labradorite*, *oligoclase*, *sodalite*

$$Na_4(AlCl)Al_2(SiO_4)_3,$$

and *nepheline* $K_2Na_6Al_8Si_9O_{34}$, whilst it is an essential constituent of many zeolites, such as *analcime* $NaAlSi_2O_6,H_2O$, and *natrolite*

$$Na_2Al_2Si_3O_{10},2H_2O.$$

Sea water contains about 2·6 p.c. of sodium chloride, and many mineral springs and certain lakes also hold a considerable amount of this substance in solution.

Preparation of metallic sodium. A short account of the history and earlier methods for the preparation of metallic sodium has been given under POTASSIUM.

The first impulse to the preparation of sodium on a manufacturing scale was given by Deville (De l'Aluminium, Paris, 1859, 60, 120; Ann. Chim. Phys. 1856, [iii.] 46, 415; Dingl. poly. J. 134, 369; 141, 303), who employed it to replace potassium in the manufacture of aluminium. He obtained it by exposing a previously calcined mixture of sodium carbonate, coal, and chalk or lime to a white heat in wrought-iron retorts set in a furnace. Sodium distilled over, and was collected in flat receivers of peculiar shape, designed so as to offer a large condensing surface and by rapid cooling of the vapour prevent the formation of explosive compounds of the metal and carbon monoxide, although the liability to the formation of these bodies is much less than in the case of potassium. The method, however, was very costly and uneconomical, as only about one-third of the theoretical yield of sodium could be obtained.

A material improvement on this process was effected by Castner (D. R. P. 40415, 1886) in 1886, who replaced the sodium carbonate by caustic soda, and heated this with powdered carbide of iron (prepared by adding finely-divided iron to melted pitch, and coking the mixture in cylinders). This process was successfully worked on the large scale for some time and effected a considerable reduction in the price of sodium, but was eventually superseded by another process, also introduced by Castner, consisting in the electrolysis of fused caustic soda. This obviated many of the difficulties met with in the older purely chemical processes, and enabled sodium to be produced in large quantities at a relatively small cost. At the present time the whole of the sodium of commerce is manufactured electrolytically.

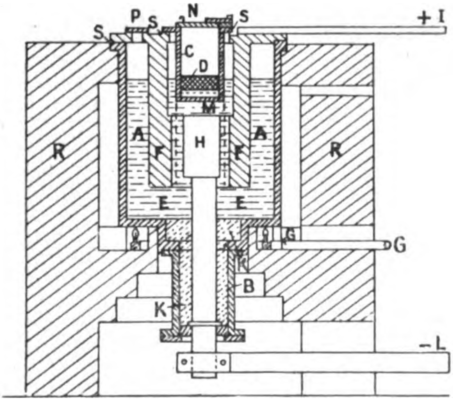

FIG. 1.

The apparatus employed by Castner (J. Soc. Chem. Ind. 1891, 777) is shown in the accompanying diagram (Fig. 1). It consists of an iron vessel A, mounted in brickwork R, in which the caustic soda is melted by means of the gas burners G. The vessel A is provided with one or more extension pipes B, through which the metallic negative electrode H passes, the intervening space K being filled with molten caustic which becomes set, and seals H in position. Immediately above this electrode is fixed a tubular iron receptacle C, fitted with a lid, N, and having a cylindrical piece of wire gauze, M, attached to its lower end. This gauze surrounds H, and rests between it and the positive electrode F. P is an opening for the escape of gas and for the insertion of a thermometer, and S is an insulating medium such as asbestos. The current is supplied through the conductors I and L. On passing the current the fused caustic soda is decomposed, and the liberated sodium D, being specifically lighter than the electrolyte, rises to the surface of the caustic in C, whence it is removed from time to time by a perforated iron spoon which allows the molten caustic to drain through while retaining the metal. Fresh caustic soda is added to the bath from time to time, thus rendering the process continuous. The size of the electrodes and their distance apart must be in proportion to the strength of the current employed. If they are too large, a quantity of the liberated sodium will dissolve in the bath and be lost through recombination, and if too small the resistance will be so increased that the bath becomes unduly heated. Any increase of temperature is followed by a proportionate loss of product and waste of energy; but it is possible so to adjust the electrical current and the quantity of alkali forming the electrolyte that the proper temperature will be maintained in a previously melted bath without applying external heat, or even by an increase of current to melt the bath, subsequently reducing the current until the proper working temperature is obtained. The apparatus is also frequently water-jacketed to assist in maintaining an even temperature. In order to secure a fair yield of the metal for the current applied it is necessary that the temperature of the electrolyte should not rise more than 20° above the melting-point of the alkali, *i.e.* should not exceed 330°. A current of 1000–1200 ampères with an E.M.F. of 4–5 volts is usually employed. Theoretically only oxygen should be liberated at the anode and sodium at the cathode; but in practice a certain quantity of hydrogen is always evolved at the cathode as well, owing to the electrolysis of the water formed in the process.

$$2OH=H_2O+O$$
$$H_2O=H_2+O.$$

Slight but harmless explosions of the hydrogen and oxygen formed sometimes take place. As one equivalent of water is produced for every two equivalents of sodium hydroxide decomposed, it is not possible to obtain more than 50 p.c. of the theoretical yield of sodium, the yield in actual working being usually nearer 40 p.c.

The Castner process is worked in England at Wallsend-on-Tyne by the Castner Kellner Co., and in Germany by the Farbwerke von Meister, Lucius & Brüning at Höchst am Main, and by the Elektrochemischen Werke Natrium at Rheinfelden. It is also operated by the Compagnie d'Electrochimie at Gavet in France, and by the Electrochemical Co. at Niagara Falls, U.S.A.

Another apparatus for the production of sodium by the electrolysis of fused caustic soda is that of Rathenau and Suter, which is used by the Electrochemischen Werke, Bitterfeld, Germany. The negative electrodes are allowed just to dip into the molten electrolyte contained in the iron vessel (Fig. 2). The surface tension causes the electrolyte to rise up slightly, so that the electrodes are not actually below the surface of the molten caustic. Metallic sodium is produced at the ends of the electrodes and partially solidifies; it is then removed by means of perforated ladles as in the Castner process. The current density in this process must not exceed 10 ampères per sq. cm.

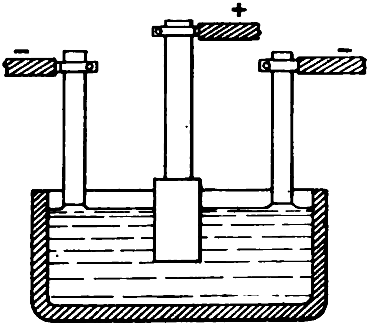

FIG. 2.

A slightly different process is that of Becker, worked by the Usines de Rioupéroux in France, a mixture of sodium carbonate and caustic soda being electrolysed in the decomposition cell shown in the following diagram (Fig. 3).

The cathode B is cone-shaped, and the sodium as it is produced rises to the collecting hood *d*, made of iron or ferronickel, and connected to the negative electrode through a resistance, so that when the metallic sodium comes into contact with the sides of the hood it is in electrical connection with the cathode, and is not further acted on by the molten electrolyte. The

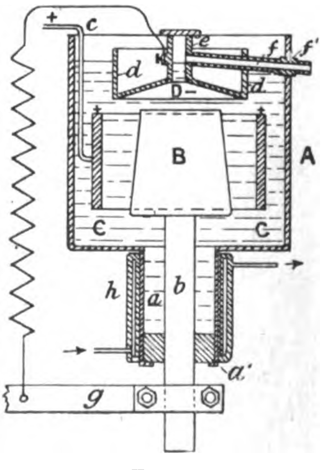

FIG. 3.

sodium being specifically lighter than the electrolyte rises in the hood and flows out through *f*. The hood *d* is cooled either by water or simply by a current of air circulating round it, so as to prevent the metal distilling over in vapour through the tube *f*, should the temperature rise too high. The temperature of the bath (550°) is much higher than in the Castner process, owing to the sodium carbonate raising the melting-point of the electrolyte. Each cell requires a current of 1250 ampères, and produces 40 kilos. of sodium in 24 hours.

The process of Darling, worked at Philadelphia, U.S.A., differs from the preceding ones in that the electrolyte consists of fused sodium nitrate. As the liberated sodium would react with the nitrate to form sodium nitrite, a divided cell is used, the anodic compartment containing fused sodium nitrate, while the electrolyte in the cathode cell consists of fused caustic soda. The Na cations are liberated at the kathode, and the NO$_3$ anions split up at the anode into NO$_2$ and O, which are passed into water to form nitric acid. The apparatus employed in the process is depicted in the accompanying diagrams (Figs. 4 and 5).

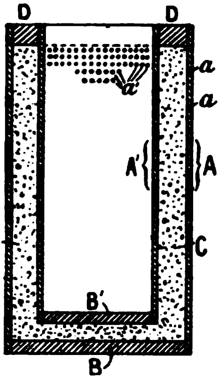

FIG. 4.

It consists of an inner cell (17) of perforated sheet iron, which is placed in an outer cell also of perforated iron, the intervening space being filled with a mixture of Portland cement and magnesia. This cell is used as the cathode compartment, and is filled with fused caustic soda. It is placed within a closed iron vessel (7), which contains molten sodium nitrate. The cathode compartment is surrounded by the iron anode formed by the cell (7), the bottom of this latter being covered to a depth of 6 ins. with Portland cement, upon which the inner cell rests. The iron outer cell (7) is connected with the positive source of current, the cathode being the 4-in. iron tube (22). About 5 p.c. of the total current is allowed to pass through the metal diaphragm (17) by means of a regulating resistance (31), and although this causes a waste of energy it greatly prolongs the life of the cell. Any gases which are generated escape by the pipe (27). At the commencement of the electrolysis the charge must be melted by applying external heat. Fresh charges of sodium nitrate are introduced into the anodic compartment from time to time, and the process thereby rendered continuous. In actual practice twelve such cells are worked together, each one taking 400 ampères at 15 volts.

Many attempts have been made to employ the cheaper sodium chloride as an electrolyte in the production of metallic sodium, but with only partial success. The chief drawback lies in the high temperature necessary to maintain the bath properly fused. At this temperature the liberated sodium unites with the excess of sodium chloride to form the so-called sodium subchloride, which either undergoes oxidation at the surface of the mass, or unites with the chlorine set free at the anode to reform the original NaCl. The intense activity of the liberated chlorine is a further objection to the process. Various attempts have been made to lower the fusing-point of the electrolyte by the addition of various salts, the most successful being that of Grabau, whose process was formerly worked commercially. It consisted of the electrolysis of a mixture of sodium chloride with either potassium chloride or alkaline earth chlorides. The addition of sodium fluoride has also been tried (Konsort. für Elektrochemie Nürnberg, D. R. P. 160540, 1904).

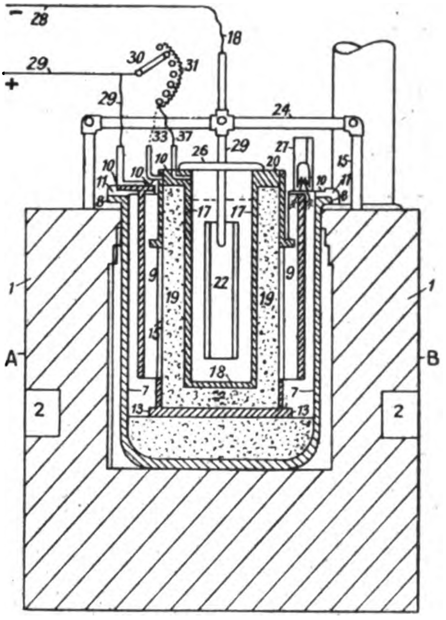

FIG. 5.

A list of patents relating to the manufacture of metallic sodium, together with an indication of the improvements claimed, is given below:—

J. Dickson, Eng. Pat. 2266, 1862 (electrolysis of the fused chloride); E. Sonstadt, Eng. Pat. 1763, 1863 (replacement of the chalk or lime in the ordinary process by gypsum); J. Anderson, Eng. Pats. 2801, 1867; 2134, 2216, 3493, 1871; 513, 1089, 1872 (heating the slag obtained by the action of hot air or steam on strongly-heated minerals containing silicates of sodium or potassium with carbon in a current of highly heated carbon monoxide); H. Larkin and W. White, Eng. Pats. 1990 and 3505, 1869; 23, 1871 (modification of the distillation process); W. Clark, Eng. Pat. 473, 1875 (electrolysis by a specially arranged current); W. Anderson Smith, Eng. Pat. 363, 1876 (use of a mixture of soda or potash with pitch, also a modified retort and condenser); W. P. Thompson, Eng. Pat. 2101, 1879 (decomposition of the hydroxide by fluid iron in a Bessemer converter); C. A. Faure, Eng. Pat. 6058, 1882, and 5489, 1883 (heating the alkaline compound in hydrogen or nitrogen by an electric current); A. L. Nolf, Eng. Pat. 4349, 1882 (electrolysis of a strong solution of sodium chloride with a mercury cathode); F. P. Harned, D. R. P. 26961, 1883 (modification of the mixture used); E. A. Höffner, D. R. P. 30377, 1884 (electrolysis of the fused chloride with a copper or silver anode); S. G. Thomas, Eng. Pat. 6367, 1884 (passage of heated water-gas through the usual mixture without applying external heat); Max Sprenger, D. R. P. 39554, 1886 (electrolysis of the chloride *in vacuô*); E. C. Kleiner-Fiertz, Eng. Pat. 8531, 1886 (electrolysis of cryolite); J. B. Thompson and W. White, Eng. Pat. 8426, 1887 (heating a coked mixture of alkaline carbonate and tar); O. M. Thowless, Eng. Pat. 12486, 1887 (use of a mixture of separately heated alkaline carbonate and coke); Curt Nelto, Eng. Pats. 14602 and 17412, 1887 (*cf.* Eng. & Min. Journal, 45, 449) (passing fused soda in a thin stream through strongly heated charcoal or coke); L. Grabau, Eng. Pat. 9904, 1887 (comprises the cooling of the cathode in electrolytic processes; the metal rises to the surface and is drawn off by a pipe); H. C. Bull, Eng. Pat. 10199, 1887 (electrolytic); A. B. Cunningham, Eng. Pat. 3601, 1888 (heating charcoal with caustic soda); G. A. Jarvis, Eng. Pat. 4842, 1888 (modification of the process for reduction by coke); W. G. Forster, Eng. Pats. 9391, 10785, and 14394, 1888 (reduction of fused alkali with coal-gas); H. M. Wallis, Eng. Pat. 12626, 1888 (modification of the mixture commonly used); W. White, Eng. Pat. 13125, 1888; H. S. Blackmore, Eng. Pat. 15156, 1888; G. M. Westman, Eng. Pat. 17736, 1888; W. White, Eng. Pat. 9784, 1889 (all relating to modifications of the mixture or distillation apparatus); T. Parker and A. E. Robinson, Eng. Pat. 11707, 1889 (electrolysis of a mixture of the hydroxide or carbonate and carbon); L. Grabau, Eng. Pat. 16060, 1890 (previously described); Castner, Eng. Pat. 13356, 1890 (previously described); H. C. Bull, Eng. Pat. 10735, 1892 (electrolysis of the fused chloride in a divided cell); C. J. T. Vautin, Eng. Pat. 10197, 1894 (production of a lead-sodium alloy by the electrolysis of fused sodium chloride with a cathode of molten lead, the alloy being run off and distilled in a retort lined with magnesia or carbon); J. A. Kendall, Eng. Pat. 23045, 1895 (reduction of a mixture of carbonate or hydroxide and carbon in hydrogen gas); G. Wolfram, Eng. Pat. 18604, 1898 (distillation of a mixture of caustic soda and calcium carbide); T. Ewan, Eng. Pat. 14739, 1902 (use of a divided cell in the electrolysis of fused caustic soda); Cassel Gold Fxtraction Co., Fr. Pat. 330987, 1903 (modified apparatus for electrolysis); T. Parker, Eng. Pat. 19196, 1903 (calcination of a mixture of sodium aluminate and carbon in an electric furnace, sodium volatilising); J. Raschen, G. Clayton, and the United Alkali Co., Eng. Pat. 2152, 1904 (employment of sodium-lead alloy as anode in electrolysis of caustic soda; P. L. Hulin, Eng. Pats. 22824, 1908; 6063, 1910 (modified apparatus for the electrolysis of fused caustic soda); A. C. Vournasos, Eng. Pat. 23689, 1908 (preparation of sodium by heating a mixture of salt and lead shot in a special furnace); Chemische Fabrik Griesheim Elektron, Eng. Pat. 29795, 1909 (heating sodium sulphide with calcium carbide); P. A. Emanuel, U.S. Pats. 957754–957756 and 957848, 1910 (production of sodium from various sodium salts by heating with carbon); R. J. McNitt, Eng. Pat. 20519, 1910 (electrolysis of fused salt in presence of lead); E. A. Ashcroft, Eng. Pats. 12377, 1903; 5013, 1910 (electrolysis of a mixture of sodamide and caustic soda with a fused lead anode); The Nitrogen Co., Eng. Pat. 20386, 1910 (formation of an alloy of sodium with a heavy metal by electrolysis, and utilisation of this as anode for electrolysing a bath of fused alkali cyanide); P. L. Hulin (J. Ind. Eng. Chem. 1911, 130) (modified apparatus for the electrolysis of caustic soda).

In the laboratory sodium can be made by a process described by Bamberger (Ber. 1898, 451), which consists in heating a mixture of sodium peroxide and charcoal or calcium carbide in a covered crucible to 300°–400°. Metallic sodium is produced, and condenses on the cover of the crucible.

$$3Na_2O_2+2C=2Na_2CO_3+Na_2.$$
$$7Na_2O_2+2CaC_2=2CaO+4Na_2CO_3+3Na_2.$$

Properties.—Freshly-cut sodium exhibits a silvery metallic lustre, which rapidly disappears on exposure to air owing to the formation of a thin film of oxide, the production of which is accompanied by a greenish phosphorescence (Linnemann, J. pr. Chem. 1858, [i.] 75, 128). According to Long (Chem. Soc. Trans. 1861, 123) sodium crystallises in acute octahedra which belong to the quadratic system.

At a temperature of −20° sodium is hard, at 0° it becomes ductile, and at the ordinary temperature it is of a waxy consistency. On heating it softens at 50° and melts at 92° (Holt and Sims, *ibid.* 1894, 65, 432), 97° (Karnakow and Puschin, Zeitsch. anorg. Chem. 1902, 30, 109). Sodium boils at 877·5° (Ruff and Johannsen, Ber. 1905, 38, 3601), giving a vapour which in thin layers appears colourless, but has a purple colour when viewed in quantity by transmitted light, and exhibits a green fluorescence. Its absorption spectrum has been examined by Roscoe and Schuster (Proc. Roy. Soc. 22, 362), and by Wood and Moore (Phil. Mag. 1903, 6, 362), and the ultra-violet portion by Wood (*ibid.* 1909, 18, 530). The sp.gr. of sodium has been determined by Baumhauer (Ber. 1873, 6, 665), who obtained the values 0·9735 at 13·5°/13·5° and 0·9943 at 10°/10°. Later determinations by Dewar (Chem. News, 1902, 85, 289) and Richards and Brink (J. Amer. Chem. Soc. 1907, 29, 117) have afforded the values 0·9724 at 0°/0° and 0·9712 at 20°/20° respectively. Ramsay (Ber. 1880, 13, 2145) found the sp.gr. of fused sodium near its boiling-point to be 0·7414. No satisfactory determination of the vapour density of sodium has at present been carried out, owing to the difficulty of finding a suitable material for the construction of the apparatus capable of resisting attack by the sodium vapour (*cf.* however Ruff and Johannsen, Ber. 1905, 38, 3602). The molecular weight of sodium was determined by Ramsay (Chem. Soc. Trans. 1889, 55, 521) by Raoult's method. He found the molecular weight to vary between 15·1 and 21·6 according to the ratio of the metal to the solvent (mercury); but the method is open to objection on account of the existence of numerous well-defined compounds of sodium and mercury.

Sodium has been obtained in the colloidal state, forming an unstable violet solution in ether, by passing an electric current of high potential by means of aluminium poles through the granular metal contained in a porcelain dish and covered with ether (Svedborg, Ber. 1905, 38, 3616).

Sodium oxidises rapidly when exposed to moist air, but can be distilled unchanged in air or even oxygen provided that all traces of moisture be excluded. It is far less readily acted on by halogens than potassium. Dry chlorine has no action on sodium, even at the melting-point of the latter (Wanklyn, Chem. News, 20, 271; Cowper, Chem. Soc. Trans. 1883, 155); neither has bromine at temperatures up to 150°, whilst sodium and iodine can be heated together to 350°–360° without combination (Merz and Holzmann, Ber. 22, 872). Dry hydrogen chloride can also be left in contact with sodium for many weeks without appreciable action resulting. The presence, however, of mere traces of water is sufficient to cause immediate and violent combination in all these cases. Heated in the air sodium takes fire and burns with a yellow flame, forming a mixture of oxides. Thrown on to cold water it swims on the surface, disengaging hydrogen and dissolving, but not evolving sufficient heat to ignite the gas. If water at 60° be used, or the free motion of the metal be hindered by increasing the viscosity of the liquid by the addition of gum or starch, the evolved hydrogen ignites, burning with a characteristic yellow flame.

With the exception of gold, silver, and copper, sodium conducts heat and electricity better than any other metal.

Metallic sodium is largely used in the manufacture of cyanides, sodamide (used in the artificial indigo industry), and sodium peroxide, and also finds application in the laboratory, being employed in many organic syntheses, in the preparation of pure caustic soda and in conjunction with alcohol as a powerful reducing agent. The most characteristic analytical reaction furnished by sodium is the intense yellow colour imparted to the non-luminous flame of a Bunsen burner by all compounds of the metal. Viewed through a spectroscope two characteristic yellow bands of wave length 5896 and 5890, known as Fraunhofer's D lines, are seen, and so delicate is this test that so small a quantity as 3×10^{-10} grm. of sodium can be detected by it. All the salts of sodium are soluble in water, so that no satisfactory precipitation reactions for its detection exist. The least soluble salts of sodium are the pyroantimoniate $Na_2H_2Sb_2O_7$, which requires 350 parts of cold water for solution, and the dihydroxytartrate. According to Ball (Chem. Soc. Trans. 1909, 2126) a solution of bismuth potassium nitrite containing cæsium nitrite forms a reagent capable of detecting as little as 0·01 mg. sodium even in the presence of considerable amount of potassium, a yellow precipitate being formed.

Sodium alloys. A large number of alloys of sodium with different metals have been prepared, the most important being those with potassium. These are liquid at the ordinary temperature and resemble mercury in appearance. They are produced either by melting the constituent metals together under rock-oil, or by fusing sodium with caustic potash (Jaubert, Ber. 1908, 41, 4116; Bull. Soc. chim. 1908, [iv.] 3, 1126). The alloy NaK_2 is now made commercially by fusing sodium with anhydrous caustic potash at a temperature of 350°. It oxidises rapidly on exposure to air, igniting spontaneously and yielding a mixture of the peroxides of sodium and potassium, which is used for the regeneration of deoxygenated air in life-saving apparatus.

Sodium and **ammonia.** Sodium dissolves in liquid ammonia with the production of an intensely blue liquid; this on evaporation yields a copper-red solid which, according to Joannis (Compt. rend. 109, 900), has the composition $NaNH_3$. The solid residue easily loses ammonia, finally leaving a crystalline mass of metallic sodium. Ruff and Geisel have, however, shown (Ber. 1906, 39, 828) that no definite chemical compound exists, and the liquid must be regarded merely as a solution of sodium in ammonia. The solution slowly decomposes on standing, with formation of sodamide—

$$Na_2+2NH_3=2NaNH_2+H_2.$$

This reaction can be considerably accelerated by the addition of platinised asbestos, which acts as a catalyst.

Sodium amalgam is best prepared by adding successive small pieces of sodium to gently warmed mercury; as each piece dissolves it produces a flash of light and emits a hissing noise. With 1 part of sodium to 100 of mercury the amalgam formed has an oily consistency, but with 80 parts of mercury to one of sodium a pasty mass results, and with smaller ratios of mercury to sodium hard crystalline amalgams are obtained. The fluid amalgams are only very slowly decomposed by water, but those containing a larger proportion of sodium react vigorously, evolving hydrogen. The rate of decomposition is greatly accelerated by the addition of a small amount of zinc sulphate or lead acetate, which acts catalytically. By allowing an amalgam containing 3 p.c. of sodium to stand under water crystals of a compound $NaHg_6$ can be obtained (Kraut and Popp, Annalen, 1871, 159, 188), which at a temperature of 40°–42° change into $NaHg_5$ (Kerp and Böttger, Zeitsch. anorg. Chem. 1900, 25, 1). Kurnakow (*ibid.* 1900, 23, 439) and Schüller (*ibid.* 1904, 40, 385) have prepared and examined a number of sodium amalgams, many of which are definite chemical compounds. According to Schüller the compound of maximum m.p. (360°) possesses the formula $NaHg_2$. If sodium amalgam be treated with solutions of the other alkalis or alkaline earths, partial replacement occurs, an amalgam of the metal employed being produced (Byers, J. Amer. Chem. Soc. 1908, 30

1584; Böttger, J. pr. Chem. 3, 283). Sodium amalgam is employed in the laboratory as a reducing agent, and an amalgam containing 2–3 p.c. of sodium is used to some extent in gold extraction processes to prevent the 'sickening' of the mercury by reducing the oxide of the base metals which collect on it and interfere with the proper working of the process.

Sodium Compounds.

Only two well-defined oxides of sodium are known, *i.e.* the monoxide Na_2O and the dioxide Na_2O_2, although according to Johannis (Ann. Chim. Phys. 1906, [viii.] 7, 75) a sesquioxide Na_2O_3 can be obtained by the action of oxygen on sodammonium.

Sodium monoxide is produced, together with the dioxide, by the combustion of sodium in air or oxygen. If the supply of oxygen be limited and the sodium be not heated above 180°, only the monoxide is formed (Holt and Sims, Chem. Soc. Trans. 1894, 442). It can be obtained perfectly pure by partially oxidising the metal and separating the unchanged sodium by distillation *in vacuô* (Rengade, Compt. rend. 1906, 143, 1152). The monoxide is also formed when metallic sodium is heated with the nitrite or nitrate, nitrogen being liberated.

Sodium monoxide is a white, hygroscopic substance of sp.gr. 2·27, and melts at a red heat. Hydrogen reduces it to metal at 170°–180° (Rengade, Ann. Chim. Phys. 1907, [viii.] 11, 424). It combines with fluorine, iodine, and sulphur with incandescence, and reacts violently with water, forming sodium hydroxide.

Sodium dioxide or **peroxide** is obtained when the metal is burned in an excess of air or oxygen. It is now made on the large scale according to Castner's process (Eng. Pat. 20003, 1891), which consists in placing sodium on aluminium trays loaded on to small waggons, which are then run through an iron tube, provided at each end with tightly-closing iron doors, set in a furnace and heated to 300°. A current of dry air, free from carbon dioxide, is passed through the tube, the peroxide produced being withdrawn at one end and fresh charges of sodium introduced at the other. The technical product thus obtained contains about 93 p.c. of sodium peroxide. Pure sodium peroxide is yellow and, unlike the monoxide, is not deliquescent (Jaubert, Compt. rend. 1901, 132, 35). It absorbs carbon dioxide with formation of sodium carbonate and liberation of oxygen, and a mixture of this oxide with potassium peroxide is used in life-saving apparatus to regenerate air contaminated by respiration. With CO it yields sodium carbonate, and with N_2O and NO sodium nitrite. Charcoal and the alkaline earth carbides reduce it to metallic sodium at a temperature of 300°–400° (Bamberger, Ber. 1898, 31, 451). Although sodium peroxide is not decomposed when heated alone it readily gives up oxygen to other substances mixed with it, and hence is largely used in the analysis of many refractory minerals, such as pyrite and chromite. As fused sodium peroxide acts most energetically on platinum, iron, &c., it is necessary to use crucibles of nickel, as this is less attacked than other metals. In the presence of moisture the peroxide acts powerfully on organic substances such as paper, oxidation frequently taking place with explosive violence. Sodium peroxide dissolves readily in water with formation of caustic soda and hydrogen peroxide, a portion of the latter simultaneously undergoing decomposition into water and oxygen owing to the heat evolved during solution. By exposing the peroxide to moist air free from carbon dioxide, or by the cautious evaporation of its solution in cold water, tabular hexagonal crystals of a hydrate $Na_2O_2,8H_2O$ can be obtained, which on standing over sulphuric acid lose water, forming the dihydrate

$$Na_2O_2,2H_2O.$$

The octahydrate is also produced by adding 1½–2 times its volume of alcohol to a solution of caustic soda and hydrogen peroxide (Schöne, Annalen, 1878, 193, 241). The hydrate dissolves in cold water without decomposition, but on heating the solution oxygen begins to be evolved at 30°–40°, the decomposition of the salt being complete at 100°.

Sodium peroxide is employed as an oxidising agent, as a source of oxygen in the laboratory, and in the preparation of bleaching solutions containing hydrogen peroxide.

Sodium hydroxide, *see Caustic Soda*, p. 45.

Sodyl hydroxide. According to J. Tafel (Ber. 1894, 27, 816, 2297), a substance of the formula $O:Na{\cdot}OH$ is produced by the action of absolute alcohol on sodium peroxide at 0°, according to the equation

$$Na_2O_2+C_2H_5OH=NaOC_2H_5+O:Na{\cdot}OH.$$

It is a white powder, soluble in cold water, the solution decomposing on heating into caustic soda and oxygen, the same decomposition taking place with explosion when the dry substance is heated.

Sodium fluoride NaF occurs native in small quantities in nepheline syenite in the Los Islands, and in considerable amount as the double fluoride of aluminium and sodium, *cryolite* ($3NaF{\cdot}AlF_3$), found in Greenland. It may be obtained from this latter source by treating the powdered mineral with an excess of strong caustic soda solution in iron pans, whereby the alumina is dissolved and sparingly soluble sodium fluoride remains behind. The pure salt is best made by neutralising a solution of hydrofluoric acid with sodium hydroxide or carbonate.

Sodium fluoride crystallises in colourless cubes of sp.gr. 2·766 (Schröder), which on heating melt at about 900°, but volatilise slightly at a lower temperature. The salt is only sparingly soluble in cold water (100 parts of water at 15° dissolve 4 parts NaF) and the solubility increases only slightly with the temperature. For the electrical conductivities of solutions of sodium fluoride of varying strengths, see Kohlrausch and Steinwehr (Sitz. der Berl. Akad. 1902, 581).

Sodium fluoride unites with hydrofluoric acid to form an acid salt, $NaF{\cdot}HF$, which can be obtained in rhombohedral crystals from a solution containing an excess of hydrofluoric acid. The crystals decompose on heating, evolving HF and leaving sodium fluoride. A number of double fluorides of sodium with other metals have also been prepared, for which see Wagner, Ber. 19, 896.

Uses. Sodium fluoride is occasionally employed as an antiseptic, and has been recommended for use in lotions in certain affections of the skin.

Sodium chloride. *Chlorure de sodium, hydrochlorate de soude, sel marin*, Fr.; *Steinsalz, Kochsalz, Salz, Salzaures Natrium, Chlornatrium*, Ger.; *sal*, Lat.; Ἅλς, Greek.

Sodium chloride, or common salt, is found in nature as the mineral *halite*, or *rock salt*. It crystallises in cubes, occasionally associated with other forms derived from the regular system. Hardness, 2; sp.gr. 2·2. It is colourless and transparent when pure, but is usually tinged yellow, red, brown, or green.

Owing to its wide distribution on the earth salt has been known from the very earliest times. It is frequently mentioned in the Bible. The Jewish law commanded the people to season the meat offering with salt (Lev. ii. 13). The Jews used a very impure argillaceous kind of rock salt, from which they extracted the salt by means of water, leaving the clay as mud. This mud still contained some salt, and was either used directly for agricultural purposes, or was allowed to lie on the manure heaps before being used, where, after prolonged exposure in presence of nitrogenous matter, the salt was partially converted into sodium nitrate. Hence we find the expressions (Matt. v. 13), 'Ye are the salt of the earth: but if the salt have lost his savour, wherewith shall it be salted? it is thenceforth good for nothing, but to be cast out and trodden under foot of men'; and (Luke xiv. 34) 'Salt therefore is good: but if even the salt have lost his savour, wherewith shall it be seasoned? It is fit neither for the land nor for the dunghill: men cast it out.'

Occurrence of salt. Salt is very widely distributed. Immense deposits of it, in the form of rock salt, are found in many parts of the world. It is the principal solid constituent of sea-water and of many salt lakes, and is found in brine springs and most mineral waters. There are few countries in which it does not occur, as also there are but few geological formations from which it is absent. In America rock salt is met with in very old strata, some of the recent discoveries of it being in the Silurian rocks.

In New York State, Michigan, and in Ontario it is found in the Upper Silurian formation, and usually lies at a depth of over 1000 ft. from the surface. South of Rochester (New York), in what is known as the Warsaw district, the rock salt is found in three superposed beds. The top layer is 60 ft. thick; then follows 10 ft. of shale. The second bed is 20 ft. thick, and is separated from the third by 30 ft. of shale. The Ontario deposits are found in the counties of Essex, Lambton, Middlesex, Huron, and Bruce lying along the shores of lake Huron. The beds are struck at depths varying from 970 to 1650 ft., and in some places they reach a thickness of 250 ft.

Rock salt is also known in Manitoba and Athabasca (*see* Geology and Economic Minerals of Canada, Depart. of Mines, Ottawa, 1909).

The rock salt found in Michigan is principally at Saginaw, Detroit, and Bay City. In Utah there are extensive deposits embedded in red clay. Salt is also found in Virginia, Ohio, Louisiana, and Kansas. The deposits which occur in Louisiana lie in the post Tertiary formation, while those of Kansas are found in the Permian. The latter have been proved to be most extensive, reaching into Oklahoma.

Rock salt is known in Mexico, Colombia, Venezuela, and the Argentine. There are immense deposits in Chile and Peru. It is found at Kulpi in Armenia, at Nachitschevan, and in many places in the Caucasus. It is claimed that the rock salt deposit near the town of Iletz Zaschtchiti in the province of Orenburg, S.E. Russia, is the richest in the world (Chemical Trade Journal, Feb. 1910, 179).

The district of Ferghana Turkestan is rich in salt deposits. Rock salt is widely found throughout the basin of the river Donetz in southern Russia, and at Vsolje where it occurs in Oolitic limestone. It is also known at Balachna on the Volga and in the Crimea.

On both sides of the Carpathians rock salt abounds, most of it in Tertiary formations. In Galicia the principal mines are at Wieliczka (where the deposit is said to be 1200 ft. thick), at Stebnick (where three beds have been found), and at Bochnia. Transylvania and Wallachia possess many mines. In the Tyrolean Alps rock salt occurs in Oolitic limestone. In the Austrian portion, the principal deposits are at Salzburg, Aussee, Ischl, Hallstadt, and Hallein; while in Bavaria, salt is found at Berchtesgaden and Reichenthal, and in Hungary at Marmores. At Volterra, in Italy, there are several deposits at 150–308 ft. from the surface.

In Spain rock salt is plentiful; but the most remarkable deposit is that of Cardona (Barcelona), where there are two hills of very pure white salt, each about a mile in circumference.

Germany is rich in salt. The principal formations are those of Stassfurt which lie in the Bunter sandstone, and are first reached at about 832 ft. from the surface. The salt is here accompanied by beds of potassium and magnesium salts (*see* POTASSIUM).

Salt is also found at Heilbronn in Würtenberg, Wimpffen in Hesse, and Rappenau in Baden, at Langenberg and Köstritz in Central Germany, at Gera in Reuss, at Buffleben in Coburg Gotha, and at Artern in Prussia.

Deposits are found in the Vosges district at Dieuze and Vic in Lorraine, and near to Nancy in France in Keuper marls. Switzerland possesses salt at Bex in the Rhone valley found in the Lias.

The Pyrenees are rich in brine springs and rock salt deposits. The beds of Dax and Villefranche are probably Tertiary. At Jebel Usdum, south of the Dead Sea, there is a hill which consists throughout of a single mass of rock salt, covered with a thin layer of calcareous marl. Salt is found in Algeria in cretaceous rocks, and in Abyssinia. In the interior of Libya it is found associated with limestone in cliffs. Herodotus mentions five mountains which lie about equal distances from one another, across a tract of country 10 days' journey in extent (*see* H. B. Tristram, The Great Sahara, 72).

Rock salt is found in India in the red marls and sandstones of the Devonian group. The salt range of the Punjab contains hills of very pure salt and runs across the districts of Jhelum and Shakpur from the bank of the Jhelum river to Kalabagh in Bannu district. Similar deposits are found in Kohat and Mandi.

In China the salt bed is a triangular tract having the Min river from Ching-ting-fu to its junction with the Yangtze at Sui-fu for its base, and its apex near Tzelintsing an area of some 1500 square miles.

The first discovery of rock salt in the British Isles was made at Marbury near Northwich in Cheshire in the year 1670.

In 1779 it was found at Lawton in Cheshire, and deeper borings at Marston in 1781 revealed the existence of a second or lower bed of salt. These Cheshire beds lie in the Saliferous marls of the Upper Trias formation above the New Red Sandstone, probably identical with the Keuper marls and Bunter sandstone of Germany. At Northwich the top bed is about 75 ft. thick, and lies 135–150 ft. below the surface. It is covered by boulder sands, clays, and red or blue marl. Below the top rock salt there is a bed of hard marl 30 ft. thick, which contains here and there veins of salt and masses of gypsum. Under this a second bed of rock salt is found about 105 ft. thick. Deeper borings reveal the presence of successive thin beds of salt. At Marston near Northwich the Salt Union drilled a borehole 2610 ft. deep, starting at 77 ft. above ordnance datum, and found a bed of salt 90 ft. thick at 124 ft., then 28 ft. of marl, succeeded by rock salt 92 ft. thick. Below this they found marl and thin beds of salt for 966 ft., and then passed through sandstone and marl or pure sandstone for 1310 ft.

A borehole over 2000 ft. deep is reported to have been drilled recently at Holford (3 miles east of Marston) that has shown the existence of beds of rock salt 1027 ft. from surface, aggregating 503 ft. thick.

At Winsford in Cheshire the beds are similar to those at Northwich, the top rock being about 70 ft. thick and the bottom 120 ft. Rock salt is also found in Cheshire at Sandbach and Lawton. At Droitwich and Stoke Prior in Worcestershire the salt beds lie in the same formation as in Cheshire. At Shirley Brook, in the same county, rock salt is found 273 ft. below the surface. It is met with at the village of Preesal, near Fleetwood in Lancashire, at a depth of 278 ft. (*see* Thompson, Trans. Manchester Geol. & Mining Soc. 30, 105), and is also found near to Barrow-in-Furness and in the Isle of Man at the Point of Ayre at 617 ft. below the surface (*see* Dawkins, Quart. Jour. Geol. Soc. 58, 1902). At Stafford Common in Staffordshire it is 263 ft. deep. In the neighbourhood of Middlesbrough, in the county of Durham, rock salt has been proved to exist over an area of 20 square miles. The most northerly bore-hole is at Greatham, where salt was found at a depth of 889 ft. below sea level. To the south, at North Ormesby, in Yorkshire, the bed is 1340 ft. from the surface, while the most easterly bore-hole at Lackenby strikes the salt at 1685 ft. (119 ft. thick), and the most westerly one at Haverton Hill reaches it at 797 ft. The average thickness of the main bed of salt is 84 ft. It lies in marls below a thick bed of red sandstone (*see* Durham Salt District by E. Wilson, Quart. Jour. Geol. Soc. Nov. 1888; also John Marley on the Cleveland and South Durham Salt Industry, N. of England Inst. of Mining Engineers, 1892, 27). Rock salt is found at Duncrue and Eden near Carrickfergus, and at Magheramorne near Larne in Ireland.

Origin of rock-salt deposits. The great variability in the position of the salt deposits renders it impossible to consider them as constituting a definite geological formation, but points to the probability that their origin is due either to volcanic action or to the evaporation of water which held the salt in solution. The great argument in favour of an igneous origin rests upon the fact that sodium chloride and hydrochloric acid are emitted by volcanoes; but the occurrence of layers of bitumen and certain organic remains, together with the fact that cavities containing liquids are found in the rock salt, renders this theory untenable.

The general character of the beds, too, favours the assumption that they are of aqueous origin. They are rarely found filling cavities or dykes after the manner of volcanic rocks, but are in layers of very considerable area. These immense beds of rock salt most probably owe their origin to the evaporation of inland seas, and a careful examination of their constitution affords evidence which goes far to prove this theory. The manner in which the deposits were formed appears to be as follows. When, by slow upheaval of the land or by the accumulation of a bar or sand bank, a portion of the sea became partially shut off, the heat of the sun was sufficient to evaporate as much water as was supplied by the sea or by rivers.

Then the volume of water in the part so separated became gradually richer in dissolved salts. The upper layers when concentrated by the sun became specifically heavier and sank to the bottom, the more dilute rising to take their place. As the quantity of salt in solution rose, all those living organisms which were endowed with the means of locomotion left their homes and returned to the open sea, while those which were lacking in this particular died off. Their remains (such as did not dissolve) are found as insignificant impurities in the gypsum which formed around them. For by degrees the lower portion of the water became so rich in mineral constituents that it could no longer retain them in solution, and they began to separate out. The least soluble salt was, of course, the first to deposit, and this was followed by the others in the inverse order of their solubility. The calcium carbonate and ferrous carbonate, if present, would precipitate first, and then the calcium sulphate would follow in the form of gypsum. As the degree of concentration still continued to rise the sodium chloride began to separate out, depositing on the bottom of the basin in a hard compact mass. In cases where the connection with the sea was still maintained, or where rivers continued to send in water, these various phases would be to a certain extent contemporaneous; for the incoming water would bring with it fresh quantities of calcium carbonate and calcium sulphate, and these salts would precipitate along with the sodium chloride. Nor would this separation of the salts in the inverse ratio of their solubilities proceed with absolute exactitude, for the less soluble might carry down with them minute quantities of the more soluble ones. For instance, it is by no means uncommon to find magnesium sulphate mixed with rock salt, especially where there has been aluminous mud washed in to serve to carry it down. Again, certain combinations of the same salt occur, such as *simonyite*, and *bischofite* is found in solution in cavities in rock salt in Cheshire, where also *hydrophilite* is not infrequently found. As the sodium chloride continued to deposit, the mother liquor gradually grew richer in the more soluble salts until the point was reached when they too began to crystallise. Potassium chloride and magnesium chloride separated from the solution in combination as the mineral *carnallite*. Potassium sulphate, magnesium sulphate, and magnesium chloride became associated as *kainite*, while some of the magnesium sulphate crystallised in the form of *kieserite*.

It is obvious that when the supply of fresh water from the ocean was continued at all there would be a deposit of salt accompanying the more soluble substances. The calcium sulphate, however, which precipitated from this sea water would, in falling, pass through the layers of mother liquor which had reached a high degree of concentration; hence it crystallised as *anhydrite*. The whole of this process of crystallisation was, of course, subject to an immense variety of disturbing influences. The rate of deposition would vary greatly with the season of the year, not only on account of the heat of the sun and the height of the tides, but also on account of the amount of water due to the rainfall. There were probably actual changes in climatic conditions giving at one time a tropical heat and rapid deposition of salt, and at another copious rainfall which arrested crystallisation and caused the rivers to bring down plentiful supplies of mud. In examining beds of rock salt we find evidences of such disturbances in the frequent occurrence of layers of clay, sandstone, or marl, which show that during certain periods there was little or no deposit of salt. In many cases the disturbance was sufficient to remove the whole of the mother liquors, and there we find little or no trace of the potassium and magnesium salts.

Such is the generally accepted theory of the formation of the great deposits of rock salt. The ocean has for ages been receiving the waters of rivers and springs charged with matter dissolved during the passage of the water through or over the various rock formations. Such substances as were required to build up the structure of marine animals and plants were by them extracted from the water; the rest would obviously, in course of time, accumulate, because the volume of sea water was kept nearly constant by continual evaporation.

Such formation of salt deposits may be seen proceeding at the present time, two of the best examples are afforded by the Kara Boghaz or Black Gulf on the eastern shore of the Caspian Sea and the Runn of Cutch in India (*see* Thos. Ward, Trans. Manchester Geo. Soc. 18, 396; Riemann, Monographien über Chemisch-technische Fabrikations-Methoden Band, xviii.; Halle, 1909, 8).

Rock salt. Rock salt is always found in England associated with a coloured marl, and through having undulating lines of this impurity running through its mass, it generally presents the appearance of stratification.

The tinge of colour varies with the colour

of the marl and marlstone with which it is interstratified. It varies from dark red or brown to light amber or white. The yellow rock salt is preferred, on account of its greater purity. The table on p. 9 shows the composition of the salt obtained from deposits in various parts of the world.

The Cheshire salt mines which are now being worked are all in the lower bed. The rock obtained is purer than that from the upper one, and there is less trouble required to keep out surface water and brine. The modern mine is provided with two shafts placed from 10 to 15 yards apart, with generally (unless the winding shaft be tubed) another permanent shaft for pumping the surface water, sunk only as deep as the water penetrates. In sinking the shaft it is especially requisite to protect the rock salt at the sides from being dissolved by water. All such shafts are roofed over to keep out rain and snow, and are carefully cased down to a solid foundation below where surface water penetrates in the ground. The casing was originally made of wood; but lately this has been replaced by iron. The method of procedure in Cheshire is as follows:—

A solid foundation, such as is generally to be found at a certain bed of marlstone between the top and bottom beds of rock salt, is obtained, and then a ledge 12 ins. wide all round is cut in it, care being taken to remove any small concretions of rock salt which may be in the marl. A bed of concrete is cast upon this ledge and carefully dressed on the surface to receive a cast-iron ring. The bottom length of tubing (called the bell mouth) is generally about 6 ft. long, and is in three segments which, when united, taper from a diameter of about 4 or 5 ft. at the bottom to 3½ ft. at the top, and on this begin the iron cylinders or tubes 3½ ft. diameter and 6 ft. long. The space behind the bell-mouth is carefully filled with cement rammed well down to the concrete foundation.

In the bottom bed workings the height of the rock salt that is being worked varies from 15 to 18 ft. in Cheshire, and from 30 to 40 ft. at Carrickfergus. The mode of working the mines in both districts is to drive out in the upper part about 5 ft. 9 ins. high, which is called the 'roofing,' and to follow up with what is called the 'benching,' leaving pillars of rock salt to support the roof. In driving the roofing a little holing and cutting has to be done with a pick, and as much as possible is blown out with gunpowder, after which the roof is dressed off with a pick. The benching in Cheshire varies from 9 ft. 3 ins. to 12 ft. 3 ins. in thickness, and in Ireland from 24 ft. 3 ins. to 34 ft. 3 ins. This is blown off by a succession of shots, arranged in a slanting direction from the top to the bottom. In some of the mines machines are used. In charging the shot the fine rock salt made in drilling the hole is put next to the powder and coarse-grained rock salt upon that. The stemmers and prickers are all made of iron, as rock salt does not strike a light with iron or steel.

Flat hemp ropes are generally used for winding. In some cases iron-wire rope is used, but it has to be kept well greased to prevent it rusting. Tram roads are used below ground. It is found by experience that the pillars which are left to support the roof should be in proportion to the depth of the mine. At a depth of 330 ft. it is found necessary to leave 1 pillar for every 11½ times its area of rock worked. The pillars are left 10 yards square, and stand 25 yards apart. There is a crushing and grinding mill at the bank of nearly every rock-salt pit, and in this the rock is ground to more or less fine powder when so required for shipment (*see* V. Buschman, Das Salz dessen Vorkommen und Verwertung, Willhelm, Engelmann, Leipzig; also F. A. Fürer, Salzbergbau und Salinenkunde, Vieweg und Sohn, Brunswick).

The rock salt which is found in the neighbourhood of Stassfurt, in Prussia, is accompanied by deposits of a great variety of other minerals, especially those rich in potassium and magnesium. After boring through the Bunter sandstone, a bed of red clay and gypsum is encountered, under which lies the upper layer of rock salt, varying in thickness from 150 to 300 ft. For particulars of Stassfurt deposits *v.* POTASSIUM, vol. iv. p. 337.

The salt deposits in the districts of Tarapaca and Atacama, in Chile and Peru, in great measure resemble those of Stassfurt. There is, however, one remarkable point of difference—the Peruvian beds contain large quantities of sodium nitrate or Chile saltpetre. The source of this nitrogen has long been a matter for discussion; but recent researches afford most probable explanations of its origin. It is noticeable that all these 'calichales' or 'salitrales,' as the spots are called where the 'caliche' or impure soda saltpetre is found, lie near to the coast, just inside the low-lying coast Cordilleras. The coast in this part of Chile is studded with small islands containing deposits of guano rich in ammonia, and this (in the form of very fine dust) is carried by the prevailing west wind far inland, and would doubtless fall into the saline lakes when in process of evaporation. The oxidation of this nitrogenous matter would doubtless readily take place under such climatic conditions as obtained when the salt deposits were formed.

The greater prominence of the more soluble potassium and magnesium salts in the nitre-bearing Chilean deposits furthers the supposition that they were formed from mother-liquors decanted from salt lakes further inland by volcanic upheaval. The theory that these mother-liquors, running down to the sea, were intercepted by the coast mountains is borne out by the fact that where there are no hills along the shore there are no nitre beds.

Manufacture of salt from brine.

The manufacture of salt has been carried on in England since the time of the Romans, who, there is little doubt, made it from brine. Brine is formed by fresh water reaching the surface of the rock salt, either at the outcrop of the strata or through a fissure in the overlying marl. In Cheshire it is pretty certain that the water gains admission at a higher level than the rock salt, for when the brine is first struck it rises up the shaft to a considerable height, in some cases nearly to the surface. The natural brine is, as would be supposed, only found on the top of the upper beds of rock salt. It is reached by sinking a huge well or shaft, sometimes as much as 10 ft. in diameter. For the purpose of keeping water out, the shaft is lined with cast-iron cylinders carefully jointed together (see description of rock-salt mine shaft), or with timber backed with puddle. This shaft is carried down until the marl is reached, and then a bore-hole is driven until the brine is tapped. The top bed of rock salt in Cheshire is usually covered with a bed of marlstone, locally called 'the flag,' which is very hard and impervious to water. For a few feet below the flag the marl in which the rock head brine runs is of a granular structure, locally known as 'horse beans' or 'shaggy metal,' and is probably the remains of marl or other impurity originally combined with the rock salt, but left behind as the rock salt is dissolved into brine. On piercing the flag the brine rises into the shaft with great force. Common lift pumps are employed to raise the brine to the surface. They are suspended by a chain of rods depending from a rocking shaft or R bob at the top of the well. One engine, placed near the top of the shaft, generally works a pair of pumps. The brine is delivered into reservoirs which are lined with puddle-clay and brickwork.

The clay suffices to make them watertight, and the bricks, which are laid without mortar on the top of the puddle, keep it from being washed away. Very frequently, large wooden tanks are used as brine reservoirs. These are constructed of stout planks held together by wooden plugs (nails cannot be used on account of corrosion) and carefully caulked with oakum. The brine is distributed to the salt pans through pipes. In many places it is common to employ pipes made out of the trunk of a tree bored out in the core and tapered at one end. The taper end fits into the core of the next pipe.

Such ranges are found to stand changes of temperature better than iron ones. In Austria also there are many miles of such ranges of pipes. The strength of brine varies very greatly. It is, of course, dependent upon the volume of water which passes over the rock salt, the area of the surface over which it runs, and the length of time it is in contact with it. The table on this page shows the composition of brine in various places and countries.

In some countries where the brine is found too weak to make the ordinary method of evaporation a profitable one, recourse is had to a device to strengthen the brine by evaporation at the ordinary temperature. This is done by means of so-called graduation towers or houses (German, *Gradirhäuser*). They consist of scaffolding which incloses bundles of brambles or thorns, built up in regular walls. The weak brine is pumped up to the top, and carefully distributed by means of perforated troughs all over the summit of the pile. It then falls from twig to twig, and is divided into a fine shower on its way to the ground, thus exposing an immense surface to the action of the air or wind. At the bottom it falls into a collecting trough, whence it is returned to the top of the same or another tower until it becomes sufficiently concentrated. In time, the thorns become coated with a scale of calcium carbonate and sulphate, and then they have to be renewed. This incrustation is technically known as thorn-stone (German, *Dornenstein*). The graduation houses should

be built lengthwise in the direction of the prevailing wind. The rapidity of evaporation depends upon the hygrometric state of the atmosphere. On rainy days graduation cannot go on. Experience shows that from May to August is the best season. It has been calculated that in ordinary good weather 60 kilos. (13 gallons) of water are evaporated in the course of 24 hours for every square foot of surface of the thorns. This method of evaporation is employed among other places at Moutiers in France, and at Nauheim, Dürrenberg, Rodenberg, and Schönbeck in Germany.

In some districts where rock salt is found the water does not naturally percolate to the strata, and therefore no brine is struck when borings are made. An artificial brine is readily prepared by turning a stream of fresh water down on to the bed of salt, and then pumping it up again as it becomes saturated with salt. The strong brine, being much heavier than water, collects at the bottom of the shaft, so the pumps are made to draw from the bottom, and are only run so long as the brine delivered keeps up to strength. The yield of such a brine shaft, of course, depends upon the area of the surface of the rock salt which the water can act upon, and this it will be seen is always increasing. The whole of the brine evaporated in the Middlesbrough district is made in this way. Water from the sandstone strata is allowed to flow down the well outside the pump barrels, and thus solution of the salt takes place at the top of the bed, by which a cavity is formed. As the brine is pumped from the bottom of the cavity more water flows down, and thus the cavity becomes larger and its productive power is increased. As the specific gravity of brine is about 1·2, the column inside the suction pipe rises to ⅚ of the height of the water column outside.

The removal of these subterranean beds of rock salt by the agency of water occasions in some districts very serious consequences. In carefully worked mines the pillars which are left are ample to support the superincumbent strata so long as the mine is kept dry. But if, by any chance, water finds its way in large quantities into a salt mine the pillars are rapidly dissolved, and a large area of roof is left without any support. Then a subsidence of the land, occurring more or less rapidly, is sure to take place. The water which finds its way down to the rock-salt beds may run for miles along its surface, and so gradually remove an ever-increasing layer of the salt. If there is no natural outlet the solution of salt ceases when the water becomes saturated; but if the brine is pumped out for manufacturing purposes an equivalent volume of fresh water is induced to flow in, and so the destruction of the salt bed is greatly intensified. This constant removal of the support causes as constant a subsidence of the outlying lands, and it is by no means uncommon in the brine-pumping districts for pieces of land to sink at the rate of a foot a year (*see* Subsidences in the Salt Districts of Cheshire; their History and Cause, Thos. Ward, Trans. Manchester Geol. Soc. vol. xix., part vii. 1886–7).

The manufacture of salt from brine is essentially a very simple process. It is merely necessary to evaporate a certain amount of water and collect the salt which deposits. This is effected either by artificial heat or by the heat of the sun. When the former is employed, it is obvious that the best process is that which secures the greatest evaporation for the smallest expenditure of fuel. Until recently, the method universally adopted was to use an open shallow pan and heat it by a fire placed underneath. The Romans in Cheshire used leaden pans which contained only a few gallons of brine; but the modern pans are made of wrought iron plates riveted together and frequently hold as much as 50 cubic metres. Apart from this variation in the construction and size of pans, the process has been little affected by the various and numerous patents taken out for improvements until about 1892.

The following is a list of some of the most important of the patents:—

In 1764 John Baker patented a salt-pan covered over from end to end with a brickwork arch, and so arranged that the hot gases which had already passed under the pan should be drawn over the surface of the brine.

In 1772 Daniel Scott and John Mackay proposed to arrange pans three high, and conduct the steam from the bottom boiling pan through false bottoms under the other two.

In 1801 James Manly patented a process for purifying brine. He proposed to heat, in order to remove part of the impurity, and then to add sodium carbonate to it.

In 1806 Richard Tomkinson designed a salt-pan which contained a hollow iron cylinder running right down the centre and out at the other end. The middle of the pan was deeper than the sides, and the cylinder was supported so that the brine surrounded it at all times. The fire was placed in the cylinder at one end of the pan.

In 1808 William Steel patented a plant consisting of three separate vessels. The boiling vessel was provided with an air-tight cover, and the steam from it was conducted under a second vessel. The hot air and flame from the flue of the first was taken under a third vessel.

In 1824 W. A. Jump and W. Court proposed to heat the first brine in metallic pipes, placed in the flues under the pan.

In 1831 W. A. Jump patented a pan provided with mechanical rakes to draw the salt to the side of the pan.

In 1833 W. Newton proposed to blow hot air through the evaporating brine.

In 1838 Joseph Hall patented a circular revolving pan. The salt, as it formed, was scraped by means of a fixed rake into a pocket at the circumference of the pan. He also described a semicircular pan with a reciprocating motion. He claimed that in such pans the heat was more evenly distributed and the wear consequently less.

In 1839 Edward Law patented a machine for evaporating brine by exposing an extensive surface to the action of a brisk current of air. The apparatus consisted of an upright shaft or axis carrying ten frames covered with canvas. These were constantly moistened with brine while the machine was turned rapidly on pivots.

In the same year (July 16, 1839, No. 8155) an important step was taken by John Reynolds, who invented a process for improving the manufacture of salt by 'causing the steam produced by boiling brine or salt water in a closed vessel to transfer its heat to and thereby boil brine or salt water in a second closed vessel, so that the steam from such second closed vessel may in like manner transfer its heat to brine in a third vessel, and so on, by maintaining in each of a series of closed vessels in which brine is subjected to evaporation such relative pressure as will cause the respective boiling-points of the brine contained in each to be lower from the first to the last of the series, so that the steam or vapour produced from the brine in each vessel may be condensed in a vessel of thin metal immersed in the brine of the next succeeding vessel. The graduations of pressure may be obtained either by diminishing a pressure superadded to that of the atmosphere, or by diminishing the pressure of the atmosphere alone.'

In 1855 L. J. F. Margueritte proposed to precipitate salt from a solution by passing hydrogen chloride into it.

In 1864 D. Hall and A. L. Roosen patented the application of surface heating for the evaporation of brine. The pan was covered with a brick arch, and the heat from the furnace was allowed to pass over the surface of the brine, and then afterwards, together with the steam evolved, under an ordinary open salt-pan.

In 1889 Alberger, Williams and Alberger patented a combination of tubular steam heaters and a circular open pan termed a 'grainer.'

In 1893 C. Hirzel proposed to freeze brine at −20° and separate the hydrate.

In 1898 Vis patented the use of calcium chloride to prevent the calcium sulphate in brine scaling a pan.

In 1899 Vis patented an arrangement for preventing scaling in vacuum apparatus.

In 1899 Duff patented a special arrangement of multiple effect vessels.

In 1900 Vis proposed the purification of brine by electrolysing it until caustic soda was formed in sufficient quantity to precipitate the calcium and magnesium salts when treated subsequently with carbon dioxide.

In 1902 Sachse and Kaufmann patented apparatus for keeping the tubes of a vacuum evaporator clear by causing a weighted chain to bump over the top tube plate.

In 1903 Trump took out a patent for vacuum apparatus containing a circulating pump which, by causing the crystals and mother liquor constantly to be returned to the evaporator, allowed the crystals to grow larger and at the same time tended to prevent the formation of scale by scouring action.

In 1903 Tee patented a process for making white salt by melting rock salt, blowing heated air through the liquid, allowing impurities to settle and then drawing off the clear salt into vessels to cool.

In 1908 Malcolm and Munton patented a process for preventing scaling in vacuum evaporators by purifying the brine. The magnesium salts are removed by adding partially electrolysed brine (*i.e.* brine containing some caustic soda) to the raw brine and then the calcium salts are precipitated by the addition of more electrolysed brine and treatment with flue gases (*i.e.* CO_2).

Of late years the greatest improvements which have been made in the manufacture of salt have been in the direction of the triple effect apparatus described by Reynolds in 1839.

The cost of fuel is so large an item in the cost of production of salt that any economy effected in its use materially increases the margin of profit. With the ordinary open pans, 1 ton of fuel (slack with 15–20 p.c. of ash) will make from 2 to 2·5 tons of salt; but a well constructed triple effect plant will yield 5–6 tons of salt per ton of fuel. In addition to giving greater economy in consumption of fuel, these vacuum pans have a much larger production capacity than the ordinary pans.

While, with a direct-fired pan of large size, it is considered good to get 15 tons of salt per 24 hours, it is not uncommon for a set of multiple effect vacuum evaporators to yield 500 tons per day, and some are now being built to produce 720 tons per set of three vessels. The evaporators are constructed with a central heating portion, a dome-covered upper part and a conical lower portion communicating with a salt receiver.

Heat is applied to the vessels through tubes which prevent the brine from coming into actual contact with the heating medium.. Steam or any hot gases, such as flue gas or exhaust from gas engines, can be employed for heating the first vessel in the series. The steam which is evolved from the boiling brine in the first vessel is employed for heating the second of the series, and that from the second serves to heat the third. Where a fourth vessel is employed, the heating is effected by steam from the third. The steam evolved from the last vessel of the series passes to a vacuum engine either direct or after a condenser. With this arrangement, evaporation takes place in each vessel at a lower pressure, and therefore at a lower temperature, than in the preceding vessel, so, while the pressure in the first may be little below atmospheric, that in the last is a high vacuum.

To facilitate the removal of salt without interruption of the process of evaporation, it is usual to make a long leg to the evaporators so as to maintain a column of brine equal to the vacuum and allow the crystals to fall into a receptacle which lutes the bottom of the leg. It is common to provide this with an elevator and so remove the salt as it forms to a storage hopper.

Fig. 6 shows the arrangement of a typical multiple effect plant. In this plan (copied from a recent patent) four vessels are shown, marked A1, A2, A3, and A4. The heating chambers are marked B1, B2, B3, and B4. That of B2 is shown in part section to illustrate the arrangement of tubes through which the brine circulates. The long legs C of each pair of vessels meet in one boot at an elevator bottom, and the salt is raised by the elevators E to the receptacle F. G is a condenser for producing vacuum by the condensation of steam.

Fig. 7 shows an end view of the same plant. Each vessel has a separate brine-feed pipe from a common main.

Fig. 8 (p. 15) illustrates another form of plant where the vessels are placed at different heights, so as to give a length of leg in proportion to the vacuum in the vessel. Here each evaporator has its own elevator.

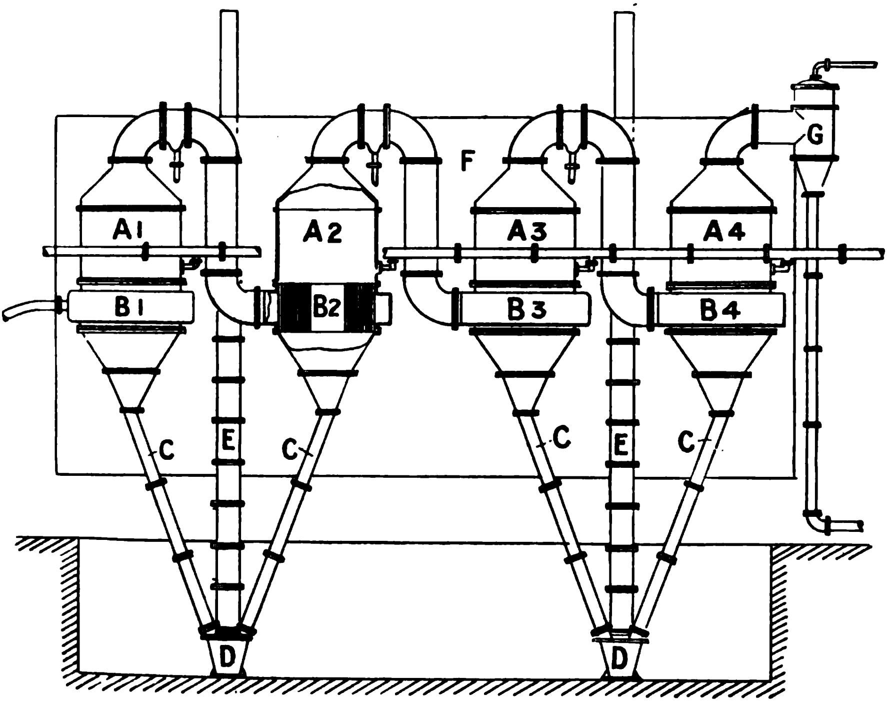

FIG. 6.

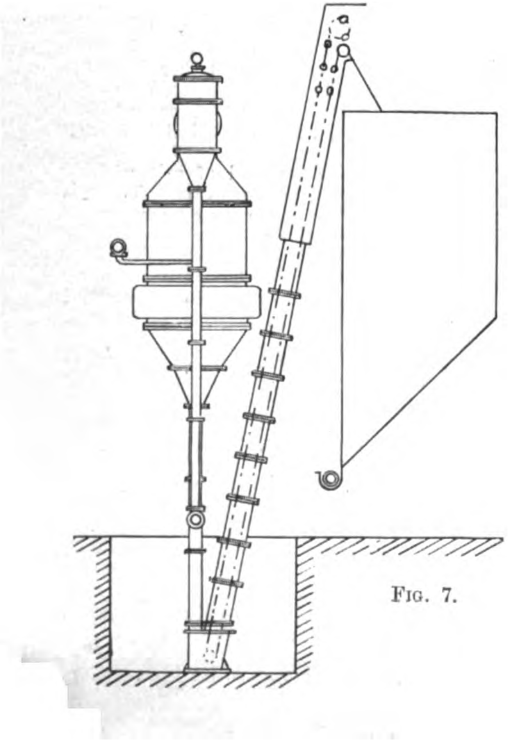

FIG. 7.

This process has rendered the manufacture of salt remunerative in places where heat was in some form or other being wasted. One of its first applications was in utilising the exhaust steam from the lumber mills of Michigan, and latterly it is being found suitable for making use of the steam from turbines and for generating electricity. The great source of trouble in working the process is the impurity of ordinary brine. The calcium sulphate, which every natural brine contains, separates in the form of scale on the tubes. This scale, containing anhydrite and a large quantity of salt, has to be constantly removed because it seriously interferes with the transfer of heat.

Many devices have been tried to overcome this difficulty. Some of the most obvious are those which deal with the partial purification of the brine prior to its use in the evaporators. Other mechanical ones have been fairly successful, notably that patented by Trump in 1903. The best, however, appears to be the addition of calcium chloride to the brine during evaporation, as suggested by Vis in 1898. This causes precipitation of the calcium sulphate in the form of small crystals that mix with the salt and does not allow scale to form on the tubes. The salt, on withdrawal from the apparatus, is washed free from calcium chloride with fresh brine. The washings are sent with the brine fed into the evaporators and so the calcium chloride is used over and over again.

Salt makers experience one difficulty in working vacuum plant, and that is, the grain of the salt produced is always fine. Where a coarse grain of salt is required, brine which has been heated in a vacuum evaporator has to be allowed to flow through an ordinary open pan or a grainer so as to permit the crystals of salt to form slowly and to grow.

In the ordinary process of manufacturing salt the brine is run into a shallow pan, which is heated from below, and is made of such a shape as will expose as much surface as possible both to the action of the fire and of the air. The oldest pans of which there is any record were made of sheet lead, and were only about 3 ft. square and 3–4 ins. deep, holding little more than 15 gallons. These so-called 'leads,' when filled, were set aside in a warm place or on a hot flue, until the brine deposited its salt. About the middle of the seventeenth century iron pans superseded the leaden ones.

Writing in 1748, Brownrigg describes pans then in use as being made of 'plates of iron joined together with nails and the joints filled with a strong cement. Strong iron hooks hang down from beams of iron fixed across the pan and are linked to other hooks on the bottom of the pan and thus prevent it from bending down' (The Art of Making Common Salt).

In 1765 the largest pans used at Northwich were 20 ft. long by 9 or 10 ft. wide. At the present time the smallest employed are 25 ft. long by 20 ft. wide and 15 ins. deep, while some of the pans used for making coarse salt are 70 ft. long by 25 ft. wide and 18 ins. deep.

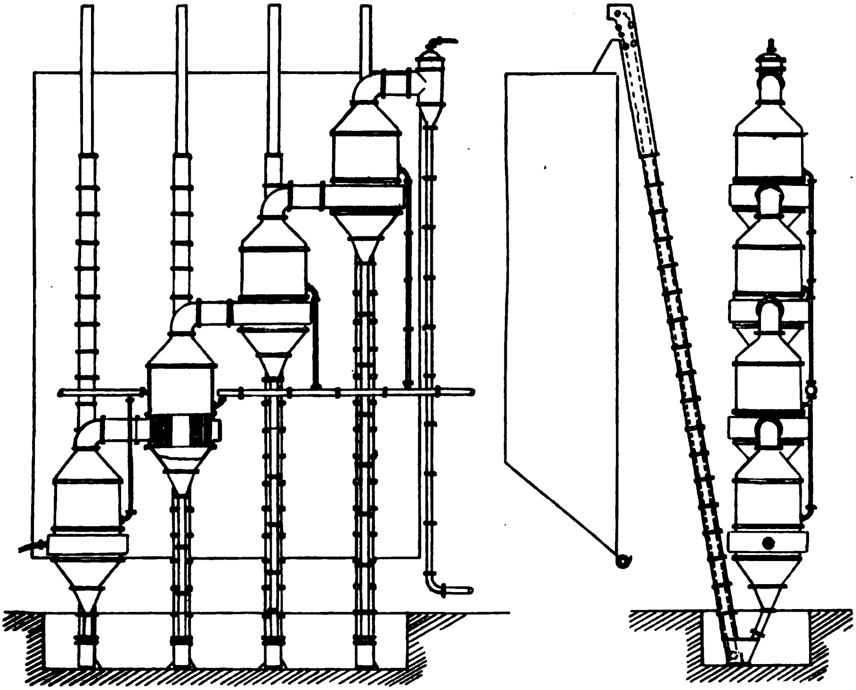

Fig. 8.

The pans are placed upon brickwork, which serves for a support and also forms the walls of the flues. The fireplaces are placed in the front, and vary in number from 2 to 4, according to the size of the pan and the work it has to do. The flues are frequently carried straight from front to back of the pan. In some pans the portions marked F in Figs. 10 and 12 are shut off from the flues in order that when the salt is raked up to the side, previous to drawing, it does not cause super-heating of the pan plates. Fig. 9 shows the front view of a salt pan; Fig. 10 is a cross section at the break shown in Fig. 11; Fig. 11 is a longitudinal section: Fig. 12 is a plan of the flues.

The pans are made of wrought-iron plates carefully riveted together like boilers. The plates which lie directly over the fires are made of greater strength than the rest of the pan, on account of the greater wear which they have to stand. As these plates have to be renewed more frequently than any others, they are made smaller, and are so arranged that they can readily be cut out (*see* Fig. 13). Each set of fire-plates A, A, A, A, is separated from its neighbours by a midfeather plate B, B, which rests upon the wall dividing two fireplaces. The two outer sets are separated from the side of the pan by a similar long plate. The bottom and sides of the pan are joined by means of an angle iron, to which each is firmly riveted (Fig. 14).

As above stated, the plates A which lie in the vicinity of the fires are subjected to the greatest wear. When they become over-heated they sink and stretch, and, in so stretching, they tear the plates C at the front of the pan. It is obvious that the removal of the front plate would necessitate frequent interference with the angle iron, and this would entail a greater expenditure of labour; therefore it is found advisable to place two rows of plates along the front. All the plates used in the neighbourhood of the fires are ⅜ in. thick, while those employed for the back parts are ¼ in. Some French pans have the fire-plates raised towards the centre above the level of the rest of the pan (*see* Fig. 17), in order that the salt, when formed, may float off the fire-plates. Salt-pans should be made to extend about 1 ft. or 1 ft. 6 ins. beyond the front wall, in order to keep the angle iron well out of the fires. They are also made to overlap the side walls by about 6 ins., for the double purpose of keeping the angle iron clear of the flues, and for allowing what is known as toe-room for the man who draws the salt out of the pan. If the drawer can place his toe under the pan, he is able to get his leg flat against the side of the pan. This affords him greater power in stooping over the pan, and prevents him wearing the skin off his knee. The best method of setting the pan on the side walls is to build up a 9-in. wall, and make the top course of bricks only 4½ ins. deep (*see* Fig. 15).

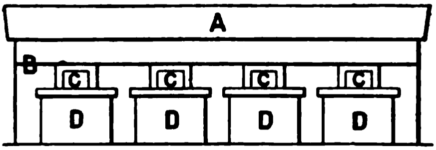

FIG. 9.—SETTING OF SALT-PANS.
A. The salt-pan. B. The front wall or fore-bye.
C, C, C, C. The fireplaces. D, D, D, D. Ash holes.

What is technically known as the 'standing side' consists of a gangway of 2-in. planks about 2 ft. wide, which runs the entire length of the pan, on a level with the top of the 9-in. side wall. On both sides of the pan, and often across the back, there runs a platform composed of 2-in. planks well jointed together, and caulked with oakum. These stages are technically known as the 'hurdles,' and serve for a receptacle for the wet salt freshly drawn from the pan. They have a fall towards the centre or half-length of the pan, and are bordered on the pan side by a gutter in order that the brine which drains from the salt may run back into the pan (Fig. 16). It is customary on the Continent to cover in the salt-pans with a wooden shelter, provided with an upright shoot to take off the steam. In such cases this cover serves instead of the hurdles, and it possesses the distinct advantage that the heat from the pan serves in a great measure to dry the salt. In some Continental works a tramway runs down the centre of this wooden cover, and the salt is taken off in trucks (*see* Figs. 17 and 18).

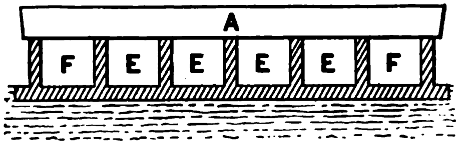

FIG. 10.—SETTING OF SALT-PANS.
A. The salt-pan. E, E, E, E. The flues.

Fine-grained or lump salt. Fine-grained salt is made in the smallest-sized pans. These are 25–35 ft. long and 20–24 ft. wide, and 15–18 ins. deep. The brine is boiled and reaches the temperature of 226°F. or 107·5°C. As the salt forms it is raked off the fire-plates to the side of the pan from time to time. Twice or three times in 24 hours the salt is drawn from the pan.

The salt is lifted out of the pan on a perforated sort of shovel, known as a 'skimmer' (Fig. 19). As it is drawn out of the pan it is placed either in wooden boxes (Fig. 20) standing on the hurdles, or thrown on to the hurdles in bulk. As it cools in the boxes the hot brine which it contains crystallises, and suffices to cement the whole together into a solid mass. This is knocked out of the box and placed in the stoving chamber to dry. This hot room is generally heated by the waste heat from the flues of boiling pans. The fine table salts are prepared by crushing and grinding the lumps after drying.

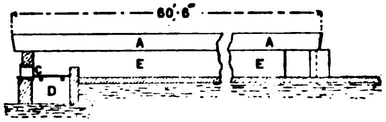

FIG. 11.—SETTING OF SALT-PANS.
A. The salt-pan. C. The fireplace. D. Ash hole.
E. Flue.

Common salt. The name 'common' is given to that grain of salt which is made for use in various manufacturing operations. It is made at a temperature of 160°–180°F., or 61°–82°C., in pans 45 ft. long by 25 ft. wide and 18 ins. deep. The salt is raked off the fires about every 2 hours, and drawn out of the pan every 24 or 48 hours. After draining on the hurdles for some hours it is shipped off in railway waggons.

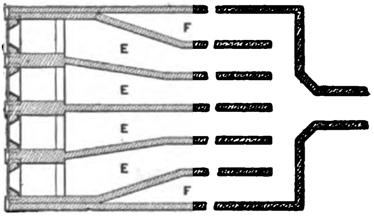

FIG. 12.—SETTING OF SALT-PANS.
E. Flues. F. Blank spaces.

Fishing salt. Fishing salt is a coarse-grained variety manufactured for the fish-curing trade. It is made at a temperature of 100°–140°F., or 37·7°–60°C., in pans 50–60 ft. long by 24–25 ft. wide and 2 ft. deep. The salt is drawn out once a week or once a fortnight, according to the grain required. These pans are often heated by the flue gases from boiling-pans. A little alum is added to the brine to harden the crystals of salt.

Bay salt. Bay salt is the coarsest-grained salt manufactured. The pans employed are very large, sometimes even 140 ft. long by 25–30 ft. broad. The temperature of the brine is kept at about 100°–120°F. The salt is drawn every 3 weeks or month.

The salt manufacturer frequently manipulates his brine in order to obtain the exact grain of salt that he requires. The addition of gelatin, glue, or any kind of grease causes the salt to form in very small crystals, whilst the addition of alum has the opposite effect. The operation of adding such substances is technically known as 'poisoning the pan.' Alum is employed in the manufacture of the variety of salt known as 'hopper salt.' It causes the salt to crystallise in hollow cubes, and as these float about before falling to the bottom of the pan they become surrounded by others, and gradually form into the shape of a shoot or hopper (Fig. 21).

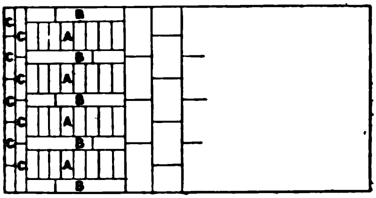

Fig. 13.—Plan of Salt-pan, showing Arrangement of Plates.

Natural brine is seldom a solution of pure sodium chloride, but generally contains other salts in solution, as will be seen from the foregoing analyses (p. 11). Certain of these substances separate out during the process of evaporation, and not only render the salt impure, but give trouble in the pan. If the brine contains calcium bicarbonate, the application of heat produces a precipitation of calcium carbonate.

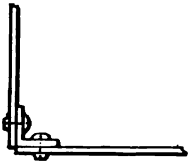

Fig. 14.

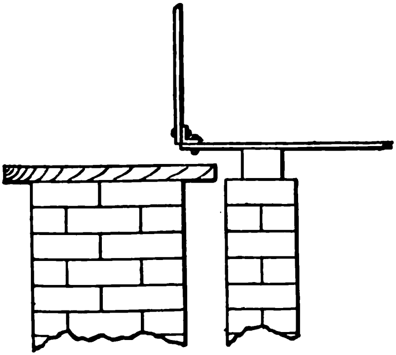

Fig. 15.

When this occurs in a salt-pan the calcium carbonate (which is almost always accompanied by oxide of iron) deposits on the top of the fire plates, and forms what is technically called 'sand scale.' This has to be broken from time to time with a blunt pick and fished out of the pan, otherwise the plates would get red hot and burn away. When a pan begins to leak, the brine often crystallises as it drops into the flue, and forms a stalactitic mass, which is locally called a 'cat.' This is not the only trouble caused by a leaky pan, for, in addition, hydrochloric acid is frequently formed, through the decomposition of sodium chloride by sulphur dioxide in the presence of water. The sulphur dioxide is generated by the combustion of small quantities of pyrites in the fuel. All British salt works are now under Government inspection, and the chimney gases are tested from time to time by the inspectors.

If brine contains calcium sulphate, it deposits it when heated. This falls to the bottom of the pan, and forms a scale which frequently contains a large quantity of salt. It sometimes accumulates to a thickness of 4 ins. and is known as 'pan scale.' On account of the growth of scale and the consequent decreased

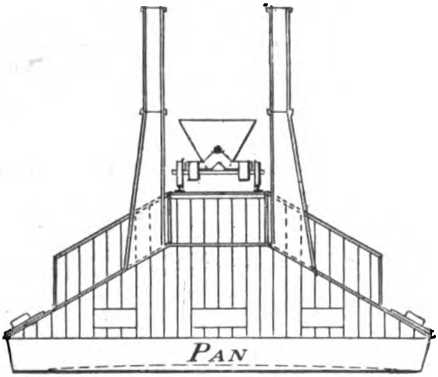

Fig. 18.—Front view of a French Salt-pan, showing Chimneys to carry off the Steam.

Dotted line shows curve of the pan over the fires.

efficiency of the pan, it becomes necessary after working for a given time to run off all the liquid from the pan and remove the scale. This operation is termed 'picking' the pan.

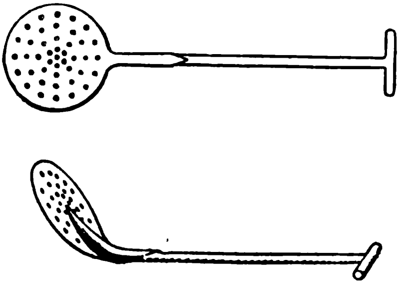

Fig. 19.

Solar salt. In some places, where the natural brine is so weak or fuel is so scarce that evaporation by artificial heat is not remunerative, salt is made by exposing the brine to the rays of the sun in large wooden pans resting on the ground. Such pans are frequently provided with movable covers which are pushed aside in fine weather and drawn over if rain comes.

Along the sea-coast of countries which possess a dry climate or habitually experience a hot summer, salt is made by solar evaporation of sea water.

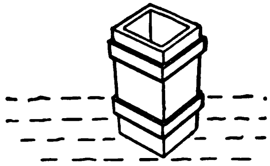

Fig. 20.—A Box for Lump Salt.

A large piece of land, slightly below high-water mark, is levelled and surrounded by a wall or bank. The ground is, if necessary, puddled with clay to make it water-tight, and the enclosed space is divided into compartments by internal walls. Sea water is admitted at high tide, and, after being allowed to deposit any solid matter it may contain, is run from compartment to compartment until salt crystallises out. This is then raked together into heaps and allowed to stand while the more deliquescent salts, such as magnesium chloride, run away.

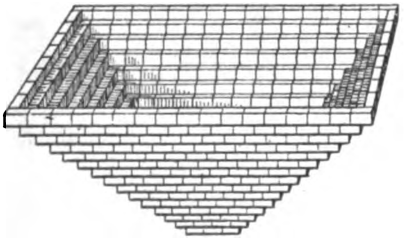

Fig. 21.

These salt gardens (German, *Salz-Gärten*) are freely worked in Portugal, Spain, France, Austria, Corsica, Italy, Cyprus, Smyrna, and in India, and produce very large quantities of salt. The product is naturally much more impure than that made from brine derived from rock salt.

The mother-liquors are comparatively rich in bromides of calcium and magnesium, and are sometimes employed for the extraction of bromine.

In some cold countries, such as Russia and Sweden, salt water is allowed to freeze, and the ice, which consists of nearly pure water, is removed. By repeating this several times, a mother-liquor is obtained which is sufficiently strong to boil down. The salt obtained does not contain more than 75–85 p.c. of sodium chloride.

J. I. W.

Sodium bromide can be prepared by neutralising a solution of sodium hydroxide or carbonate with hydrobromic acid, but is usually made technically by adding bromine to a hot solution of caustic soda, mixed with powdered charcoal. Sodium bromide and bromate are first produced, but on evaporating the solution to dryness and heating the residue, the latter is reduced by the charcoal.

$$6NaOH+3Br_2=5NaBr+NaBrO_3+3H_2O$$
$$2NaBrO_3+3C=2NaBr+3CO_2.$$

Sodium bromide forms white crystals which, when produced from solutions below 50°, contain two molecules of water and belong to the monoclinic system. Above that temperature the anhydrous salt, crystallising in cubes of sp.gr. 3·014, is obtained. A second hydrate, $NaBr,5H_2O$, separates out from strongly cooled solutions of the salt. The anhydrous salt melts at about 760°; it dissolves in water with considerable absorption of heat, its solubility being given below (De Coppet, Ann. Chim. Phys. 1883, [vi.] 30, 420):—

Temp.	—10°	0°	20°	40°	60°	80°	100°	120°
Grams NaBr in 100 gms. water	75·1	79·5	90·3	105·8	117	118·5	120·5	122·5

The saturated solution boils at 121° It is also soluble in alcohol and in acetone, one part of the salt requiring at the ordinary temperature 14 parts of ethyl alcohol or 4·6 parts of methyl alcohol for solution. For the sp.gr. of sodium bromide solutions, *see* Kremers (Pogg. Ann. 1855, 96, 39); for their electrical conductivity, *see* Ostwald (Allgem. Ch., Leipzig, 1893), and for their refractive indices *see* Borgesius (Wied. Annalen, 1895, 54, 233).

Sodium bromide is occasionally employed in medicine in place of the potassium salt, which it resembles in its physiological effects.

Sodium iodide. This salt can be prepared artificially in a manner analogous to that given under sodium bromide (*q.v.*), or by double decomposition between solutions of ferrous iodide (prepared by acting on iron filings with iodine in the presence of water) and caustic soda. It separates from solutions at temperatures under 65° in white, slightly deliquescent crystals containing two molecules of water, which are isomorphous with the corresponding hydrates of sodium bromide and chloride. Above 65° the anhydrous salt is obtained. Panfiloff (J. Russ. Phys. Chem. Soc. 25, 272) has obtained the hydrate $NaI,5H_2O$ by cooling a solution of the salt to —14°. Sodium iodide melts at about 650°. The sp.gr. of the anhydrous salt is 3·665. The salt is very soluble in water, 100 parts of this liquid dissolving at

0°	10°	20°	30°	40°	50°	60°	80°	100°
159	169	179	190	205	228	257	295	302

parts of sodium iodide (De Coppet, Ann. Chim.

Phys. 1883, 30, 420). The boiling-point of the saturated solution is 141°. One part of the salt dissolves in 1·7 parts of ethyl or 1·2 parts of methyl alcohol at ordinary temperatures, and it is also very soluble in acetone. If sodium iodide be kept fused for a considerable time in contact with air, it loses a little iodine. Heated with carbon in presence of air it is almost completely converted into carbonate. For the electrical conductivity of sodium iodide solutions, *see* Kohlrausch and Holborn, Leitvermögen der Elektrolyte, Leipzig, 1898. For the melting-points of mixture of KI and NaI, *see* Kurnakow and Shemtschushni, Chem. Zentr. 1906, i. 527. A compound $NaI_8,2(C_6H_5NO_2)$ has been isolated by Dawson and Goodson (Chem. Soc. Trans. 1904, 85, 796) from a solution of sodium iodide in nitrobenzene saturated with iodine, in the form of greenish metallic crystals which deliquesce in the air. Sodium iodide, like sodium bromide, is used to a small extent in medicine in place of the potassium salt. See also vol. iii. p. 153.

Sodium hyposulphite, *see* under *Hyposulphurous acid*, art. SULPHUR.

Sodium sulphides. *See* p. 29.

Sodium sulphites. Three sulphites of sodium are known, *i.e.* the normal sulphite, the bisulphite, and the metabisulphite.

Normal sodium sulphite can be prepared in the anhydrous state by heating sodium bisulphite with the theoretical amount of sodium bicarbonate or by passing ammonia gas into a solution of sodium chloride and ammonium sulphite. If a cold, saturated solution of the heptahydrated salt be heated, a crystalline precipitate of the anhydrous salt is formed.

The salt is unalterable in air and dissolves readily in water; by evaporation of the solution white, monoclinic crystals of the heptahydrate are obtained. These have a sharp taste, effloresce on exposure to air, and dissolve fairly easily in water, yielding a solution which reacts alkaline. The solubility for different temperatures has been determined by Kremers—

Temperature	0°	20°	40°	100°
Grams Na_2SO_3 per 100 of water	14	29	50	33

According to Mitscherlich (Pogg. Ann. 1827, 12, 140) the solubility of the salt reaches a maximum at 33°, which temperature represents the transition-point of the hydrated into the anhydrous salt.

Dilute solutions of sodium sulphite oxidise rapidly, but a 20 p.c. solution is stable (Lumière and Seyewetz, Revue gén. chim. pur. et app. 1896, 7, 111). The oxidation is greatly accelerated by the presence of small quantities of copper sulphate, whilst potassium thiocyanate and mannitol have a retarding action. On heating in air sodium sulphite yields a mixture of sulphide and sulphate—

$$4Na_2SO_3=3Na_2SO_4+Na_2S.$$

On the large scale sodium sulphite is prepared by passing sulphur dioxide through a solution of sodium carbonate or through a vessel filled with the crystallised salt, until the product has an acid reaction. The resulting solution, consisting chiefly of bisulphite, is converted into the normal sulphite by adding sodium carbonate to the boiling solution until no more carbon dioxide is evolved. The liquid is then allowed to settle, decanted and evaporated to the crystallising-point.

(i.) $Na_2CO_3+2SO_2+H_2O=2NaHSO_3+CO_2$.
(ii.) $2NaHSO_3+Na_2CO_3=2Na_2SO_3+CO_2$.

Sodium bisulphite $NaHSO_3$ is produced by saturating a solution of sodium carbonate with sulphur dioxide. It forms a white powder, smelling of sulphur dioxide, is only sparingly soluble in water, and is precipitated from its aqueous solution by alcohol. On heating, it decomposes, evolving sulphur and sulphur dioxide and leaving a residue of sulphate. A crystallised trihydrate and tetrahydrate have been obtained by strongly cooling the solution of the bisulphite made in the above mentioned way; both are very unstable, and rapidly change into the stable metabisulphite.

Sodium metabisulphite $Na_2S_2O_5$ is prepared by supersaturating a solution of sodium carbonate with sulphur dioxide, when it is obtained in anhydrous crystals on cooling the solution. The salt only slowly oxidises on exposure to air at the ordinary temperature; on cautious heating at 80° it loses 1 molecule of SO_2, and on further rapid heating evolves sulphur and sulphur dioxide, leaving sodium sulphate

$$2Na_2S_2O_5=2Na_2SO_4+SO_2+S$$

(Schultz-Sellack, J. pr. Chem. [i.] 110, 459).

It is made technically by the method described above or by passing sulphur dioxide over monohydrated sodium carbonate (Carey and Hurter, Eng. Pat. 4512, 1882).

The normal, bi-, and metabisulphites of sodium are largely employed in various industries, chiefly as antiseptics, reducing agents, and sources of sulphur dioxide. The boiling solution of the sulphite has the property of readily dissolving the resin, gum, &c., contained in wood without in any way affecting the cellulose. Hence the bisulphite is used in preparing the 'sulphite pulp' now so largely made from wood for use in the manufacture of paper. It is also employed in the calico-printing and colour industries as a reducing agent, and as an 'antichlor' for removing the last traces of chlorine from the bleached pulp obtained in paper-making. It also finds application as an antiseptic for steeping grain, preserving food, &c., and a strong solution is employed as a sterilising medium for brewers' casks. Owing to its property of combining with many organic aldehydes and ketones to form crystalline, mostly insoluble, additive compounds which can easily be isolated and purified, it is used in the laboratory in the identification and purification of these classes of compounds. Normal sodium sulphite finds application in medicine as an antiseptic and as an antizymotic for internal use. Its solution has been proposed for use in gas analysis, owing to its power of absorbing nitric oxide. Both the normal and metabisulphites are extensively employed in the preparation of photographic developers for preventing the oxidation of the pyrogallol, hydroquinone, &c., which these contain, and the normal salt has been proposed by Abney (Phot. News, 1885, 370) as a substitute for the sodium thiosulphate used to dissolve out the unaltered silver salts in the process of fixing photographic prints. A large number of double sulphites of sodium with other metals are known, the most interesting being the sodium potassium sulphite, which was formerly thought to exist in two isomeric forms. This view has, however, been shown to be incorrect (Barth, Zeitsch. physikal. Chem. 1892, 9, 176; Arbusoff, J. Russ. Phys. Chem. Soc. 1909, 41, 447).

Sodium thiosulphate. See p. 29.

Sodium silicates. The solubility of silica in alkalis was well known to the alchemists, a method for preparing sodium silicate being described as early as 1520. They were also well acquainted with many of the properties of the resulting solution, such as the coagulation which takes place on adding an acid. Sodium silicates are prepared by fusing together silica and sodium carbonate or by digesting finely-divided silica with caustic soda solution. The composition of the resulting silicate varies with the duration of the heating, the temperature, and the relative amounts of silica and alkali employed. A number of sodium silicates have been prepared and examined by Ordway (Amer. J. Sci. [ii.] 32, 162, 337; 33, 27, 35; 35, 35, 185), but the metasilicate Na_2SiO_3 is the only well-defined one. It may be obtained pure by digesting the theoretical amount of freshly-precipitated, hydrated silica with caustic soda solution. On adding twice the volume of alcohol it is precipitated as a white, crystalline powder. Only the metasilicate has been obtained in the crystalline condition, the others forming amorphous, glassy bodies.

Pure sodium metasilicate is a white, crystalline salt, melting at about 1000° (Kultascheff, Zeitsch. anorg. Chem. 1903, 35, 187). Hydrates containing 5, 6, 7, 8, and 9 mols. of water have been described, but their existence is somewhat doubtful. The aqueous solution of the salt has an alkaline reaction owing to hydrolytic dissociation. Kahlenberg and Lincoln (J. Phys. Chem. 1898, 2, 81) state that at a dilution of 1 grm. mol. in 48 litres the hydrolysis is complete, according to the equation:

$$Na_2SiO_3+H_2O=SiO_2+2NaOH$$

the silica being in colloidal solution.

Aqueous solutions, even dilute ones, of sodium silicate are precipitated by alcohol. On treatment with acids, even carbonic acid, the salt is completely decomposed with separation of gelatinous silica; the alkaline carbonates and chlorides, especially ammonium chloride, also precipitate the silica. Salts of the alkaline earths give precipitates of insoluble double silicates. Commercial sodium silicate, also called soluble glass or water-glass, usually approximates to the composition $Na_2O,4SiO_2$, containing about 79 p.c. of silica. It is prepared on the large scale by two processes, known as the dry and wet methods respectively. In the dry method, a mixture of powdered quartz or white sand and either sodium carbonate or sulphate is fused in a Siemen's regenerative furnace or similar gas-fired furnace for 5–8 hours at a temperature of about 1100°. Continuous coal-fired furnaces are also in use, which are capable of turning out 1250 kilos. of water-glass in 24 hours with a consumption of 1500 kilos. of coal.

The product is run out in a fused condition into an iron receptacle and allowed to cool. Typical mixtures employed for the charge are given below, the coal being added to assist in the reduction of the carbonate or sulphate.

1	2
100 lbs. powdered quartz	100 lbs. powdered quartz
28 lbs. calcined sodium carbonate	60 lbs. calcined sodium sulphate
	15–20 lbs. coal
3	4
180 lbs. white sand	180 lbs. white sand
110 lbs. sodium sulphate	100 lbs. 50 p.c. sodium carbonate
10 lbs. coal	3 lbs. coal

The fused product is broken up by a stone-breaker or ground by suitable machinery and dissolved by long boiling with water, preferably under pressure. The resulting solution is allowed to clarify, and is then evaporated to 40°Bé. in iron pans. The small proportion of sulphide sometimes present from the reduction of the sulphate can be removed by adding a little copper scale or litharge when preparing the solution. 100 lbs. of the solid yield about 300 lbs. of a solution of 40°Bé.

The wet method of preparation is largely employed on account of the greater uniformity of the product, and the fact that it is obtained at once in the form of a solution. It consists in digesting silica—preferably infusorial earth—with a solution of caustic soda of sp.gr. 1·22–1·24 (prepared by causticising a solution of sodium carbonate with lime) under three or four atmospheres pressure. The liquid is heated by blowing in steam and is kept stirred by machinery. Complete solution is attained in about 3 hours, as shown by withdrawing a sample, when the suspended matter ought to settle rapidly and be of a brick-red colour (Fe_2O_3), whilst the liquid should be almost free from alkaline reaction. The caustic soda must not be above 1·24 sp.gr. as a stronger solution holds the fine sand and ferric oxide in suspension for a long time, such solutions not clarifying properly even after standing for several days. The clarified liquid is drawn off and concentrated to the required strength (usually 1·7 sp.gr.) in iron pans. 2·8 parts of infusorial earth are employed for every part of caustic soda, and the resulting water-glass solution has a density of about 1·18, the decrease in specific gravity being due to the dilution produced by the condensed steam. Instead of infusorial earth, other forms of silica, such as powdered flints, quartz, &c., can be employed, but the digestion must then be continued for a longer time and under 7–8 atmospheres pressure.

A pure silicate may be made from the crude product by passing a current of carbon dioxide through the solution, filtering off the precipitated hydrated silica and redissolving it in caustic soda.

The aqueous solution of sp.gr. 1·7 usually has the following composition: silica 32–33 p.c., soda 16–16½ p.c., other sodium salts 2½–3 p.c., water 48–49 p.c.

A water-glass known as ‘double soluble glass’ and containing about equal proportions of sodium and potassium silicates, is prepared by using the proper quantities of potassium and sodium carbonates in place of sodium carbonate alone. It is said to give a thinner solution than either the potassium or sodium salt of corresponding strength.

Commercial water glass is sometimes colourless, but usually has a brownish or greenish colour. It is nearly insoluble in cold water, but dissolves completely, although slowly, in boiling water, the solubility decreasing as the percentage of silica in the substance increases. Silicates containing more alkali than corresponds with the composition $Na_2O{\cdot}2\frac{1}{2}SiO_2$ are deliquescent, and too poor in silica to be applicable to the ordinary uses of water-glass (Ordway, Amer. J. Sci. [ii.] 35, 193).

The following is a list of patents dealing with the manufacture of water-glass :—

Ransome, Eng. Pats. 10360, 1844; 10665, 1845; 1666, 1853; 645, 1855; 2267, 1856. Kuhlmann, Eng. Pat. 367, 1853. Losh, Eng. Pat. 14208, 1852. Gossage, Eng. Pats. 762, 1854; 799, 1099, 1859. Kayser, Williams, and Young, Eng. Pat. 11493, 1887. Sievert, Eng. Pat. 4021, 1890. Crosfield and Markel, Eng. Pat. 18998, 1894. Garroway, Eng. Pat. 2489, 1896. I. J. Brown, Eng. Pat. 24237, 1902. Watson, Eng. Pat. 25394, 1904.

Sodium silicate is largely used on account of its detergent properties as an addition to soap, principally to those intended for toilet use, as it imparts hardness and durability. Two typical analyses of such soaps are given below :—

	I.	II.
Soda . .	12 p.c.	12·5 p.c.
Silica . .	10 „	8·5 „
Water . .	30 „	33·0 „
Fatty acids .	48 „	46·0 „

Water-glass is also employed in the calico-printing and dyeing industries as a fixing agent for pigments; in printing indigo; as a resist for certain colours, and in the finishing of cotton goods. It is a constituent of certain lead-free enamels for glazing pans, &c., intended for domestic use, and is occasionally employed in the basic linings of Bessemer converters. It is used in fixing fresco-painting (stereochromy), for rendering wood, paper, &c., uninflammable, in bleaching jute, for preventing wood from rotting, and for preserving eggs. A mixture of 2 parts fluorspar and 1 part powdered glass made into a thick paste with water-glass is used as a cement for glass and porcelain. The so-called 'artificial vegetation' is made by dropping small fragments of cobalt chloride, ferrous sulphate, and many other salts into a solution of sodium silicate, when frond-like appearances, due to the formation of insoluble metallic silicates, are producd.

Sodium silicate is largely used for impregnating sandstone and other porous stones as a protection against weathering. The stone is treated with a solution of water-glass, followed by the application of a solution of calcium chloride or aluminium sulphate, which causes the deposition of an insoluble silicate in the pores of the stone, greatly increasing its hardness and durability. The soluble sodium salt formed is removed by a subsequent washing (*see* also Burnell, J. Soc. Arts, 8, 240). An important application of water-glass is in the manufacture of artificial stone. The following is an outline of the process used at an English works for the manufacture of chimney-pots, mouldings, &c. The sand or sandstone employed having been ground wet and passed through a 40-mesh sieve is thoroughly dried and mixed in a revolving pan provided with scrapers and edge mixers with sufficient liquid water-glass to form a moist, coherent mass. It is then pressed into moulds and is saturated before removal with a solution of calcium chloride (prepared by running hydrochloric acid over calcspar) drawn through by a vacuum equal to about 20 ins. of mercury. Calcium silicate having thus been formed as above, the stones are transferred to boiling tanks heated by steam, and, after a sufficient time to complete the setting, are conveyed to washing tanks, in which they are subjected to the action of running water for a fortnight, to remove the whole of the sodium chloride.

Sodium sulphate, technically called 'sulphate,' or 'salt-cake,' was first obtained by its discoverer, Glauber, as described by him in 1658, exactly in the same way as it is prepared now, by the decomposition of common salt by sulphuric acid. The crystallised salt, containing 10 molecules of water of hydration, is still called 'Glauber's salts.' Both the anhydrous and the hydrated salts are found in many places in nature; the former, as a mineral, is called *thenardite*, the latter *mirabilite*. Large quantities of sodium sulphate occur native, especially in Spain, at Lodosa, in the Ebro valley, and elsewhere, and in the Western States of North America.

The double sodium and calcium sulphate called *glauberite*, also occurs naturally in large quantities and in many places.

Sodium sulphate is frequently obtained as a *by-product* of other manufactures, of which we mention only two.

Impure sodium sulphate is obtained in the (now almost obsolete) manufacture of hydrochloric acid in cast-iron cylinders from common salt and sulphuric acid; this product, called *cylinder-cake*, mostly contains from 7 to 10 p.c. of undecomposed sodium chloride. On the other hand, the *nitre-cake*, obtained in decomposing sodium nitrate by sulphuric acid, always contains a considerable proportion of acid sodium sulphate $NaHSO_4$.

A certain quantity of sodium sulphate, principally in the state of Glauber's salts, is made from the residues left on dissolving the crude carnallite ('Abraumsalz') at Stassfurt. The latter contains a large quantity of insoluble *kieserite* $MgSO_4,H_2O$, which, on being exposed to the weather, or brought into contact with water for some time, gradually yields soluble magnesium sulphate $MgSO_4,7H_2O$. The residues at the same time contain much common salt, and, if necessary, more of the latter is added, so as to bring up the quantity to the proportion of 2 NaCl to 1 $MgSO_4$. When this mixture is dissolved in water and the solution is exposed to a natural or artificial cooling a few degrees below 0°, the following decomposition (noticed by Scheele as early as 1787) sets in :—

$$MgSO_4+2NaCl=Na_2SO_4+MgCl_2.$$

The sodium sulphate crystallises as Glauber's salts, the magnesium chloride remaining behind. Many thousands of tons of Glauber's salts are made at Stassfurt in this way.

By *heating metallic sulphides with common salt in the presence of air*, sodium sulphate is produced in considerable quantities. This process has been known for more than a century in metallurgy, where it is employed for extracting silver and copper from their ores. In this case, of course, the metal is the product really aimed at, and the sodium sulphate is in actual practice run to waste in the shape of impure solutions. In 1842 Longmaid introduced a modification of this process, by which the sodium sulphate was obtained in a marketable form; but this was only practicable when employing ordinary iron pyrites, free from copper, and the sodium sulphate obtained in this way could not compete with that made in the usual way from common salt and sulphuric acid, as found out in the working of Longmaid's process in several places through a number of years. A similar process is employed up to this day for the recovery of copper from cupreous pyrites; but here the sodium sulphate is lost, all attempts to recover it having failed on account of expense.

Iron pyrites is, however, employed in a different manner for manufacturing nearly all the sodium sulphate found in trade—namely, either by first manufacturing sulphuric acid and employing this for decomposing common salt, or by the direct process of Hargreaves and Robinson, in which the pyrites-kiln gases are made to act upon common salt under such circumstances that sodium sulphate and hydrochloric acid are produced. We shall now describe these two processes.

The *decomposition of sodium chloride by sulphuric acid* is the process employed by Glauber, and by Leblanc, and at present produces by far the larger part of the sodium sulphate used. We shall omit mention of the obsolete processes of performing this operation in glass retorts or iron cylinders, and describe the process as now carried out.

The raw materials for the salt-cake process are:

1. *Common salt*—that is, impure sodium chloride. In England 'pan-salt' is generally used, the porous condition and coarse grain of which is of great advantage in the process; it is also generally fairly pure, but contains varying quantities (8 to 10 p.c.) of water. Rock salt is also employed to a great extent; this must be coarsely crushed, not finely ground, and should be as free as possible from calcium sulphate. As is to be expected, the impurities and their amounts permissible in salt to be used for the production of salt-cake depend on the purpose for which the salt-cake is afterwards to be used.

2. *Nitre-cake*—that is, the residue from the manufacture of nitric acid, consisting of a mixture of a normal and acid sodium sulphate. Nitre-cake is frequently mixed off with an ordinary charge of salt. The free acid determined by analysis replaces part of the sulphuric acid which would otherwise be required to decompose the salt used. The nitre-cake is broken into lumps which readily melt in the decomposing pan.

3. *Sulphuric acid.* This should be neither too weak nor too strong, preferably about 140°—that is, at the strength it usually comes from the Glover tower. Stronger acid acts too rapidly, and yields badly mixed batches; weaker acid retards the operation and injures the pots.

The decomposition of NaCl by H_2SO_4, though commencing at ordinary temperature, is not completed until a dull red heat is attained. It is the usual practice, therefore, to divide the operation into two stages, the first of which is performed almost always in a cast-iron pot, the second in a brick furnace.

The two stages are generally expressed as:

1. $H_2SO_4+2NaCl=NaHSO_4+NaCl+HCl$
2. $NaHSO_4+NaCl=Na_2SO_4+HCl$.

In practice more than 50 p.c. of the reaction takes place in the first stage. The actual amount depends on the temperature of the charge in the decomposing pan or pot, and varies from 65 to 75 p.c. of the whole.

The *salt-cake pots* are now always made in the shape of shallow cast-iron dishes, 9 to 11 ft. in diameter, and 1 ft. 9 ins. to 2 ft. 6 ins. deep; the thickness of the metal varies from 5 to 7 ins. in the centre, and from 2 to 3 ins. at the sides. These 'pots' weigh from 5 to 6½ tons, and must be made of a special mixture, so as to combine resistance to chemical action with toughness and resistance to changes of temperature. Their edge is sometimes quite plain, sometimes provided with an ordinary horizontal flange; but, best of all, with an upstanding margin on a horizontal flange as shown in Fig. 22 (*v.* p. 23). In the latter case they are arched over in such a way that the arch is sprung from the pan-edge itself, so that any leak occurring here cannot cause the escape of hydrochloric acid into the fire-flues. The arch or dome over the pot is built of acid-resisting brick, usually set in a mixture of salt and mortar. The common custom is to fill the pot with salt and then heap on more salt until a conical mound of salt is obtained of the desired shape, and the arch is then built, using the mound of salt as the centering.

Near the decomposing-pan there must be a cistern for measuring the sulphuric acid to be run in for each charge. It is preferable that this acid should be moderately warm, and this can be attained by employing as gauge-vessel an iron pan lined with lead, and placing this over a hot flue.

The sulphuric acid from the gauge-vessel is run into the pan through a luted lead pipe which passes through the dome or arch and delivers a slow stream of acid on to the salt in the centre of the pan.

The *calcining-furnace* (*roaster or drier*) may be of various patterns—either a reverberatory (*open*) furnace, or a muffle-furnace (*close* or *blind* roaster). The open-furnaces have now nearly all disappeared and been replaced by muffle-furnaces owing to the greater difficulties and expense of efficiently cooling and condensing the hydrochloric acid produced in the roaster when mixed with the products of combustion from the fireplace; on the other hand, the muffle- or closed-furnaces are naturally more difficult to construct and cost more in repairs.

Figs. 22 and 23 show a common form of open-furnace with the pan attached in sectional elevation and plan. *a* is the fireplace of the furnace, the area of which is comparatively small compared with that of the furnace-bed; *b* is the furnace-bed, with two working doors *f*; *c*, the outlet for the mixed fire-gas and acid-gas; *d*, the decomposing pan, covered by an arch resting upon the pan-flange; *e*, the gas-pipe;

h, a balanced double cast-iron damper, which closes the passage *k* (Fig. 23) (the 'shoving hole') between pan and furnace; *m*, the fire-grate of the pan, covered by the arch *n*, pierced by a number of holes; *o o*, a circular wall on which the pan is supported, equally pierced with holes, so that the flame escapes into the annular space outside, and thence into the main flue. It is evident how the setting of the pan aims at causing the flame to avoid striking the pan, and to distribute the heat as equally as possible.

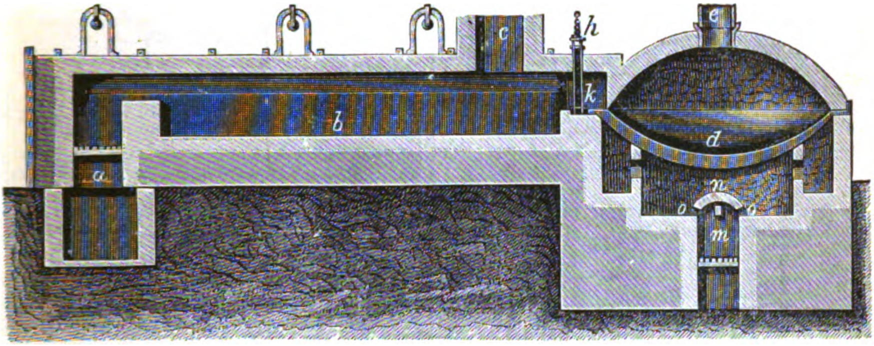

FIG. 22.

In the early days of the muffle salt-cake furnaces very considerable difficulties were experienced in keeping the furnace sufficiently arch tight to prevent leakage of the HCl from inside the muffle into the chimney flue. This was not only a source of loss of HCl, but was liable at any time to cause an infringement of the Alkali Acts which specify in Great Britain a maximum HCl content of the chimney gases of 0·2 grn. HCl per cubic foot.

To meet this difficulty suggestions were made by Muspratt and by Gamble of means to place the flue gases under a higher pressure than the gases inside the muffle and thus to cause any leakage which might take place to be from the fire-gas flue into the muffle. In 1876 Deacon brought out the 'plus pressure' salt-cake furnace which bears his name, and which is to-day by far the most extensively used of all the hand salt-cake furnaces (Figs. 24–27).

The plan adopted by Deacon was extremely simple, and consisted in the building of the fire-place on a lower level than the furnace, thus utilising the pressure due to the ascending current of hot gases to balance the pull of the chimney in the flue space over the furnace arch.

Figs. 24 and 27 show how the flame generated on a grate far below the top of the muffle is made to play, first on the top, then under the bottom, of the muffle, which is supported by a number of dwarf walls. The flame then travels on by an exit flue under the bottom of the pan, which is thus heated without any expenditure of special fuel.

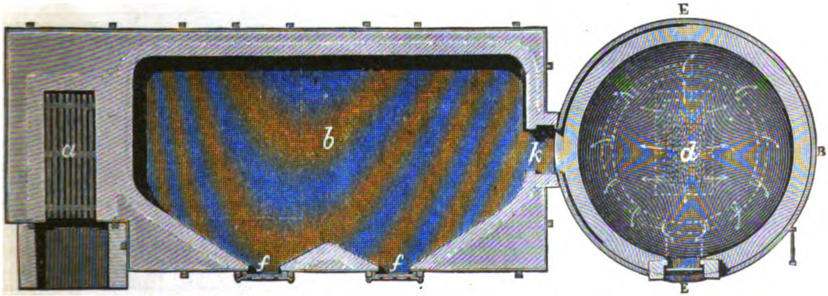

FIG. 23.

It will be noticed in both the illustrations of the open-furnace and the Deacon-furnaces, Figs. 22 and 23, that great care is taken in the setting of the pan so as to ensure, as far as possible, equal heating over its surface. This care is essential to the life of the pan which depends on the mixture of iron used in the casting, on the strength of the vitriol used, on the design of the pan setting, and, of course, also on the carefulness of the men working the charges. With attention to these points salt-cake-pans will last while the furnaces produce up to 4000 tons of salt-cake.

Whether the roaster be an open or a blind one, the work in salt-cake making, as far as the pan is concerned, is almost entirely the same. Only the size of the batches differs in the two cases. With open roasters, which admit of finishing a batch once an hour, or even oftener, batches are made of 6 or 8, or at most 10, cwt. of salt. With close roasters, requiring 2 hours for each batch, they are in England made larger, up to 18 cwts. of salt; but on the Continent even then smaller batches are preferred. In any case, the pan, after removing the last batch, is carefully cleaned from crusts, which would burn fast and cause it to crack prematurely. A small quantity of the next charge of salt is then thrown into the pan, and the sulphuric acid, preferably heated to some extent, is started running in; the rest of the salt is then thrown in as quickly as possible. The quantity of the acid must, of course, be exactly regulated, and in measuring it in the gauge-vessel (*cf.* p. 22), not merely the volume and the hydrometric strength, but also the temperature of the acid must be carefully observed, since the specific gravity by itself is no index of the strength of acid, without taking into account the temperature. A table for reducing the specific gravities of sulphuric acid of various strengths to any other temperature between 0° and 100°C. is given in The Technical Chemist's Handbook, by Lunge.

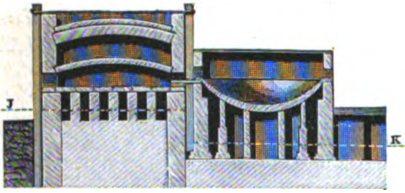

FIG. 24.

As the Twaddel hydrometer is practically universally employed in England, it is useful to remember that for sulphuric acid of the strength here used, 10°F. in temperature corresponds to a rise or fall of 1°Tw. in specific gravity.

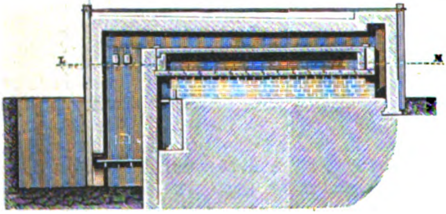

FIG. 25.

Theoretically, 100 parts of pure sodium chloride would require 83·82 parts of pure monohydrated sulphuric acid, or 106·28 parts of acid at 144°Tw., measured at 15°C. But common salt is never pure NaCl. This must be taken into account as well, by daily testing the salt at least for moisture, and allowing, say, 2 p.c. for other impurities. Thus, 100 parts of salt containing 95 p.c. of NaCl would take 79·63 parts of SO_4H_2 or 100·97 parts by weight of sulphuric acid of 144°Tw., measured at 15°C. This means 100·97/1·72=58·70 litres of acid of 144°Tw. for each 100 kilos. of 95 p.c. salt, if the acid be measured at 15°C.; but, if the temperature were 100°C., the rates of the specific gravities (as per the table quoted above) is as 1·64 and 1·72, and hence the 58·70 litres will become 61·56 litres, or, directly calculated, 100·97/11·64=61·56 litres.

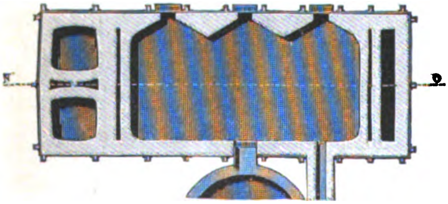

FIG. 26.

Practically a little more acid must be employed, partly because the mixture can never be theoretically perfect, partly because a little sulphuric acid or anhydride is volatilised, especially in the roaster. With open roasters the excess of vitriol required is about 5 p.c.; with close roasters, only 2 or 3 p.c. Whether the proportions employed have been correct or not must be decided in each particular case by testing the salt-cake, which ought not to contain more than 0·5 p.c. undecomposed salt, or above 1 p.c. free acid (calculated as SO_3).

The first reaction between the ingredients in the salt-cake pot is very violent, and there is a tendency of the mass to rise and to froth over, which is counteracted by throwing in a little tallow. The salt should be dissolved in the vitriol, which is easily done with common pan-salt, but much less easily with rock salt, and is assisted by occasional stirring, the handle of the rake passing through a hole in the charging door. The fire is then increased to drive off more hydrochloric acid, but not too much, lest the batch becomes too stiff; the work is regulated in such manner that the batch is ready to be 'cast' or 'shoved' into the roaster, just when the last charge has been drawn from the latter. For this purpose the damper *h* (Fig. 22) is raised. The work in the roaster must be carried on in such manner that the batch is thoroughly turned over and mixed.

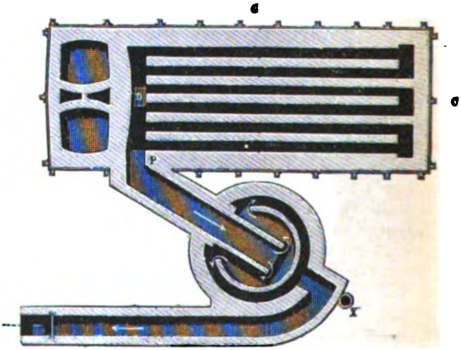

FIG. 27

The temperature within the furnace should ultimately be a red heat, and no more vapours should be seen rising from the mass. Still, it usually happens that, on drawing the batch out of the furnace, gases are given off (those of sulphuric anhydride being less pungent than those of hydrogen chloride), and, to avoid nuisance, the mass is frequently first drawn into a closed box, where it cools down and is then removed without causing inconvenience.

The yield of salt-cake is very nearly that calculated by theory from the dry salt. It may be taken as about 120 parts upon 100 of dry salt. Calculated upon the sulphur burnt in the pyrites kilns, it varies from 405 to 430 parts to 100 of sulphur actually burnt, open furnaces yielding rather less than close ones (owing to the volatilisation of SO_3).

The consumption of fuel varies in hand-furnaces from 30 to 50 parts to 100 of salt-cake; it is higher with close roasters than with open ones, but the difference is less where the pans are heated by the waste fire of the muffle-furnace.

Mechanical salt-cake furnaces have been constructed by many inventors to economise labour and coals. We mention among such furnaces those of Jones and Walsh (1875; improved in 1887; *cf.* Chem. News, 35, 51); Black and Hill (1877); Cammack and Walker (1876); Black and Larkin (1884); Thomson and Worsley (Eng. Pats. 21945 and 21946, 1894). Some of these have not answered in the long run, and we shall confine ourselves to a description of one of the most successful of mechanical salt-cake furnaces, that of Mactear (1879, described and discussed J. Soc. Chem. Ind. first General Meeting, 1881, p. 29 *et seq.*), and shown in Fig. 28. It consists of a revolving circular bed, covered by a fixed arch, the fire passing between them, and the access of air being prevented by a 'lute' filled with salt-cake. In the centre there is a kind of pot into which both salt and acid are continuously fed, and in which they are mixed. The pasty mass overflows into the outer beds, and is both continually stirred and gradually carried to the outer circumference by means of a number of stirrers, which are protected against the action of the fire and the acid gases by being placed between the gas-flues. The finished salt-cake, arriving at the outer edge, falls into the delivery trough running all round the furnace, and at the same time forming the 'lute.' The acid vapours and products of combustion pass away together in two flues, arranged at each side of the row of stirrers. The bed of the furnace is lined with fire-brick, boiled in tar and set in a special cement, which becomes even harder when subjected to the action of the heat and sulphate.

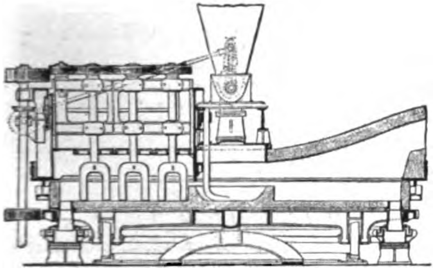

FIG. 28.

A great point in the Mactear furnace is the continuous decomposition of salt. Thus a continuous and even stream of hydrochloric acid is evolved, and, although this is mixed with all the fire-gases, it was claimed that the condensing-plant required is decidedly less than that found necessary with close furnaces. This, however, is not in agreement with modern practice, and makes no allowance for the much more extensive and expensive cooling plant necessary to cool the gases when mixed with the products of combustion as they are with the Mactear furnace than in the case of a muffle-furnace, such as the Deacon 'plus pressure' salt-cake furnace.

The Mactear furnace was first fired with coke; then 'Wilson' producers were attached to it (compare above); but these have had to be given up again for coke, so that the hoped-for economy in firing has not been realised

The Black and Larkin furnace, which is combined with an ordinary pan, is a peculiarly constructed muffle, heated from without by a number of small fires, both above and below, practically on the 'plus-pressure' system, with a very efficient mechanical stirring apparatus, thus permitting all the work to be done with closed doors, and avoiding 'low-level escapes.' Naturally the condensation of the hydrochloric acid is as easy in this case as with ordinary close roasters. One such furnace decomposes from 72 to 80 tons of salt per week. These furnaces have been successful, and are still at work in the place where they were originally introduced. Another mechanical furnace, composed of two revolving cylinders, is that of A. Walker (Eng. Pat. 9760, 1887). Generally speaking, although mechanical salt-cake furnaces have been used for so many years and have absorbed so much skill and patience in their design, they have not been generally adopted, owing to the fact that their undoubted economy in labour and power of producing a more uniform salt-cake is more than balanced by the higher first cost, cost of repairs, and the difficulties of condensation.

The direct process of manufacturing sodium sulphate from common salt, sulphurous acid, and air, without the intervention of sulphuric acid, has been the subject of many efforts, commencing with Gossage's, in 1850. None of these had any practical success until Hargreaves and Robinson (beginning from 1870) introduced a number of improvements which have made that process practicable and successful. We shall here describe it in its improved form.

The process consists in conducting the gases from pyrites kilns of the usual type, mixed with a suitable quantity of steam, through a series of large cast-iron cylinders, charged with common salt, in such manner that the fresh gas meets with the salt which has been the longest time exposed to the treatment, whilst the nearly-exhausted gas is brought into contact with fresh common salt. In this way, on the one hand, the salt is completely converted into sulphate, and, on the other hand, the pyrites kiln gases are nearly as fully utilised as they would have been by passing them into vitriol-chambers. The reaction:

$$2NaCl+SO_2+O+H_2O=Na_2SO_4+2HCl,$$

takes place at a temperature of about 500°–550°C., and this must be maintained against the radiation into the surrounding space by external heating; but as the reaction itself produces heat, the amount of fuel required is not exorbitant—if care is taken to avoid undue loss of heat during the process. This is all the more necessary, as the process is a slow one: it takes from 2 to 4 weeks before the salt, charged into one of the cylinders, can be taken out in the shape of finished salt-cake.

The first step is bringing the salt into such a condition that the gases can readily pass through it and yet reach all parts of it to the very core. Salt of fine grain must be used, and usually either the salt known as 'butter salt' or powdered rock salt, or a mixture of both, is taken. A method of preparation generally adopted is as follows: The salt is crushed and moistened by water or exhaust steam. It then falls from a hopper upon an endless chain of plates, each about 12 ins. broad and 5 ft. across, of a tot length of about 100 ft., or more, rising up in a sloping oven and returning underneath. On falling upon that travelling-platform, the salt is mechanically beaten down into a layer of 1–1½ in. thickness, which is at once cut, by means of mechanically-moved knives, into cakes about 3½ ins. square. These now enter into an oven, which is heated by the waste heat of the cylinders or direct fire, and pass through it at such a rate that they arrive perfectly dry at the upper end. As the chain turns downwards the dry cakes detach themselves and fall down upon a grating. They are now dense enough to retain their shape in the cylinders, and to be handled without formation of any material quantity of dust, and yet porous enough to be entirely penetrated by the gases, their regularity of shape securing regularity of draught in the process.

It is of vital importance that uncaked or powdery salt shall not get into the cylinders, as if it does, it forms areas impermeable to the flow of the gases, and thus prevents the reaction from being completed.

The decomposition of the salt takes place in a series of cylinders, from 8 to 20 in number, about 15 ft. in diameter, and 12 ft. high, and holding 40 tons of salt-cake, or even more. They are surrounded by small vertical flues connected with a fireplace below, and their tops are protected against cooling by a thick layer of ashes. Inside there is a movable grate, on which the salt rests. A number of manholes in the top serve for charging; a large door above the bottom for discharging. A set of large cast-iron pipes serves to admit the burner-gas into any of those cylinders and for passing it through the whole series, the gas always entering at the top and going away at the bottom. The connections between the main gaspipe and any one cylinder and those between the single cylinders are opened or closed by a very simple arrangement—viz. by dividing the connecting elbow pipes or 'siphons' in two halves, and either shutting the connection by inserting an iron plate or else leaving it open, always luting the joint by a mixture of mortar and salt. From the last cylinder of the series the gases pass through an opening in the bottom of the drawing doorway, into a flue.

Fig. 29 shows such a set of 8 cylinders seen from the top. Fig. 30 shows the section of one of the cylinders. A_1 to A_8 are the cylinders, B the discharging doors, C C the iron pipes for burner-gas with their connecting siphons D and circulating siphons E; F is the outlet opening, G the gas-flue for the exit gas; J is an opening in the top by which cold air can be admitted, in case the cylinders get too hot through the heat of reaction.

The pyrites burners employed are specially constructed with a view to avoiding radiation and sending the gas as hot as possible into the cylinders. The necessary steam is superheated by the waste heat of the gases, and is usually introduced in the upper part of the burners.

The gases are drawn through the whole system by means of a Root's Blower or a cast-iron fan placed between the cylinders and the acid condensers. By keeping the blower so hot that no liquid acid can be condensed in it, it is protected against the action of the acid; but the ends of the shaft, passing through the blower, must, on the outside, run in water-cooled bearings. The exhaust steam of the engine is utilised for the steam required for mixing with the burner-gas.

The amount of fuel required in a special case was as follows (calculated upon 20 cwts. of salt-cake):

For heating cylinders . . .	4 cwts.
For preparing salt . . .	3 ,,
For steam	0·75 cwt.
	7·75 cwts.

In other cases nearly 10 cwts. of fuel has been required, but in any case no more fuel is needed than in the ordinary process of making sulphuric acid and employing this for decomposing the salt.

The amount of fuel required for heating the cylinders depends naturally on the construction of the plant, the care taken to avoid radiation losses and to get the pyrites gases as hot as possible into the leading cylinders. It also depends on the rate at which the plant is working. The more rapidly heat is generated in the cylinders the less the proportion of that heat which will be lost by radiation. The chemical composition of the salt has been held to materially affect the possible speed of working, and the evidence goes to show that other things being equal the salt containing the largest quantity of iron salts decomposes the most rapidly. This is the usually accepted explanation of the fact that the output of the same plant using powdered rock salt is greater than when using 'butter salt' which contains materially less iron.

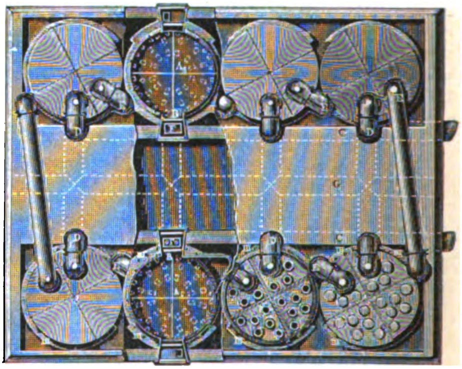

Fig. 29.

Hargreaves (Fr. Pat. 384144, 1907) promotes the reaction by the addition of 0·1–1·0 p.c. of copper or iron salts before moulding into cakes, the amount used depending on the purity of the product required.

In large well-designed plants when the speed of reaction is high no fuel is required to heat the cylinders. Great care is necessary in watching and controlling the temperature of the Hargreaves cylinders. If the later cylinders get too hot through the rapid action of strong hot sulphurous acid gases on the almost untouched salt, the salt itself will flux and form areas through which the gases cannot penetrate to complete the reaction.

The advantages of the Hargreaves process are a great saving in space and either, when making the same quality of salt-cake lower process costs than the sulphuric acid and salt process, or, with about the same process costs the power to make a higher grade salt-cake more free from iron than is possible in the ordinary process with the cast-iron decomposing-pan. The disadvantages are the great cost of the plant, which, unlike the lead vitriol chambers, does not return a large proportion of the initial cost on dismantling; the very careful supervision required with the consequent liability to serious difficulty and expense if the supervision even for a short time breaks down; and again the impossibility of utilising the hydrochloric acid gases evolved for the production of chlorine by the Deacon-chlorine process, owing to the quantity of sulphur dioxide and carbon dioxide they contain from time to time. This sulphur dioxide in the Deacon decomposers is fatal to the activity of the catalyst there used, viz. cupric chloride. The Hargreaves process is worked successfully in England in several manufactories, and also on the Continent, but has failed to extend materially in recent years.

Salt-cake free from iron (or nearly so) is required especially for plate-glass, window-glass, and so forth. The Hargreaves sulphate is frequently pure enough for this purpose. On the Continent it is sometimes made by employing decomposing pans made of lead, which are certainly much more difficult to manage than the cast-iron pots otherwise used. The batch must be taken out much thinner, and the firing must be much more careful than with cast-iron pots. Purified sodium sulphate is also made by dissolving ordinary salt-cake, precipitating the iron present by the addition of a little bleaching powder and lime and evaporating to dryness.

Glauber's salt is crystallised sodium sulphate $Na_2SO_4,10H_2O$. It is manufactured for a few purposes, principally for medicinal use and for freezing mixtures. A considerable quantity is obtained from the residuals of the Stassfurt salts, and from the mother-liquor in the manufacture of sea-salt. It is required in two very different states—viz. in very small or in large crystals. The small acicular crystals are obtained by making the solution as strong as possible at a temperature of 34°C., settling, running into shallow coolers, and stirring the solution until it has cooled down. The larger crystals ('soda fashion') are made by dissolving the sulphate at 50°, until the sp.gr. is 1·257 (at 40°), settling for an hour, and running into deep coolers (2–5 ft. deep), where the liquor is kept quite undisturbed. In order to facilitate the formation of large crystals, wooden staves or pieces of twine, weighted with a little lead, are hung in the vats. The cooling lasts from 5 to 20 days, according to the size of the vats and the season, the crystals are large (an inch and more thick), hard and shining, and they must be dried at a temperature not exceeding 30°, to prevent efflorescing.

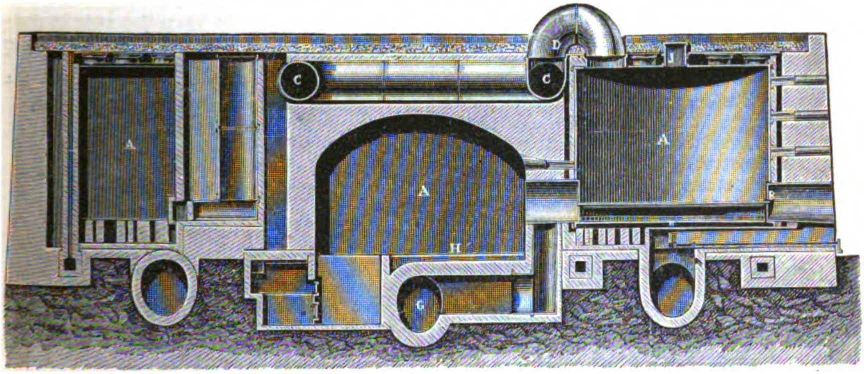

FIG. 30.

Testing of salt-cake.—It is usual in the factory to test the salt-cake only for free sulphuric acid and undecomposed sodium chloride, as these are the impurities over which the workman has control; the other impurities—iron, lime, alumina, &c.—depend on the quality of the salt used.

The usual methods of analysis adopted are given in Lunge's Technical Chemist's Handbook.

Two characteristic analyses of salt-cake are given below,

	Hand furnace salt-cake from white salt	Hargreaves salt-cake low in iron
Na_2SO_4 . . .	96·2	98·0
$NaCl$ . . .	0·5	0·2
H_2SO_4 . . .	1·5	0·3
$CaSO_4$ and insol. .	1·8	1·424
Fe_2O_3 . . .	—	0·076
	100·0	100·0

The chief uses of salt-cake are for the manufacture of caustic soda by the Leblanc process, for the manufacture of sodium sulphide and of glass. For the manufacture of practically all qualities of glass except lead glass, salt-cake is superior to soda ash because: It is cheaper per unit of alkali, and owing to the higher temperature at which the glass furnaces work when using salt-cake a higher proportion of silica can be used, thus again cheapening the cost and also producing a harder and more durable glass.

Sodium sulphide Na_2S. In practice sodium sulphide is always obtained by the reduction of sodium sulphate. The preparation of sodium sulphide has been the subject of much work and many patents. Arrot (Eng. Pat. 1370, 1859) Gossage (Eng. Pat. 2612, 1859), Wilson (Eng

Pat. 1361, 1859), Claus (Eng. Pats. 819 and 2616, 1869), Willans (Eng. Pat. 293, 1860), and Weldon (Eng. Pats. 3370 to 3390, 1876; and 444, 445, 1877). Winkler, in Chem. Ind. 1880, 129, gives a description of the method of making sodium sulphide in a small reverberatory furnace from a mixture of salt-cake and 25–30 p.c. of coal, which was in use for many years. Essp (Zeitsch. angew. Chem. 1889, 284) also describes the production of sulphide in a reverberatory furnace from salt-cake and 60 p.c. of coal-dust.

Gossage and Matheson (Eng. Pat. 3218, 1888) propose the mixing of a considerable quantity of NaCl with the salt-cake. Gossage and Williamson (Eng. Pat. 20921, 1892) proposed to add to the mixture of salt-cake and coal 35 or 40 parts of Leblanc black-ash waste in order to prevent the action on the furnace lining.

The Société Industriale de Pont Saint Martin and A. Piccinini (Zeitsch. angew. Chem. 1908, 782) prepare sodium sulphide in a kiln from coke and sulphate by heating the mixture in an electric furnace. Another interesting proposition is that of Gossage, Matheson and Hawlicek (Eng. Pat. 121480, 1886), who suggest the use of furnaces of the lime-kiln type for the production of sodium sulphide.

Ellershausen (Eng. Pat. 17815, 1890) describes the difficulties in maintaining the fabric of the furnace against the action of the sulphide, and ascribes them to the overheating of the charge. He constructs his furnace with a fire-bridge 2 ft. high above the furnace-bed, and avoids overheating the bridge by means of an internal air channel. The flue above the fire-bridge is contracted towards the centre of the furnace-bed, so that the sides do not get as hot as usual. The bed is also made to rise towards the bridge so that no melted sulphide can accumulate there. The sides of the furnace round the bed are made of firebricks in such a manner that they are independent of the outer walls, and are easily renewed. Lunge thus describes the working of this furnace from his personal observation (Sulphuric Acid and Alkali, vol. iii. p. 296): 'The charge consists of 7 cwt. salt-cake, and 3½ cwt. coke breeze, not specially mixed, but put in the usual way, first upon the back bed and brought there to a dark red heat without any fusion. The fusion takes place on the front bed, where the mass turns first thin and then again thickens, just like an ordinary black-ash charge, but without exhibiting the well-known 'candles.' It is, however, not so pasty as black-ash, and more porous. It is drawn out into an iron box after first lowering the furnace damper to prevent its burning during the discharging. The mass cools down in these boxes without any special precautions. Sixteen such charges are finished during 24 hours with a consumption of 1¼ tons of coal. The heat is not so high as in black-ash furnace, and the furnaces do not require much repair. . . . It is very remarkable that in this case the furnace bottoms did not suffer very much, seeing that they were made exactly like those of black-ash furnaces (*see* Leblanc Soda Process, p. 39), except that they were a little sloping from the firebridge; the slope towards the working door is common to both. The reason is probably this, that with the large quantity of small coke 50 p.c. the mass always remains porous; the infusibility of coke is also an advantage in comparison with ordinary mixing coal. During work the damper must always be kept down as much as possible to avoid unnecessary entrance of air; if this is not done the mass turns more liquid, evidently by the formation of polysulphides, and the furnace suffers much more. The crude sulphide on analysis shows only a trace of polysulphides, no sulphate at all, about 1½ p.c. thiosulphate, and about 10 p.c. of the soda as carbonate, the remaining soda being present as Na_2S; there is about 25 p.c. insoluble. This is certainly an excellent product.'

The crude sulphide or sulphide 'black-ash,' was, after cooling, originally broken up into lumps, packed and sold. One or two cases, however, of fire on board ship occurred which were attributed to spontaneous combustion of the crude sulphide, and carriage in this form was stopped (J. Soc. Chem. Ind. 1896, 838). The crude sulphide is now all lixiviated in vats similar to those described under the Leblanc process for lixiviating Leblanc 'blackash' (*see* Figs. 34 and 35), the only difference being that it is necessary to keep the vats in the case of sulphide much hotter than in the case of Leblanc soda (*see* p. 43).

The vat liquor, after settling, is run into crystallising cones and allowed to cool, when crystals of $Na_2S,9H_2O$ separate out of approximately the following composition:—

Na_2S	32·0 p.c.
$Na_2S_2O_3$	1·4 „
Na_2SO_3	1·4 „
H_2O (by diff.) . . .	65·2 „
	100·0 „

The crystals after well draining are packed in casks.

Sodium sulphide is moderately soluble in water, and crystallises in white, quadratic crystals, of sp.gr. 2·471, which contain 9 mols. of water. Other hydrates have also been described (Parravano and Fornaini, Gazz. chim. ital. 1907, 37, ii. 521); *see* Göttig (J. pr. Chem. 1886, 34, [ii.] 229), Abstinthe (J. Soc. Chem. Ind. 1886, 534).

The aqueous solution of the salt reacts strongly alkaline owing to hydrolysis. A more concentrated form of sodium sulphide is made by concentrating the vat liquor usually in the so-called caustic pots. The liquor is concentrated until the temperature rises to about 160°, when a sample will be found to test 60 p.c. Na_2S. The fire is then drawn and the pot allowed to settle for 4–6 hours, and then the sulphide is packed in an exactly similar way to caustic soda into the ordinary caustic soda drum (*see* Fig. 43).

The sulphide so prepared has the following composition:—

Na_2S	62·8 p.c.
$Na_2S_2O_3$	2·9 „
Na_2SO_4	1·1 „
NaCl	1·7 „
Fe_2O_3	0·44 „
Water (by diff.) . .	31·06 „
	100·0 „

The concentrated sulphide is also put on th market in disks 2–4 ins. thick and in broken pieces of various sizes.

It will be observed that the concentrated sulphide contains over 30 p.c. of water. It has been found by experience that this quantity of water entirely prevents all danger of the spontaneous combustion mentioned above as being traced to the impure anhydrous sulphide packed direct from the furnaces.

Sodium sulphide is largely used as a depilatory in the tanning industry, and in the colour industry as one of the raw materials of the so-called sulphur colours, and as a solvent of these colours in the dye-bath. It is also used in the manufacture of water-glass.

A disulphide, trisulphide, tetrasulphide, and pentasulphide of sodium have also been prepared. *See* Böttger (Annalen, 1884, 223, 335, 338), Locke and Anstell (Amer. Chem. J. 1898, 20, 592), and Hugot (Compt. rend. 1899, 129, 388).

Sodium thiosulphate (hyposulphite)

$Na_2S_2O_3,5H_2O$.

This compound was first prepared in 1799 by Chaussier. Small quantities of the salt may be made by taking about 1 lb. of pure, well-dried sodium carbonate, mixing with it about one-third its weight of flowers of sulphur, and then heating the mixture in a porcelain basin to the melting-point of sulphur for some time, stirring well all the while, so as to bring every part in contact with the air. Oxygen is absorbed by the sodium sulphide formed, which is converted, with feeble incandescence, into sodium thiosulphate. When cold, the mass is dissolved in water, boiled with sulphur for some time, and the liquid concentrated by evaporation to the crystallising-point. A very pure product may be thus obtained. It can be prepared by boiling a solution of sodium sulphite with flowers of sulphur, filtering from the excess of the latter, and allowing the solution to crystallise. Another method consists in boiling sulphur with soda-lye and passing sulphur dioxide into the yellow solution until it becomes colourless. The anhydrous salt is easily prepared by passing air over anhydrous NaSH at a temperature of 100°–150°.

The earthy thiosulphates are obtained by exposing their sulphides to the oxidising action of the air; and upon this principle depends Losh's process, which is as follows: The tank waste produced in alkali works is exposed to the air for a week or more, being turned over from time to time, so as to bring every portion in contact with air. The mass is then lixiviated with water, and, on adding sodium carbonate solution to the dissolved thiosulphates of sodium and calcium, the calcium is precipitated as carbonate, and the whole of the thiosulphuric acid is converted into the sodium salt. The solution is drawn off from the insoluble precipitate, concentrated by evaporation, and the crystals of sodium thiosulphate purified by recrystallisation. A modification of this process, by Kopp, is as follows: The tank waste is mixed with 10–15 p.c. of sulphur and 12-15 times its weight of water, and is then boiled for an hour. The solution of polysulphide obtained is put into a closed apparatus, in which it can be agitated, and is treated with sulphur dioxide. The solution now contains calcium thiosulphate, and is converted into the sodium salt by addition of sodium sulphate. The solution of sodium thiosulphate is drawn off from the precipitate of calcium sulphate, and is concentrated and crystallised as before. Another method consists in allowing the liquid extract of the oxidised tank-waste to run down a tower packed with coke, where it meets with a strong upward current of air. A little steam is also injected into the tower. The polysulphides are by this treatment oxidised to thiosulphates. The solution running away from the bottom of the tower has an acid reaction, and is neutralised with milk of lime, evaporated to a sp.gr. of 1·25, and a solution of sodium sulphate added until the precipitation of the calcium is complete. The precipitate, consisting chiefly of calcium sulphate, but containing also from 2 to 5 p.c. sodium and calcium sulphites and thiosulphates, is dried at 100°, and sold to the paper makers, the calcium sulphate serving as a weighting material and the sulphites, &c., it contains acting as an antichlor. The filtered solution is evaporated to a sp.gr. of 1·65 and allowed to cool, when sodium thiosulphate and a little sulphite crystallise out.

The yield of thiosulphate can be greatly increased by suitable treatment. Schaffner (Dingl. poly. J. 193, 42) treats the yellow sulphide liquors with sulphur dioxide, exactly neutralises the excess of the latter by the addition of a further quantity of fresh sulphide liquor, heats to 75°–90°, and adds the requisite amount of sodium sulphate (determined by the analysis of a sample of the liquid). Finally, a little caustic soda is added to ensure the complete precipitation of the calcium sulphate. If traces of sulphides are still present they are removed by the addition of a little sodium bisulphite, and the clear solution is then evaporated to 43°Beaumé and allowed to crystallise. The crystals so obtained are sold directly for use as an antichlor, but if required for photographic purposes they are recrystallised once in stoneware pans.

The preparation of sodium thiosulphate has been carried out as follows: Strontium sulphide —obtained by reducing strontium sulphate by means of powdered coal—is, while still hot, mixed with water to form a thin paste. The mass is boiled with sufficient caustic alkali to combine with the sulphur of the sulphide. Strontium hydroxide crystallises out on cooling, and the mother-liquor consists of solution of sodium sulphide. On treating this liquor with sulphur dioxide, sodium thiosulphate is formed, and free sulphur deposited (J. Soc. Chem. Ind. 3, 30).

Another process consists in the reduction of sodium sulphate by furnacing with coal, the extraction of the Na_2S so obtained by water, and the treatment of this sulphide solution with sulphur dioxide.

Sodium thiosulphate may also be prepared from the spent lime of the purifiers of gas works, which contains the calcium salt of thiosulphuric acid as well as calcium sulphide.

Other patents for the technical manufacture of sodium thiosulphate are given briefly below:—

Verein Chemischer Fabriken zu Mannheim, Eng. Pat. 23217 *b* and *c*, 1907 (air is passed over anhydrous NaHS at 100°–150°); Sidler, D. R. PP. 81437 and 84240 (sodium sulphite is heated with fused sulphur in CO_2); Verein Ch. Fab. zu Mannheim, D. R. P. 88594 (production of sodium thiosulphate by the action of SO_2 and steam on a mixture of $NaHSO_3$ and S in presence of water); Clemm, D. R. P. 180554 (manufacture of sodium thiosulphate from bauxite).

The salt forms large transparent prisms, belonging to the monoclinic system. Its solution is neutral to test paper; it is without smell, has a cooling taste, and does not change on exposure to air. The crystals melt in their water of crystallisation at 45°, all the water being expelled at 215°; and at 220° they decompose, with separation of sulphur (Pape). The salt has a sp.gr. of 1·672.

It dissolves very readily in water with considerable absorption of heat. It easily forms supersaturated solutions, which may be made to contain as much as 217 parts of the salt in 100 of water at 0°. It is insoluble in alcohol. The aqueous solutions of the salt have a neutral reaction and are permanent in the absence of air and light. Freshly made dilute solutions commonly alter in strength at first owing to the action of the carbon dioxide, usually present in water, on the salt; hence in preparing a solution of sodium thiosulphate for analytical purposes it is necessary to allow it to stand for a week before standardising it. After all the carbon dioxide present in the water has reacted with the salt the solution may be kept almost indefinitely without further alteration. The solution has the property of dissolving many insoluble salts, such as lead sulphate and silver iodide. Besides the commonly occurring pentahydrate a large number of other hydrates have been prepared and studied by Young, Mitchell, and Burke (J. Amer. Chem. Soc. 1904, 26, 1389 and 1413; 1906, 28, 315).

Sodium thiosulphate is used as an antichlor for removing the last traces of the chlorine from bleached fabrics, the reaction being essentially—

$$Na_2S_2O_3+4Cl_2+5H_2O=2NaCl+2H_2SO_4+6HCl$$

According to Lunge (Bolley's Technologie, Neue Folge, 1909, 16, 74) only about one-tenth of the amount of chlorine required by the above equation is acted upon, as a large quantity of tetrathionate is formed, while a further portion of the thiosulphate is probably decomposed into trithionate and sulphide—

$$2Na_2S_2O_3=Na_2S_3O_6+Na_2S$$

since some sulphuretted hydrogen is always evolved.

Sodium thiosulphate finds an extended application in photography. Owing to its power of dissolving silver bromide, iodide, &c., a solution of the salt is employed to dissolve out the unaltered silver halogen compound from the plates or prints after the exposure has been made and the image developed, the negative or print being thus 'fixed' and rendered unalterable on exposure to light. It is also used in the bleaching of wool, straw, oils, ivory, bones, &c. (as a source of SO_2), and as a preservative against fermentation in the sugar industry. In the calico-printing and dyeing trades it is employed in the preparation of mordants; aluminium sulphate is treated with sodium thiosulphate, and the resulting solution of aluminium thiosulphate thickened as usual and printed on the fibre. On steaming the printed cloth alumina is deposited on the fibre by the decomposition of the aluminium thiosulphate, and the material can then be dyed with alizarin, &c. It has been used to fix aniline greens, and in conjunction with salts of copper to produce the so-called 'argentine effects' which depend upon the deposition of a thin film of copper sulphide on the fibre. Sodium thiosulphate is also employed in the preparation of various artificial colours, and in the reduction of indigo; in the wet methods of preparation of antimony cinnabar, and ordinary cinnabar; in metallurgy for wet silver-extraction processes, the silver being converted into chloride by roasting the ore with common salt, and the mass lixiviated with a solution of the sodium thiosulphate (*v.* SILVER); in the preparation of silvering and gilding solutions, and in the extraction of gold from ores. When treated with sodium amalgam, it gives sodium sulphide and sulphite:

$$Na_2S_2O_3+Na_2=Na_2SO_3+Na_2S.$$

The property which the salt possesses of fusing at a low temperature in its water of crystallisation and solidifying again on cooling has been utilised by Fleck in sealing glass tubes containing explosives to be used under water in torpedoes.

In medicine sodium thiosulphate is used in cases of sarcinous vomiting, and as an external application in parasitic skin diseases.

In the laboratory the salt is largely used in iodometry, the fundamental reaction being—

$$2Na_2S_2O_3+I_2=Na_2S_4O_6+2NaI.$$

For the application of this *see* the article on ANALYSIS. It has also been proposed for use in quantitative analysis for the precipitation of various metals in place of sulphuretted hydrogen. Lead, mercury, silver, copper, and chromium are all quantitatively precipitable as sulphides (or in the case of chromium as hydroxide) by boiling their solutions with sodium thiosulphate (Faktar, Zeitsch. anal. Chem. 1900, 39, 345).

Sodium thiosulphate is employed in the separation of iron and aluminium. A solution containing these two metals is treated in the cold with sodium thiosulphate; this gives rise to the aluminium thiosulphate, and, when boiled, the latter is decomposed, with evolution of sulphur dioxide and deposition of sulphur and alumina. By throwing the whole on a filter, the iron, still in solution, passes through.

Sodium thiosulphate forms a large number of double salts, many of which are of extremely complex composition. Those formed with copper and silver have been studied by Rosenheim and Steinhäuser (Zeitsch. anorg. Chem. 1900, 25, 72) and C. and I. Bhaduri (*ibid.* 1898, 17, 1). *See* also L. Shinn (J. Amer. Chem. Soc. 1904, 26, 947).

Sodium nitrite $NaNO_2$ occurs native in small amounts in Chile saltpetre, and is frequently found, although only in traces, in mineral waters. It can be prepared artificially by heating sodium nitrate, either alone or mixed with deoxidising substances, metallic lead, iron filings, or graphite being those usually employed. The salt prepared in this way, however, invariably contains some caustic soda and undecomposed nitrate. The pure salt is best made by decomposing a solution of silver nitrite with an equivalent amount of sodium chloride, or by passing the nitrous fumes evolved from a mixture of nitric acid and starch into a solution of caustic soda or sodium carbonate (Divers, Chem. Soc. Trans. 1899, 86).

It may also be obtained by the electrolytic reduction of the nitrate, but the yield obtained is only 60 p.c. of the theoretical (Muller, Zeitsch. Elektro. Chem. 1903, 9, 955).

Technical manufacture. On the large scale, sodium nitrite is made by the reduction of the nitrate, usually with metallic lead.

The lead employed must be as free as possible from zinc and antimony, and is rolled out into thin sheets previous to use. The theoretical amount of lead required for the decomposition of 100 parts of sodium nitrate according to the equation—

$$NaNO_3+Pb=NaNO_2+PbO$$

is 243 parts, but in practice an excess is invariably used.

The sodium nitrate (100 kilos.) is melted in a cast-iron vessel fitted with a mechanical stirrer. As soon as the whole is in a state of quiet fusion, 250 kilos. of lead are added, which rapidly oxidises to yellow PbO. After a short time more lead is added, and the mixture kept well stirred for three-quarters of an hour, the whole operation lasting about 3½ hours. Thorough stirring is essential, as if any of the mixture is allowed to cake on the sides of the vessel, the latter is soon corroded and rendered useless.

The product from the fusion (which should contain over 90 p.c. of $NaNO_2$) is extracted with water in wrought-iron vessels, provided with stirrers, until the solution has a density of 36°–39° Beaumé. The alkaline liquid is then carefully neutralised with dilute nitric acid, and allowed to settle. The clear solution is evaporated to 42°–43° Beaumé, allowed to stand three or four hours to clarify, and then run into lead-lined wooden tanks where crystallisation takes place. The crystals obtained contain, after being dried at 60°, 97–98 p.c. of sodium nitrite.

The mother-liquors can be evaporated several successive times after addition each time of a little fresh liquid from the vats. The purity of the nitrite thus obtained continually diminishes, as the following figures show :—

	Percentage of $NaNO_2$ contained in the crystals after drying at 60°.
Crystals from 1st evaporation	97 to 97·5 p.c.
„ 2nd „	96·8 to 97 „
„ 3rd „	96·2 to 96·5 „
„ 4th „	96 to 96·2 „

If a higher content of nitrite be required, the salt must be recrystallised. When the crystals obtained from the liquid show less than 96 p.c. of $NaNO_2$, the mother-liquor is evaporated separately in a second pan, and produces crystals containing 86–94 p.c. of nitrite, which are employed to strengthen the fresh lye. The solution separated from these is further concentrated in a third pan, and yields crystals containing 50–75 p.c. of nitrite. Those containing above 65 p.c. $NaNO_2$ are returned to the second pan, and the remainder are fused up again with lead in the manner described above. An analysis of the final mother-liquors gave their composition as :—

	p.c.
Caustic soda	10·89
Sodium carbonate	22·00
Sodium nitrite	20·52
Sodium nitrate	16·23
Sodium chloride	6·05
Sodium sulphate	17·39
Insoluble	7·23
	100·31

Another process for making sodium nitrite consists in fusing together 500 kilos. sodium nitrate and 500 kilos. caustic soda, adding 225 kilos. iron filings, and allowing the mass to react for 5–6 hours. Various other reducing agents, such as sulphur, calcium sulphide (tank-waste), barium sulphide, zinc blende, and galena have also been employed.

Properties. Sodium nitrite forms small rhombic crystals, which usually possess a faint yellow colour, although according to Boguski (J. Russ. Phys. Chem. Soc. 1899, 31, 543) the pure dry salt is colourless. The crystals melt at 271° (Divers) and dissolve easily in water (1 part of the salt dissolves in 1·2 parts of water at 15°) forming a yellowish solution which is alkaline to litmus. The salt is very sparingly soluble in absolute alcohol, 100 parts of this solvent dissolving only 0·31 part of sodium nitrite at 19·5°.

For the density of sodium nitrite solutions, *see* Boguski, Anz. Krak. Akad., 1898, 123. For conductivity measurements, *see* Roczkowsky and Niementowsky, Zeitsch. physikal. Chem. 1897, 22, 147, and Schumann, Ber. 1900, 33, 532.

Uses. Sodium nitrite is largely used in the manufacture of coal-tar colours, and also in the calico-printing industry in the preparation of certain colours, such as paranitraniline red, which are developed on the fibre.

Sodium nitrate (*cubic nitre*; *Chile saltpetre*) $NaNO_3$. This important salt occurs as *nitratine* in the natural and artificial accumulations of potassium nitrate, and in other deposits where it has been produced similarly to that salt (*v. Potassium Nitrate*, art. POTASSIUM).

The natural occurrence of the sodium nitrate, as distinguished from the potassium salt, does not appear to have been fully recognised until the present century, for it is stated in Rees' Encyclopædia, 1819 (art. NITRATE OF SODA), that it had not been found up to that time in a native state, although its manurial value had already been recognised by Lord Dundonald.

Sodium nitrate occurs in enormous quantities, and practically free from the potassium salt, in the province of Tarapaca in South America, and this, with the exception of certain deposits on the coast of Bolivia, constitutes the only source from which the salt is extracted on the large scale.

The nitrate deposits do not form beds of any definite character, but represent the outcrop of a bed of salt which appears to have been left at the bottom and sides of ancient tidal lagoons by the upheaval of the coast. Although the district is now extremely arid and only receives rain at intervals of 3 years or more, there is abundant evidence of former fertility in the large quantities of buried trees and other vegetation which are found in the vicinity, together with guano and fish remains, sea-shells, and other substances of marine origin.

The nitrate may be regarded as the product of the decomposition of this organic matter in presence of calcium carbonate and the salt left by the evaporation of the sea-water. This view is borne out by the composition of the deposit, especially by the presence of sodium iodide and iodate and of salts of magnesium and calcium. The nitrification appears to have occurred only at the outcrop of the salt, for the nitrate diminishes in quantity towards the middle, and is practically absent at the centre of the deposit.

The main nitrate belt of Tarapaca has a width of about 2½ miles, and is included between latitudes 27°S. and 19°S. for a total length of about 260 miles. It stretches along the eastern slope of the coast range of the mountains which extend from the northern limit of Peru to the Straits of Magellan, and which have an average height of about 2000 ft.

The deposit occurs some 500 or 600 ft. higher than the valley of Tamaragal, and diminishes in richness as the valley is approached, the nitrate disappearing altogether at the bottom. The average distance from the sea coast is about 14 miles, but some of the deposits are as far distant as 90 miles.

The 'caliche,' as the crude nitrate is called, is never found at any great depth. It is usually covered to a depth of 6 or 10 feet by a crust or 'costra,' consisting of a conglomerate of porphyry, felspar, magnesia, sodium chloride, &c., cemented together by gypsum, and covered by a layer of fine loose sand to a depth of 8 or 10 ins. The caliche proper forms a rock-like mass from 3 to 6 ft. deep, and varies in colour from almost pure white, through shades of yellow, orange, brown, bluish-grey, &c. The lower part of the caliche (known as 'congelo') contains but little nitrate, and abounds in the chlorides of sodium and magnesium, and in sulphates. It lies upon a pale, yellowish-brown, loose clay free from nitrate, and overlying the primitive rock.

Various qualities of caliche are worked, varying from 40 to 80 p.c. in the best quality, to 30 to 40 p.c. in the second, and 17 to 30 p.c. in the inferior kinds.

A good ground would contain a bed 3–4 ft. thick, containing 40–45 p.c. $NaNO_3$. The upper overlayer varies from 4 to 20 p.c. In poor grounds, however, 20 p.c. nitrate would become 'caliche.' The ground is broken by blasting and the big blocks divided into smaller ones with crowbars and the lumps of 'caliche' separated from the overlayer or 'costra' by hand.

The Tarapaca deposits were worked as early as 1813 by the Spaniards, who exported 23,732 quintals (of 100 pounds) in that year; but the industry was but little developed until 1852, when small refining works were established by Smith and Sandes.

The method of separating the nitrate from the caliche consists merely of a careful system of lixiviation. At the Officina of Ramirez (Tarapaca) the caliche is crushed roughly into 2-in. lumps, and is boiled in long tanks heated by steam coils.

A typical boiling tank is 32 ft. long by 9 ft. deep by 6 ft. wide, and is heated by a steam coil 5 ins. diameter, which makes the circuit of the tank five times, and is arranged in tiers about 9 ins. from the sides. The 'caliche' is supported on a false bottom about 1 ft. from the real bottom of the tank. The tanks are built in a series of six, connected by a 9-in. pipe for circulating the liquor from one to the other. The tank containing the nearly exhausted 'caliche' is fed with fresh water, the others work in series with weak liquor obtained from the nearly exhausted tank, passing through them and leaving finally from the tank last charged with 'caliche.' The hot liquor or 'caldo' finally runs off at 112°, containing about 80 lbs. nitre to the cubic foot. After cooling for 4 or 5 days in the crystallisers and crystallising out, the strength of the liquor is reduced to about 40 lbs. nitre per cubic foot. This mother-liquor is used in the systematic lixiviation of the 'caliche' described above, and is run in addition to the weak liquor from final exhaustion of the 'caliche' on to the later tanks.

A good form of crystalliser is a sheet-iron tank 25 ft. by 18 ft. by 2 ft. 9 ins. to 3 ft. deep, the inclined bottom assisting in the draining of the crystals. Six such tanks as have been described require about 44 of these crystallising vessels.

The nitrate from the crystallisers is drained and is placed on the drying floor to dry for 5 or more days, when its composition is as follows:—

	First quality	Second quality
$NaNO_3$ . .	96·5	95·2
$NaCl$ . .	0·75	2·5
Na_2SO_4 . .	0·45	0·6
H_2O . .	2·3	1·7

An important by-product in the Chile nitrate industry is iodine, which occurs in considerable quantities as sodium iodate in the 'caliche.' The iodine recovery is effected from the mother-liquor from the crystalliser which passes through the iodine house on its way back to the lixiviating tanks (*v.* IODINE). The fuel consumption averages about 1 ton coal to 7 tons nitrate produced.

For further details of the nitrate manufacture, *see* paper by Newton, J. Soc. Chem. Ind. 1900, 408, from which most of the above statements have been taken.

The following analyses show the composition of caliche. (1) Shows the composition of one of the largely-worked deposits (Forbes, Phil. Mag. 1866, 32, 135); (2) shows the composition of that worked at the Officina Ramirez (Harvey, Proc. Inst. C.E. 1885, 82, 337):—

	(1)	(2)
Sodium nitrate .	21·01	51
Sodium chloride .	55·27	26
Sodium sulphate .	4·74	6
Calcium chloride .	0·33	—
Potassium iodide .	0·87	—
Aluminium sulphate	9·81	—
Magnesium sulphate	5·93	3
Insoluble matter .	2·04	14
Moisture . .	—	—
	100·00	100

Further information on these deposits will be found in the works of Sturzer (Nitrate of Soda, 1887; edited by Wagner) and Billinghurst (Estudio sobre la Geografia de Tarapaca, and Chem. Zeit. 11, 752), and in the various Consular reports to the British and United States Governments.

Sodium nitrate is obtained when sodium carbonate or hydroxide is dissolved in nitric acid, or when common salt is boiled with that acid. On the large scale, however, it is always obtained from the natural product by repeated crystallisation. The last traces of chloride are best removed by adding a small quantity of nitric acid to the boiling saturated solution of the salt, and recrystallising.

The pure salt forms transparent, colourless, anhydrous rhombohedra, whose angles closely approximate to right angles, whence its name 'cubic nitre.' It fuses at 316° (Carnelley, Chem. Soc. Trans. 33, 276); at higher temperatures—lower than that at which potassium nitrate decomposes—it evolves oxygen with production of the nitrite, and on further heating it gives off nitrogen and nitrous fumes, leaving a residue of sodium monoxide and peroxide. The salt as usually obtained is hygroscopic; but, according to Gentele (Dingl. poly. J. 118, 203), this is due to the presence of the nitrates and chlorides of calcium and magnesium, and is not observable in the pure salt.

According to Ditte (Compt. rend. 80, 1164) 100 parts of water dissolve the following proportions of the salt:—

At 0°	66·69	At 18°	83·62
2°	70·97	21°	85·73
4°	71·04	26°	90·33
8°	75·65	29°	92·93
10°	76·31	36°	99·39
13°	79·00	51°	113·63
15°	80·60	68°	125·07

When saturated at 0° the solution may be cooled to −15·7° without crystallisation; but at that temperature the salt separates out in fine laminated plates built up of fine needles lying side by side. A hydrate of the composition $NaNO_3,7H_2O$ appears to exist (Ditte, *l.c.*).

Sodium nitrate dissolves in glycerol, but is almost insoluble in absolute alcohol; 100 parts of alcohol of 16·4 p.c. dissolve 21·25 parts of the salt (Pohl, Sitz. Ber. 6, 600).

It is used for many of the purposes for which the potassium salt is employed; but its hygroscopic nature renders it inapplicable to the manufacture of gunpowder or fireworks, &c. For the making of nitric acid, for supplying that acid in the sulphuric acid manufacture, and as a manure, it has, however, entirely replaced potassium nitrate. It is also the principal source of that salt, which is obtained from it by double decomposition with the potassium chloride of Stassfurt.

Sodium hypophosphite NaH_2PO_2 may be prepared by boiling aqueous or alcoholic soda with phosphorus until evolution of phosphoretted hydrogen ceases

$$6NaHO+2P_4+6H_2O=6NaH_2PO_2+2PH_3.$$

The solution is poured off, treated with sodium bicarbonate to convert any unchanged soda into carbonate, and is evaporated and digested with absolute alcohol, which dissolves the hypophosphite only. The salt crystallises out on cooling.

For pharmaceutical purposes it is usually prepared by double decomposition between solutions of sodium carbonate and calcium or barium hypophosphite (*v. Phosphorus oxides* and *Oxy-acids*, art. PHOSPHORUS). The filtered solution is evaporated on the water-bath with frequent stirring as the mass becomes syrupy, in order to obtain a granular salt. To obtain the salt free from phosphite, Raymond (Pharm. J. [iii.] 10, 407) treats 25 grms. of the commercial salt with 1 grm. of barium hypophosphite in solution, and dilutes to 50 c.c., adding 200 c.c. of strong alcohol after a time. The liquid is allowed to stand and filtered from the precipitated barium phosphite and hypophosphite, and the last traces of barium having been removed by careful addition of sodium nitrate, is filtered and mixed with 500 c.c. of strong alcohol and a sufficiency of ether. The pure hypophosphite which separates is dried in a current of air.

Sodium hypophosphite crystallises in small, pearly, rectangular, very deliquescent plates containing 1 molecule of water of crystallisation. It dissolves at 15° in 1 part of water, and at 100° in 0·12 part. It is also soluble in alcohol. The aqueous solution absorbs oxygen from the air with formation of phosphite (Wurtz, Ann. Chim. Phys. [iii.] 7, 37).

When heated to 200° the crystals become anhydrous, and on further heating are converted into metaphosphate and pyrophosphate, with evolution of hydrogen and spontaneously inflammable phosphoretted hydrogen:

$$5NaH_2PO_2=Na_4P_2O_7+NaPO_3+2PH_3+2H_2.$$

It explodes when triturated or heated with an oxidising agent, and has been known to explode during evaporation on the water-bath (Amer. J. Pharm. 1860, 87).

Sodium hypophosphite is a powerful reducing agent, and precipitates gold and silver from solution. With copper salts it gives a red precipitate of copper hydride Cu_2H_2. It is used medicinally.

Sodium phosphates. A considerable number of these salts belonging to the three classes ortho-, pyro-, and meta- phosphates, together with a large series of double salts, are known. The three classes of salts may be distinguished by their behaviour with silver nitrate and albumen. The orthophosphates give a yellow precipitate with the former, while the pyro- and meta- phosphates give a white precipitate; and the metaphosphate alone gives a precipitate with albumen.

Our knowledge of the various sodium phosphates is largely due to Graham (Phil. Trans. 1833, 253). The metaphosphates have been particularly examined by Maddrell (Chem. Soc. Mem. 3, 373).

Several highly-complicated phosphates not belonging to any of these classes are also known. Thus Fleitmann and Henneberg (Annalen, 65, 304) have obtained peculiar phosphates, one of which has the composition $Na_6P_4O_{13}$, by fusing tetra-sodium pyrophosphate with sodium monometaphosphate, and Filhol and Senderens (Compt. rend. 93, 388) have obtained a phosphate of the composition $(NaHO)_3(P_2O_5)_2,H_2O$ by adding soda to a solution of orthophosphoric acid until neutral to colour tests.

Three orthophosphates, respectively containing one, two, and three atoms of sodium in the molecule, are known.

Trisodium orthophosphate Na_3PO_4 is obtained by adding excess of caustic soda to hydrogen sodium phosphate, and crystallising to remove the free alkali. It may also be prepared by fusing hydrogen disodium phosphate with excess of soda and dissolving and crystallising. It forms non-efflorescent six-sided prisms of the composition $Na_3PO_4,12H_2O$. According to Mohr (Amer. J. Sci. [iii.] 14, 281), their sp.gr. at 17·5° is 2·5362. They fuse at about 73·4°; at 100° they lose 11 molecules, but they retain the last until the heat approaches redness. A hepta- and decahydrate have also been prepared. The hydrated salt dissolves in about 10 times its weight of water at 15°. The solution reacts strongly alkaline in consequence of the salt being hydrolysed to a great extent into Na_2HPO_4 and NaOH. In solutions weaker than decinormal almost the whole of the salt is thus decomposed (Salm, Zeitsch. physikal. Chem. 1907, 57, 471; Shield, *ibid.* 1893, 12, 167). In consequence of this hydrolysis a solution of the salt is decomposed by all acids, even by CO_2, with formation of disodium phosphate and the salt of the acid in question. Tribasic sodium phosphate is used in place of sodium carbonate in some photographic developers, and it has been proposed to use the melting-point of the dodecahydrated salt (73·4°) as a standard for use in calibrating thermometers.

Hydrogen disodium phosphate Na_2HPO_4 occurs in urine, in which it was discovered by Haupt in 1740, and was at one time prepared from it under the name *sal mirabile perlatum.* It may be prepared by adding sodium carbonate to phosphoric acid until alkaline, and filtering, concentrating, and crystallising the solution.

It is usually prepared from the acid calcium phosphate made by the action of sulphuric acid on bone ash. For this purpose the hot solution is treated with sodium carbonate until effervescence ceases, and the solution of hydrogen sodium phosphate thus produced is filtered from the precipitated tricalcium phosphate, and is concentrated and crystallised.

The salt crystallises in large, colourless, transparent monoclinic prisms of the composition $Na_2HPO_4,12H_2O$. They soon effloresce, forming the heptahydrate, and become opaque on exposure to the air.

They melt at 35° (Tilden, Chem. Soc. Trans. 45, 268), and have a sp.gr. of 1·5235 at 15° (Stolba, J. Pharm. Chim. 97, 503). When dried over sulphuric acid, or heated for some time to 45°, they become anhydrous.

On further heating sodium pyrosphophate is formed, the transformation being complete at 300°:

$$2Na_2HPO_4=Na_4P_2O_7+H_2O.$$

Sodium phosphate dissolves readily in water, easily forming supersaturated solutions. The solubility of the salt at different temperatures has been determined by Mulder (Scheidekund Verhand. 1864, 100).

Temp.	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°	99°
Parts Na_2HPO_4 per 100 of water	2·5	3·9	9·3	24·1	63·9	82·5	91·6	95·0	96·6	97·8	98·8

The saturated solution boils at 105°. The salt does not dissolve in alcohol. Its aqueous solution reacts alkaline due to slight hydrolysis.

According to Poggiale (J. Pharm. Chim. [iii.] 44, 273), 100 parts of water dissolve the following amounts of the anhydrous salt:—

0°	1·55	60°	55·29
10°	4·10	70°	68·72
20°	11·08	80°	81·29
30°	19·95	90°	95·02
40°	30·88	100°	108·20
50°	43·31	106·2°	114·43

When evaporated at 33°, it deposits monoclinic crystals of the composition

$$Na_2HPO_4,7H_2O.$$

Hydrogen disodium phosphate is used in certain photographic toning solutions, and to some extent in calico-printing and for weighting silk.

Sodium dihydrogen phosphate NaH_2PO_4 is prepared by adding phosphoric acid to a solution of the disodium salt until the liquid ceases to give a precipitate with barium chloride. It is obtained on cooling the hot strong solution in rhombic crystals of sp.gr. 1·90, containing 2 molecules of water, which are very soluble in water but insoluble in alcohol. A hydrate NaH_2PO_4,H_2O has also been prepared. On heating to 100° the salt becomes anhydrous, at 210° it is converted into the acid pyrophosphate $Na_2H_2P_2O_7$, and on further heating yields a mixture of metaphosphate and trimetaphosphate (Knorre, Zeitsch. anorg. Chem. 1900, 24, 369).

Many double orthophosphates containing sodium are known, the most important being 'microcosmic salt' $Na(NH_4)HPO_4,4H_2O$, which occurs in urine. It was well known to the alchemists under the names of 'microcosmic salt,' 'fusible salt of urine,' and 'essential salt of urine,' and was employed by them as a source of phosphorus. It has also been met with in nature as the mineral *stercorite*, found in some guano deposits.

The salt is obtained artificially by mixing hot solutions of 5 parts disodium phosphate and 2 parts ammonium phosphate, and allowing the solution to cool. Another method consists in mixing hot solutions of 7 parts disodium phosphate and 1 part of ammonium chloride:

$$Na_2HPO_4+NH_4Cl=Na(NH_4)HPO_4+NaCl.$$

The crystals obtained by this latter process contain a little sodium chloride, and must be purified by recrystallisation from hot water containing ammonia. Microcosmic salt forms transparent, monoclinic crystals of sp.gr. 1·55, which possess a saline taste and lose ammonia on exposure to air. The aqueous solution of the salt has an alkaline reaction and loses ammonia on boiling. On heating, the crystals melt easily and evolve water and ammonia, being converted into sodium dihydrogen phosphate. On further heating, more water is evolved and a residue of sodium hexametaphosphate remains as a clear, glassy mass. This substance possesses the property of dissolving many metallic oxides with formation of characteristically coloured compounds, hence microcosmic salt is largely employed in blowpipe analysis. With silica and many silicates it yields the characteristic so-called 'silica skeleton' bead.

Sodium orthophosphates of the composition $Na_3H_3(PO_4)_2$ and $NaH_5(PO_4)_2$ have also been prepared (Giran, Compt. rend. 1902, 134, 711; Senderens, *ibid.* 1902, 134, 713).

Sodium metaphosphates. A large number of these salts have been prepared. The different classes are known as mono-, di-, tri-, hexametaphosphates, &c., and are to be regarded as derived from the simple metaphosphoric acid HPO_3 and its polymers $(HPO_3)_n$.

According to Tamman (Zeitsch. physikal. Chem. 1890, 6, 122; J. pr. Chem. 1892, [ii.] 45, 417) the hexametaphosphates exist in metameric forms, and the different classes of the sodium metaphosphates are represented in the following table:—

$Na_2(PO_3)_2$	sodium dimetaphosphate
$Na_3(PO_3)_3$	„ trimetaphosphate
$Na_6(PO_3)_6$	„ hexametaphosphate
$Na_2[Na_4(PO_3)_6]$	metameric sodium hexametaphosphates
$Na_4[Na_2(PO_3)_6]$	
$Na_5[Na(PO_3)_6]$	
$NaPO_3$	Three insoluble monometaphosphates.

According to Warschauer (Zeitsch. anorg. Chem. 36, 137) the so-called dimetaphosphate is in reality a tetrametaphosphate. All the metaphosphates of sodium are soluble in water except the monometaphosphates. The tri- and tetra- salts may be distinguished from one another by the action of barium chloride or lead nitrate, the latter class giving white precipitates with these reagents. The hexametaphosphates are glassy amorphous salts, which yield precipitates with solutions of salts of the alkaline earths and heavy metals. For further details concerning the sodium metaphosphates, reference must be made to the original papers. *See* Tamman (*l.c.*), Knorre (Zeitsch. anorg. Chem. 1900, 24, 378), and Warschauer (*l.c.*), where an account of the literature on the subject is given.

Sodium pyrophosphates. Normal sodium pyrophosphate $Na_4P_2O_7$ is produced, as already stated, by heating the disodium hydrogen orthophosphate to 300°, when it remains as a white, glassy mass of sp.gr. 2·37 (Clarke), which melts at about 880°. The salt dissolves in water, yielding a solution having an alkaline reaction, and can be obtained by evaporation in monoclinic crystals of sp.gr. 1·82 containing 10 mols. of water. The aqueous solution is not converted into the orthophosphate by boiling alone, but the presence of an acid, even such a weak one as acetic acid, is sufficient to effect the change on heating.

Sodium pyrophosphate is occasionally used in medicine in place of the disodium orthophosphate, and also serves as the material for the preparation of the insoluble metallic pyrophosphates and their double salts.

Disodium hydrogen pyrophosphate

$$Na_2H_2P_2O_7$$

is prepared by heating sodium dihydrogen phosphate NaH_2PO_4 to 200° for several hours, or more easily by dissolving the normal pyrophosphate in glacial acetic acid and precipitating with alcohol. It then forms a white, crystalline powder which dissolves easily in water, giving a solution with an acid reaction. By evaporation it may be obtained crystallised with 4 or 6 mols. of water.

A delicate test for alkaline pyrophosphates is furnished by luteocobaltic chloride

$$[(NH_3)_6Co]Cl_3,$$

which gives a pale reddish-yellow precipitate with these salts. By means of this reaction $\frac{1}{750}$ part of pyrophosphate can be detected in the presence of ortho- and metaphosphate (Braun, Zeitsch. anal. Chem. 3, 468).

A considerable number of double pyrophosphates of sodium with potassium, calcium, barium, and other metals have been prepared.

Sodium carbonate (*Carbonate of soda*).

Natural occurrence of the sodium carbonates. The sodium carbonates are found in many mineral waters (especially those of Aix-la-Chapelle, Karlsbad, and Vichy), in the 'natron lakes' of Hungary, Egypt, Central Africa, the Caucasian steppes, and in those of North and South America; also as efflorescences in such steppes, especially in the neighbourhood of natron lakes. These efflorescences or crusts are formed either by the partial or entire drying up in summer of such lakes or ponds, or else by the evaporation of subsoil moisture, more moisture (containing soda) being always brought to the surface by capillary action. The soda thus obtained in various places is known by the names *natron, trona,* or *urao.* 'Urao,' according to Chatard (Bulletin No. 60, U.S. Geological Survey, 1887–1888), is essentially a carbonate of the formula $Na_2CO_3,NaHCO_3,2H_2O$, and is the most usual form of 'natural soda.'

The oldest-known occurrence of natural soda is that in Lower Egypt, where the natron lakes dry up in summer, leaving crusts of salt behind; in other places the 'trona' appears as efflorescences on the ground, consisting essentially of sodium sesquicarbonate, according to former assumptions, or rather, according to Chatard, of 'urao' mixed with other carbonates. Several thousands of tons of this article are yearly exported from Alexandria, principally for soapmaking. Enormous quantities of soda are found in the lakes and steppes of the 'Alkali Plain' and other parts of the great desert east and west of the Rocky Mountains. One of the most considerable of these occurrences is in Owen's Lake, in California, which, according to Chatard, contains per litre:

26·96	grms.	Na_2CO_3
5·71	„	$NaHCO_3$
11·08	„	Na_2SO_4
29·41	„	NaCl
3·14	„	KCl

with a little silica, alumina, calcium, magnesium, and boric acid. This lake contains from twenty to forty millions of tons of sodium carbonate, which is easily obtained in an almost pure state by solar evaporation in shallow ponds. The Magadi deposit in British East Africa, which is about 30 square miles in area, is estimated to contain some 200,000,000 tons of soda. The following analysis is by A. Gordon Salamon:—

Na_2CO_3	43·55
$NaHCO_3$	40·41
NaCl	0·36
SiO_2	0·07
$Al_2O_3+Fe_2O_3$	0·04
Water (by diff.)	15·57
	100·00

Magadi, which in the native dialect denotes 'soda,' is situated about 370 miles from the port of Mombasa, and some 60 miles to the south of Nairobi. The deposit of natural soda is located at about 2000 ft. above the level of the sea, and lies in a deep depression called the Rift Valley, at some 3000 ft. below the level of the Central African plateau that surrounds it.

This natural soda is a crystalline sodium sesqui-carbonate which, when calcined, at a low red heat, yields sodium carbonate (soda ash) in powder form, of 99 p.c. purity. The density of Magadi soda ash will correspond to what is known as 'heavy' finish (*v.* p. 69), which is an important point in its favour, both for considerations of sale, as well as cheap cost of transport.

The development of this natural soda deposit has been undertaken by the Magadi Soda Company, Ltd., formed in 1911 with a capital of £1,312,500. A branch line of about 92 miles is being constructed from the Uganda railway to Magadi, and a deep-water pier and sidings are in the course of construction at Mombasa, thereby establishing through railway communication between Magadi and the sea, and ships will be able to lie alongside this pier when taking in cargoes of soda. It is expected that a start will be made with the exportation of soda in the early part of 1914.

Mombasa, being, so to speak, half way to the Far East, is well situated for supplying such important markets as Japan, China, and Australia; it is also in immediate proximity to the markets of India and Cape Colony.

Soda from the ashes of plants. Whilst the soluble part of the ashes of most land plants contains chiefly potassium carbonate and other potassium salts, there exist some 'soda plants,' growing on the sea-shore or near salt-springs, the ashes of which furnish a very impure kind of soda, formerly much used by soap-makers. Most of these plants belong to the family *Atripliceæ*—namely, the genera *Atriplex, Chenopodium, Salsola, Salicornia, Kochia,* &c. The plants growing in the sea itself, especially *fuci*, yield another kind of ashes, called 'kelp' in Scotland and 'varec' in Normandy, contain very little sodium carbonate, but a large quantity of potassium chloride and sulphate, along with a little iodate, which formerly was the only available source of iodine; in its manufacture, 'kelp salt'—that is, sodium chloride containing some carbonate—was obtained as a by-product. The ashes from the real soda plants growing in Spain are known in commerce as 'barilla'; those from the south of France as 'blanquette,' 'salicor,' 'soude douce,' &c. The general name of these products is *vegetable soda*, but frequently *barilla* is used in the same sense.

Vegetable soda, being simply fluxed ashes not purified by lixiviation, contains a large proportion of residue insoluble in water; the portion soluble in water contains sodium and potassium carbonate, sulphate, and chloride, along with small quantities of sulphides and thiosulphates formed by reduction from the sulphates; it is, moreover, frequently adulterated with a large quantity of common salt. In the analyses by Girardin, the proportion of sodium carbonate varies from 2 to 13·76 p.c. (Lunge, Sulphuric Acid and Alkali, Vol. II., pt. i., p. 81.

Artificial soda.

Historical. Only when Duhamel, in 1736, had demonstrated the identity of the base of common salt with that of 'mineral alkali,' as the natural soda was then called, was it possible to think of manufacturing soda artificially. But the problem was not actually approached until about 1775, when Scheele discovered that common salt could be partially converted into caustic soda by means of lead oxide. In the same year the French Academy of Science offered a prize for a method of converting common salt into soda; and this was a stimulus to many inventors, only one of whom, Nicolas Leblanc, ultimately proved successful. His first experiments are said to have been made as far back as 1784; in 1789 his process was so far completed that he was able to submit it to the Duke of Orleans (whose domestic physician he was) in order to obtain the capital for carrying it out on a manufacturing scale. This led to several agreements in 1790, and, in 1791, to a patent which practically embodies all the principles of the Leblanc process as carried out to-day. About the same time manufacturing operations were commenced at La Franciade, at St. Denis. Leblanc himself did not profit by his invention, as his patent was taken from him by the French Revolutionary Government 'for the benefit of his country,' and ultimately the unfortunate inventor of what has proved one of the greatest industrial processes of modern times committed suicide in despair.[1]

Even before Leblanc fell a victim to the ingratitude of his countrymen, several alkali works employing his invention were founded in France. In England the first attempts at manufacturing artificial soda were made by W. S. Losh, at Walker, near Newcastle-on-Tyne, in 1806; the Leblanc process was tried there on a very small scale in 1814, and at St. Rollox in 1818. The enormous salt duty levied in England (30*l.* per ton) at that time practically prevented the establishment of alkali works. Immediately after its abolition in 1823 James Muspratt started his works near Liverpool, which for 6 years remained the only one in England, except a few small works on the Tyne. The small quantity of black ash then made in France and England contained only about 10 or 12 p.c. of alkali; Muspratt, however, from the first succeeded in making it of a strength of 24 p.c. of alkali, and in this form it was sold to the Liverpool soap makers to be used in lieu of kelp.[2] It was found when this black ash was exported that it quickly lost strength, and this led to the manufacture of sodium carbonate by lixiviation, evaporation of the liquor, and calcination of the residue.

During the ensuing 50 years an enormous development of the production of sodium carbonate, and later of caustic soda, by the Leblanc process took place in Great Britain and on the Continent, and during this period the Leblanc process was practically without a rival. Although the Leblanc process still fully maintains its position for the manufacture of caustic soda, it has been practically superseded by the ammonia soda process for the production of sodium carbonate,

Later still, electrolytic processes have been evolved and worked on a commercial scale. The various natural deposits of soda existing in different parts of the world have up to now played a small part in the soda industry.

---

GENERAL REMARKS ON THE MANUFACTURE OF SODA.

The only raw material, offered by nature in inexhaustible abundance for the manufacture of both sodium and chlorine compounds, is sodium chloride, which, as rock-salt, forms whole geological strata, and which can be obtained very cheaply as rock-salt, or by evaporation from brine, or in sunny climates from sea-water by the sun's heat. All other raw materials are of very little importance for that purpose; those which possibly contain as abundant a supply of sodium—namely, soda-felspar and certain other silicates—are not fit for the economical extraction of soda. As a source of chlorine, the magnesium chloride, produced in enormous quantities as a by-product of the Stassfurt potash industry, has been regarded as a possible rival of sodium chloride, but is, in any case, only indirectly concerned in this question, in so far as it may influence the economical aspects of the various soda processes.

The object of the alkali manufacturer is to decompose sodium chloride according to the following equation:

$$NaCl + H_2O = NaOH + HCl.$$

Thermo-chemistry, however, shows this reaction to be endothermic.

$$\underbrace{\overset{[Na{\cdot}Cl]}{97{\cdot}7} + \overset{[H_2{\cdot}O]}{58{\cdot}0}}_{155{\cdot}7} = \underbrace{\overset{[Na{\cdot}OH]}{102{\cdot}3} + \overset{[H{\cdot}Cl]}{22{\cdot}0}}_{124{\cdot}3}$$

As a rule, chemical change can only take place if the thermal units represented by the formation of the new compound or compounds are superior to those of the original compound or compounds. In order to bring about changes of an inverse order, such as that which concerns us here, we have practically only two means at our command: either the employment of a physical force more potent than heat in overcoming the latent chemical energy—that is, electricity—or else, turning the difficulty by first applying some intermediate reaction which converts the original compound into one more easily split up by chemical means, aided by a proper temperature. This necessitates the employment of auxiliary substances, which sometimes are and sometimes are not recovered in the later stages of the process; sometimes new products are formed which contain one of the constituents, either of the original substance or of the auxiliary bodies in such a form that it seems, and frequently for a time actually is, economically impossible to recover the same.

1. THE MANUFACTURE OF SODA BY THE LEBLANC PROCESS.

This process consists in first of all converting the sodium chloride into sodium sulphate (*see Salt-cake*, p. 21), and then in heating the sodium sulphate with calcium carbonate and coal until the mass has fluxed. No reaction takes place until the mixture has become a semi-fluid, pasty mass, after which the reaction is rapid and practically complete.

The fluxed mass so obtained is called 'black ash,' and the batches drawn out of the furnace are frequently called 'balls.' Black ash is a very complex mixture of substances, which undergo a somewhat rapid change by the action of the air. It is separated by the action of water ('lixiviation') into a residue—'tank waste,' 'alkali waste,' or 'soda waste'—and a solution containing the soda chiefly in the state of carbonate, along with some hydroxide and a large number of impurities. From this either the commercial sodium carbonate ('soda ash') or the commercial hydroxide ('caustic soda') is prepared by operations to be described below.

The reaction taking place in the black-ash furnace has been variously interpreted. The matter is complicated, not merely by the large number of substances found in black ash, but also by the fact that, in order to fully decompose the sodium sulphate, an excess of calcium carbonate and coal must be employed. Taking an average of the many mixtures employed in practice, we may assume that with 100 parts of pure Na_2SO_4 usually about 100 parts of pure $CaCO_3$ and 35 of pure C are employed—that is, to 1 molecule of Na_2SO_4 1·42 mols. of $CaCO_3$ and $4\frac{1}{8}$ mols. of C; or, say, $1\frac{1}{2}$ of $CaCO_3$ and $4\frac{1}{8}$ of C; and the older theories, in fact, assumed those proportions to represent the number of molecules entering into the reaction, without taking into account the fact that in a case like the black-ash process, where the mixture never enters into complete fusion and the ingredients are never absolutely mixed with one another, the decomposition of the most valuable portion, the Na_2SO_4, can be brought about only by a mechanical *excess* of the other ingredients, which ensures that every portion of the Na_2SO_4 comes into contact with them.

Apart from this oversight, the first theory of the black-ash process—that of Dumas (1830)—was based on two erroneous assumptions, namely, that CaS is soluble in water (confounding the compound $Ca(SH)_2$ with CaS, as was natural at that time); and that there exists in black ash an insoluble calcium oxysulphide 2CaS,CaO (already assumed by Thénard). Believing that the action of water must cause CaS at once to act upon Na_2CO_3, Dumas thought that this is prevented by the formation of 2CaS,CaO, and he represented the black-ash process in this way:

$$2Na_2SO_4 + 3CaCO_3 + 9C = 2Na_2CO_3 + CaO,2CaS + 10CO.$$

This would require for 100 Na_2SO_4 : 105·6 $CaCO_3$, and 38 pure C—quantities decidedly in excess of those found sufficient at many alkali works for *completely* decomposing the salt-cake, which fact alone would refute Dumas's theory.

That theory was further, but not very essentially, modified by Unger, Brown, P. W. Hofmann, and E. Kopp, and was almost universally adopted until Kynaston Gossage, and Scheurer-Kestner (1858–1867) exposed its fallacy by proving the non-existence of calcium oxysulphide in black ash, and by other reasons equally cogent. They also disputed the assumption that the principal oxide of carbon formed is CO, not CO_2—a theory upheld by Dubrunfaut, and later on by Mactear, but refuted by the extensive investigations of Kolb (Ann. Chim. Phys. [iv.] 7, 118), and by laboratory experiments made by Lunge and Fischer.[1]

As the final result of the prolonged controversy on these points, of the large-scale experiments of Scheurer-Kestner and Kolb, and of

---

[1] Compare the complete discussion of the various publications on the theory of the black-ash process in Lunge's Alkali, vol. ii. pt. ii. p. 511.

Lunge, the theory of the black-ash process may be stated as follows: the principal reaction going on is ultimately

$$Na_2SO_4+CaCO_3+2C=Na_2CO_3+CaS+2CO_2.$$

It is, however, extremely probable that this takes place in two stages, the first being the reduction of sodium sulphate by carbon to sulphide; the second being a mutual decomposition of the latter with calcium carbonate:

$$(1)\ Na_2SO_4+2C=2CO_2+Na_2S.$$
$$(2)\ Na_2S+CaCO_3=Na_2CO_3+CaS.$$

Nearly all the Na_2S is at once acted upon by $CaCO_3$ immediately after its formation, so that there is at no time any considerable proportion of it present, except in the case of abnormal work.

The above equations would require for 100 parts of pure Na_2SO_4 only 70·42 pure $CaCO_3$ and 16·9 pure C. One reason why much more of the two last ingredients must be employed for decomposing the whole of the Na_2SO_4 has been already stated, but there is an additional reason. In order to lixiviate the melted mass, it must have a certain degree of porosity, and must, moreover, be further disintegrated during the treatment with water. Without this, the lixiviation would require too much time, too high a temperature, and too great dilution of the liquor, and would thus produce a very inferior liquor, as well as a bad yield of soda. The above condition is practically attained by employing an excess of limestone and coal, which in the last stage of the process, when the temperature is at its highest, react as follows:

$$CaCO_3+C=CaO+2CO.$$

The carbon monoxide, which is formed at a period when the mass has become pasty, causes it to become honeycombed, like the dough in a fermenting loaf of bread. The CO is actually seen escaping at this stage, and burning with a flame tinged yellow by sodium. The caustic lime remains behind, and afterwards, on being hydrated, causes the balls to swell up and burst during the lixiviation. A further excess of limestone and coal, which ought not to be too great, produces greater porosity of the black ash in a purely mechanical way, since they are not fused like the remainder of the mass. Lastly, some portion of the coal is unavoidably burned before it can enter into action. All these reasons fully explain the necessity of employing an excess of limestone and coal; but it is impossible to embody this in a chemical formula, as has been attempted by Scheurer-Kestner, seeing that such excess acts merely in a mechanical way, and actually differs in different works.

It is hardly necessary to say that many subsidiary reactions take place at the same time; but these have nothing to do with the theory of the black-ash process, and merely explain the occurrence of the impurities always found accompanying the two principal products, sodium carbonate and calcium sulphide.

DESCRIPTION OF THE BLACK-ASH PROCESS.

Raw Materials.

Sodium sulphate (*salt-cake*). This is nearly always obtained by the decomposition of common salt by sulphuric acid, or else by Hargreaves and Robinson's direct process from common salt, pyrites kiln gases, and air (*cf. Sodium sulphate*).

The salt-cake for alkali-making should be a white or yellowish powder containing only porous, friable lumps, and no fluxed pieces which nearly always inclose some raw salt and decompose badly in the black-ash furnace.

Good, strong soda cannot be made with salt-cake containing more than 0·5 p.c. of undecomposed NaCl.

Good commercial salt-cake contains 96–97 p.c. of Na_2SO_4.

Calcium carbonate. Both limestone and chalk are employed—of course, the purer the better. Magnesian limestone cannot be used, and limestone or chalk containing much silica causes a great loss of soda in the insoluble state. The chalk ought to be dried, and both it and the limestone ought to be crushed to about 2-in. cubes.

The Tyneside works mostly use the chalk brought down from the Medway by colliers as ballast. The Lancashire works employ mostly Buxton limestone, which works more easily in the furnaces than does chalk, and requires less heat for the 'balling' process.

In most cases the lime mud obtained in causticising the liquors by lime is used to replace part of the limestone in the black-ash mixture.

Coal. The quality of the coal employed for the black-ash mixture is of great importance. It ought to contain as little ash as possible. and this is more difficult with the small coal or 'slack' generally used than with lump coal, which is, however, too dear for this purpose. Even after washing, such small coal rarely contains less than 5 p.c. of ash; 6 p.c. is the maximum tolerated by some German alkali works; but in England 'slack' containing 8 p.c. ash is considered as very good for mixing. The coal ashes, consisting principally of aluminium and calcium silicates and ferric oxide, cause the formation of insoluble double silicates, which lock up a considerable portion of soda in a non-available form. The more ashes the mixing-coal contains, the less soda ash will be obtained with it.

Leblanc himself employed wood charcoal, which is now excluded by its price. Good lignite or crushed coke, if otherwise pure, can be very well employed in mixing. In any case care must be taken to decide by preliminary trials on a working scale whether a certain description of coal will answer for soda-making or not, as the whole success of the operation depends upon this, and analyses cannot entirely decide this point beforehand.

The nitrogen contained in coal, which varies from 0·5 to 0·75 p.c., gives rise to the formation of cyanides, part of which are converted into cyanate by the oxidising action of the flame. The moisture of the air decomposes the cyanate, with formation of ammonia, which is evolved during the cooling of the balls. But another portion of the cyanide remains behind, and is, during the lixiviation, converted into ferrocyanide.

J. Pattinson (in Trans. Newcastle Chem. Soc. 4, 183) gives analyses of nine descriptions of mixing-coal as used on the Tyne. That described as 'good' contains, in 100 parts, 61·19–66·45 fixed carbon, 25·27–27·35 bituminous substances, 0·6–1·47 volatile sulphur, 0·1–0·3 sulphur in ashes, 4·8–8·32 ashes, and 1·01–

1·67 moisture. 'Inferior' mixing-coal contains only 56–58·8 fixed carbon, and 12·56–14·22 ashes.

Mixing-coal acts all the better the more finely divided it is; it is, however, rarely ground by itself, especially as it is mostly employed in the state of 'small' or 'slack,' but is only screened and roughly mixed with the other materials.

The proportions in which the materials are mixed naturally vary with their quality, the amount of moisture, &c. Leblanc's original proportions: 100 salt-cake, 100 chalk, 50 charcoal, are very nearly identical with those now in use.

THE BLACK-ASH FURNACES.

The furnace in which the Leblanc process was originally worked was naturally a hand furnace. Hand furnaces are now no longer used for the production of black ash, but as a matter of historical interest, the following illustrations (Figs. 31, 32, and 33) and description are added. The furnaces were substantially built and well-braced, and the position of the working doors and shape of the furnace allowed easy access for the working tools to all parts of the beds.

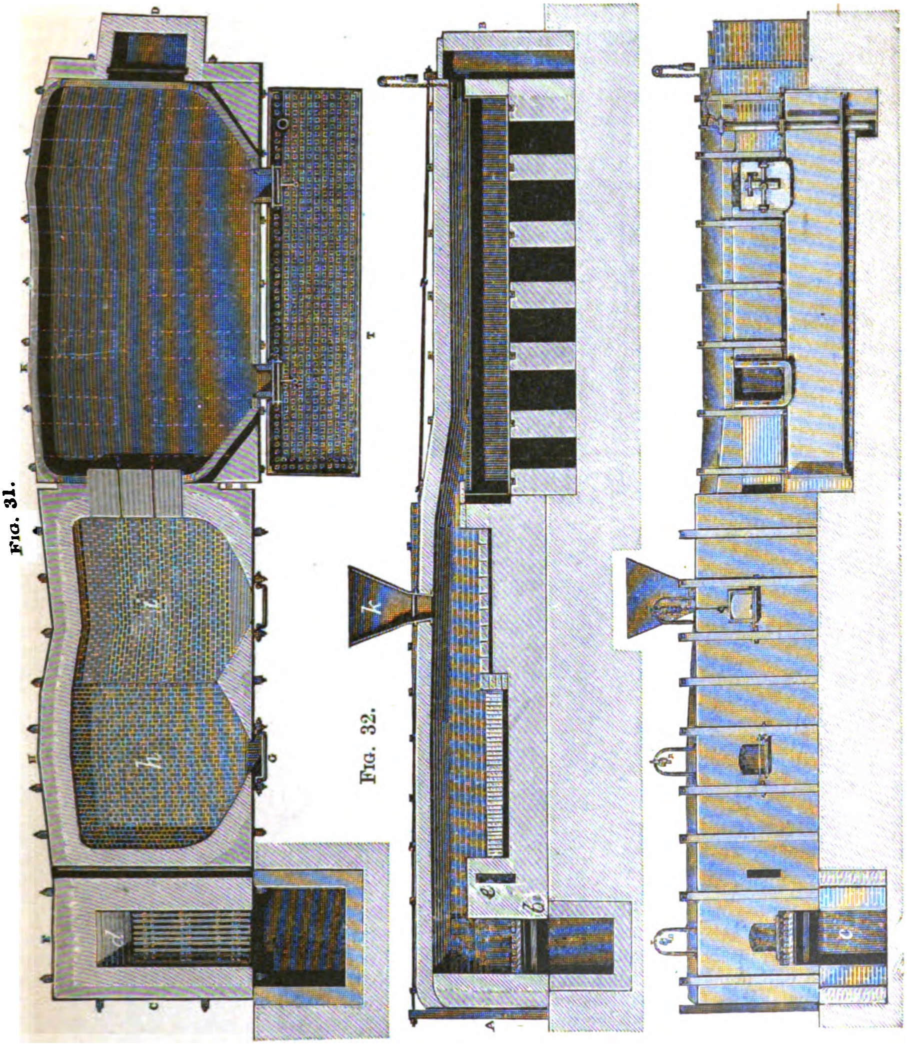

FIG. 31.

FIG. 32.

FIG. 33.

Fig. 31 is a sectional plan along line A B of Fig. 32, passing through the hollow fire-bridge, but showing the beds and the pan from the top; Fig. 32 is a sectional elevation along line C D of the plan; Fig. 33 a front elevation, showing only the firing hole and the drainer in section. Such a furnace worked off a 3-cwt. charge of salt-cake in 45–50 mins., so that with the necessary pauses for cleaning the fire, &c., 24–27 balls were made daily. *a* is the fireplace, provided with wrought-iron grate-bars; the bar *b* assists in poking up the fire from below from the fire-cave *c*. (Such 'cave-fires' were said to consume less coals than fireplaces with their ash-pits at the level of the floor, by the greater facility they offer for attending to the fire.) At *d* the fireplace is stepped backwards, so that the flame ranges all over the bridge *e*. The latter was very carefully and strongly built of the best fire-bricks procurable, and lasted about 3 months. It was 2½–3½ ft. wide, and usually built hollow. A cast-iron bridge plate, 1½–2 ins. thick, prevented the charge from fluxing through the bridge; it was protected against overheating by an air channel, open at each end. *h* and *i* are the two furnace-beds. The charge was put through a hopper *k* or else through the door, on the back bed *i*, which was 3 ins. higher than the front bed *h*; to this the charge was transferred, when it was empty, in order to be finished and drawn out through its door. Sometimes three-bedded furnaces were met with. The front bed *h* was made of bricks on end, and was set upon a layer of ground chalk or fireclay, to isolate it from the foundation. The bricks were set dry, as closely together as possible (preferably grinding them upon one another, so as to minimise the width of the joints), and were grouted on the top with a thin paste of fireclay. The long joints were made to run towards the door, and the whole bed was made to slope about 2 ins. that way, in order to facilitate the working of the tools. The back bed *i* was made of bricks on edge (*i.e.* 4½ ins. high). The diagrams show how these beds were made within fire-brick 9-in. walls, so shaped that the tools could easily reach every part of the beds, and leave no dead corners. The front or working-bed, even if made of the best material and with the greatest care, rarely lasted longer than 5 months.

On the Tyne the furnaces were cased in solid cast-iron plates, tied together by upright binders and tie-rods; but in Lancashire the plates were frequently replaced by the less substantial plan of simple straps of wrought iron, 3-6 ins. broad and ¾ in. thick. The ends of the tie-rods were tightened up by screws and nuts, or else by loops and wedges.

In front of the working-doors there were special door plates and supporting bars for the tools. The doors were best closed by fire-clay slabs, surrounded by an iron frame, and hung from a standard with chain, pulley, and balance-weight.

These hand furnaces, like the early mechanical black-ash furnaces, were erected for the manufacture of sodium carbonate, and were fitted with pans over which the fire gases leaving the furnace passed on their way to the chimney, and in which they concentrated by top heat the crude sodium carbonate solution obtained on lixiviation of the black ash. Figs. 31, 32, and 33 show the concentrating-pan, the working of which is described later under the mechanical black-ash furnace or revolver (p. 41).

The work in the black-ash furnace was carried on as follows: The mixture was put on the back bed, where it was levelled, and during its stay there was twice turned over, in order to dry it and heat it. When the charge in the front bed had been drawn out the fire was allowed to play on the empty bed for a little while to make it hot, and then the previously heated charge was pushed over from the back bed. Sometimes a portion of the ball was left a little longer on the back bed ('splitting a ball'). As soon as it was empty a fresh charge was put in. The principal work, of course, went on on the front bed, which was heated to at least the melting-point of silver.

Revolving black-ash furnaces. The kind of work done by a ball-furnace can be done more efficiently and cheaply by mechanical means, as it simply consists in keeping the charge turned over. The actual solution of this problem proved, however, a difficult task, even after the right principle, that of a cylindrical furnace revolving as a whole, had been found by Elliott and Russell, in 1853. Apart from the mechanical imperfections of their furnace, it turned out the black ash much too hard and in a very bad state for dissolving, because by the continuous rotation all the gas was driven out, and the honeycombed structure of the balls was lost. Stevenson and Williamson, in 1855, overcame both difficulties, and must be called the true originators of mechanical black-ash furnaces, usually called 'revolvers,' which have entirely superseded the hand furnaces.

Figs. 34 and 35 show an ordinary revolving black-ash furnace in sectional plan and in elevation, fitted with the top-heat pans employed to utilise the waste heat from the revolver when ash or sodium carbonate is produced from the liquors.

Fig. 36 represents a revolver fitted in accordance with the custom to-day with bottom-heated pans to utilise the waste heat.

Where black ash, as is practically always the case now, is made to manufacture caustic soda, these pans are used to concentrate the weak caustic soda solution obtained from the causticisers. It is obvious that it would be impossible to pass the fuel gases over the causticised liquor without carbonating it, and hence the less efficient bottom heating has to be adopted. *a* is the fireplace, with two working doors and a cylindrical opening, 2¾ ft. wide, for the flame to pass through. Between this and the revolving cylinder there is a fire-brick lined, cast-iron ring *b*, the 'eye,' hung by means of chain and pulleys, which allows some air to enter all round, and the necessary expansion to take place. The cylinder *c* consists of a shell of ½-in. boiler plates, 15½ ft. long and 10½ ft. wide inside; cast-iron tire seats *f f*, and cast-steel tires *g g*, are shrunk upon the barrel, and work upon the V-rollers *h h*. The cylinder is lined inside with fire-bricks, 9 ins. thick in the centre, 1½ ft. at the ends; this facilitates the running out of the charge. Two horizontal 'breakers' project from 9 to 13 ins. above the other lining, and promote the mixing of the charge in revolving. A 1½-ft. manhole closed by an iron lid allows charging and emptying the furnace. Each furnace is provided with a special engine, possessing double gearing so that it can produce either a slow movement (one revolution in 10 mins.) or a quick movement (five revolutions per minute). The gearing acts upon a spur-wheel *m*, made in one piece and bolted immovably to the furnace. The exit opening *l* communicates with the large dust chamber *m'*, to which are joined the two boiling-down pans *n* and *n'*, 28 ft. long by 8 ft. wide by 2¾ ft. deep each, with their drainers *o* and *o'*, and from these the flame goes through the flues *q q* into a chimney. The purpose of the partition *r* in the pans is to reserve one part for evaporating the mother-liquor pumped up from the drainers.

A tramway runs above the furnaces for charging them, and another (smaller) tramway runs underneath them for moving the train of discharging trolleys or bogies into which the finished charge is run from the revolver.

A furnace of this size takes charges of 30 cwts. salt-cake and gets through 15–18 tons of salt-cake in 24 hours, with a consumption of 10–13 cwts. of firing fuel per ton of salt-cake.

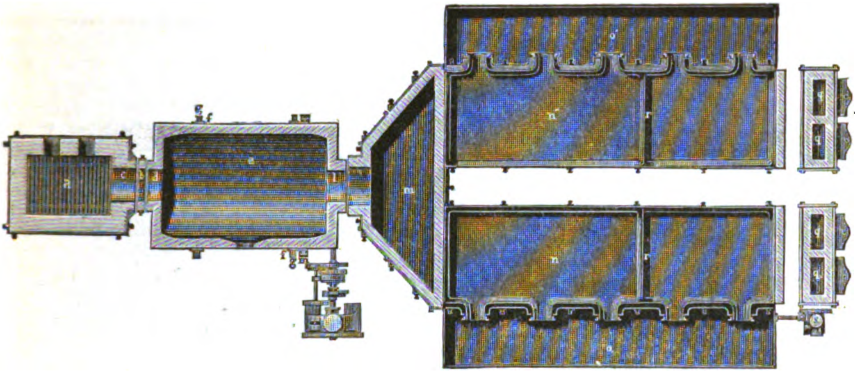

FIG. 34.

Much larger revolvers have been erected, a common size being 18 ft. in length by 10 or 12 diameter. Such a revolver will decompose a 3- or 4-ton charge of salt-cake in 2 hours. The largest revolver made is one erected by the Widnes Alkali Co., in 1887; it is 30 ft. long and 12 ft. 6 in. in diameter (described by Watson Smith in the J. Soc. Chem. Ind. 1887, 417), and decomposes a charge of 8 tons 12 cwts. salt-cake in 3½ hours; and one at the works of Messrs. Kurtz, St. Helens, which is 30 ft. 6 ins. long and 12 ft. 6 ins. diameter.

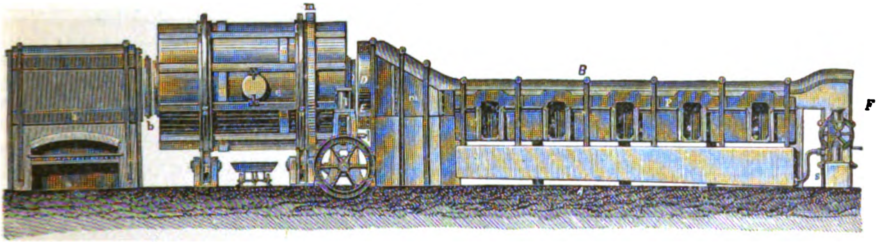

FIG. 35.

There has been much controversy as to the best way to mix and work the charge in a 'revolver.' The various methods suggested had for their object: (1st) The production of a more porous and more easily lixiviated black ash, and (2nd) the destruction of the cyanides formed in the ordinary process which are responsible for carrying iron forward in a soluble form to the end of the process.

The following methods of working the charge have been practised:—

1. The chalk or limestone and two-thirds of the coal are introduced and the revolver kept slowly turning round till the appearance of a blue flame of CO round the man-hole shows some caustic lime has been formed. This liming process lasts 1–1½ hours. Then the salt-cake, together with the remainder of the coal, is added and the rotation slowly continued until the mass is nearly fused, when the quick movement is started.

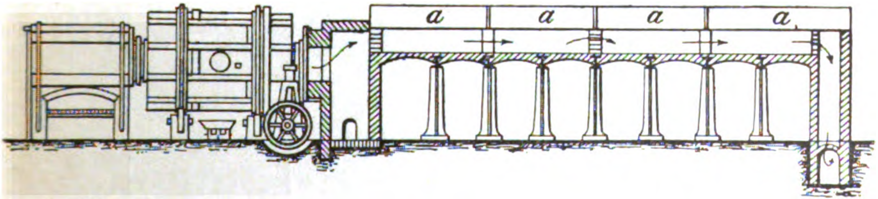

FIG. 36.

The object of 'liming' is to produce a certain proportion of caustic lime, which in the lixiviating tank will cause the balls to burst, and to be more easily dissolved.

2. Mactear in 1874 patented the following method of work. He charges the salt-cake, coal, and limestone at once, but only uses the theoretical quantity of limestone; when the charge is fused he stops the revolver and adds quicklime equal to 10 p.c. on the weight of the salt-cake, and 15 p.c. of cinders.

3. Péchiney (patents 1877 and 1878) added at the end of the charge some salt-cake which has the effect of destroying the cyanide present, and of preventing the formation of ferrocyanide.

4. Weldon patented (1878) an improvement on the Péchiney process. He added a little limestone dust to the charge along with the salt-cake suggested by Péchiney.

The advantages of the Weldon-Péchiney process were the subject of a long controversy between Weldon and Mactear.

5. Several other patents were taken out about the same time, 1878, for destroying the cyanides and ferrocyanides by Mactear, Gaskell, Deacon & Co., Pauli, Brunner, Allhusen, and Glover.

None of these processes appears to be necessary, and the present practice is to drop the whole charge into the revolver at once and work it through without stoppage or addition.

The following may be taken as the normal mixing for a black-ash revolver under modern conditions.

(*a*) When all the calcium carbonate is added as limestone; (*b*) when part of the limestone is replaced by the calcium carbonate produced in the causticisers (caustic lime mud).

Properties of black ash. The yield of black ash is about 1¾ times the weight of the salt-cake furnaced. Properly made, black ash has a blackish-brown, in some places a liver-brown, surface; on breaking, it exhibits a slate-grey colour and porous, almost pumice-like, structure, and looks homogeneous, without any black or white streaks or lumps. Balls which are quite black on the outside are made with too much coal, or are very badly wrought, so that the mixing coal was not all consumed and the ball could not be 'cleared.' If there was a deficiency of limestone, or if the balls were overheated, they are very dense, with pale pink spots outside, and on breaking their colour is pink or purple, in the worst case brick-red. Such black ash contains very much sodium sulphide or even polysulphide. Kolb found this to occur whenever the melting-point of silver was exceeded. 'Soft' balls occur when the temperature has not been high enough, so that the mass never got beyond the thinner state to the pasty, porous one. Such black ash is very difficult to lixiviate, and contains much undecomposed sulphate.

In order to check the furnace men, samples are taken from each man's work, sometimes even from every single ball, and are roughly tested for their percentage of alkali, of sulphate, and of sulphide; but as these cannot be average samples, the judgment of a practised eye on the appearance of the ball in general must always be taken into account as well. The testing-methods are the same as those used for tank liquor (*v. infra*).

Of the published analyses of black ash many are not trustworthy, because they were evidently made with a material changed by exposure to air, or because they neglect constituents which must have been present; some of them also because they give highly detailed figures for constituents for which no good analytical methods are (or were then) known. We quote only a few:—

These analyses do not show caustic soda, which is, in fact, only formed on lixiviation; neither do they count up a number of rare substances, found by some authors in the samples examined by them. But the analysts ought not to have neglected the cyanide, nor the soda present in an insoluble form. There is also no mention of Na_2S, which is never quite absent. All these are accounted for in the following partial analyses of black ash made by the Péchiney-Weldon process:—

—	Made with 60 per cent. coal on the sulphate	100 sulphate, 77·8 limestone, 36·1 coal.	100 sulphate, 85·3 limestone, 44·1 coal

Black ash keeps unchanged in the absence of moisture and carbon dioxide, but in the presence of these it soon undergoes a change (studied by Kolb, Ann. Chim. Phys. [iv.] 7, 118; 8, 135; 10, 106). The lime attracts both H_2O and CO_2; on being hydrated it swells up and cracks the balls, which gradually fall to powder. On lixiviating, they now yield less NaOH, but, on the other hand, much more Na_2S and products of its oxidation, since the action of the atmosphere on CaS produces calcium hydrosulphide, polysulphide, thiosulphate, and other soluble calcium compounds which, on lixiviation, at once react on sodium carbonate. In the course of time the reaction may thus be reversed, and the sodium carbonate may be entirely decomposed again. Hence black ash ought not to be kept too long before working it up, and ought not to be exposed to the action of the air after being once cooled down.

The action of *water* on black ash has also been studied by Kolb (*l.c.*). From his experiments he draws the following conclusions. The quantity of NaOH formed in the lixiviation vats, by the action of lime on sodium carbonate, is not materially influenced by the quantity of water, but increases both with the time of digestion and the rise of temperature. Almost exactly the same conditions govern the formation of sodium sulphide, but this is independent of that of caustic, and evidently takes place by the action of dissolved CaS on Na_2CO_3. NaCl slightly increases, Na_2SO_4 slightly diminishes the quantity of CaS entering in solution, which always takes place in the shape of $Ca(SH)_2$. Boiling CaS with water will effect this slowly. Solutions of Na_2CO_3 act all the more on CaS the more dilute and the hotter they are, and the longer they remain in contact with each other; the presence of caustic lime or caustic soda retards this action. Hence the lixiviation should be carried on as quickly and at as low a temperature, and with as little water, as possible.

Lixiviation of Black Ash.

During the first period of the manufacture of artificial soda, the black ash, as it came out of the furnace, was directly sent out to soap makers and other consumers. Usually (in England universally) the black ash is separated by *lixiviation* into a soluble and an insoluble portion. The former yields commercial soda ash, crystals or caustic; the latter, which contains CaS, as well as many impurities, was a waste product, until quite recently very imperfectly, if at all, utilised.

The lixiviation is not merely a mechanical process for dissolving the soluble matter; during its course chemical reactions set in, which are partly comparatively harmless (as the formation of some $NaOH$), but some of which may cause very much loss by the conversion of Na_2CO_3 into Na_2S, Na_2SO_4, and intermediate states of oxidation, as will be understood from the remarks made upon the action of water on black ash.

Properly made porous black ash requires only breaking up into large pieces, so that it can be handled; but dense, overheated or underheated black ash must be crushed to a coarse powder, and even then is nothing like completely exhausted, without reconverting much of it to Na_2S. It is, of course, essential that black ash should be completely exhausted, that the liquor should be pure, and that it should be as concentrated as possible. We have seen above that this can be done only by working quickly and at a moderate temperature. The latter is specially required for weak liquor, which is much more liable to act upon CaS than concentrated liquor. The former should never be hotter than 43°, and is much better kept between 32° and 37°; the latter may reach 60°.

It is further necessary to disturb the solid mass as little as possible, in order to prevent the liquor from becoming muddy; and, more particularly, any exposure of the wet solid residue to the atmosphere must be avoided, because this leads to a rapid oxidation of CaS, even as far as $CaSO_4$, and a consequent loss of soda.

The different apparatus formerly used for lixiviating soda ash need not be described here, as they are completely obsolete. The apparatus universally employed was originally invented by Professor Buff, of Giessen, but was apparently first brought into practice by Dunlop, at St. Rollox, in 1843, and made its way, first into Lancashire (about 1860). In England it seems to have been dominant about 1864, on the Continent 10 years later. Its principle is to allow the black ash to remain in the same place, and to cause the liquor to circulate in a methodical manner, so that it is brought up to concentration, and the black ash is completely exhausted at the same time, without ever being exposed to the air. By this course the liquors are much stronger and purer, and the process is much less expensive than with the plans formerly practised.

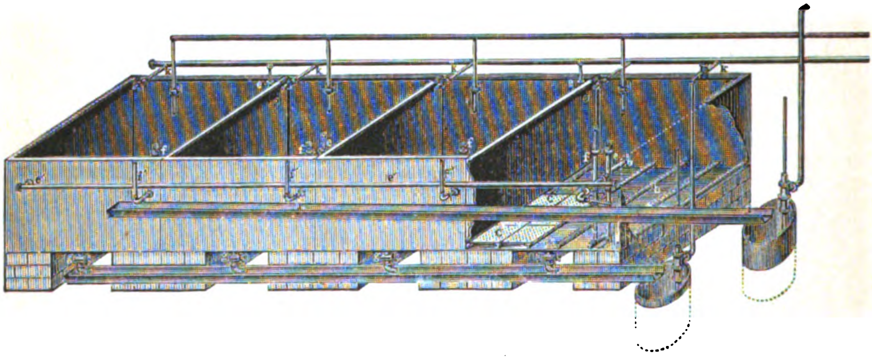

Fig. 37.

The way of carrying out the process is shown in Fig. 37. A number of 'tanks' or 'vats'—at least three, more commonly four, but sometimes five, six, or even more—is combined to form a set. The tanks must be all on the same level, and this should be so far removed from the ground, by means of pillars, that no leaks can occur without being observed. They are made of wrought iron. Near the bottom there is a row of T-pieces *bb*, for supporting the perforated plates *cc*, forming a false bottom. Whilst the true bottom is often made to slope to one side, where the outlet cock is placed, the false bottom must be quite horizontal. Each of the tanks contains two overflow pipes, one, marked *e*, for weak liquor, and another, marked *f*, for strong liquor. This is best seen on the section, Fig. 38. They are cast-iron pipes, a little wider in the upper part, with a conical plug fitting into a seat bored out at the enlargement. Above the plug-seat the pipe has a side-branch, bolted to one side of the tank, where there is a corresponding hole. The pipes pass through the false bottom, and the liquor can enter into them from below. If the plug is taken out, the liquor contained in the corresponding tank will rise from its bottom in the pipe *e* and will overflow into the next tank near its top, and thus a continuous stream of liquor may be produced right through the whole set of tanks. Where, however, it is intended not to run the liquor upon the next tank, because it is concentrated enough to be run off, the pipe *e* will be kept closed and the plug taken out of pipe *f*. All the pipes *ff* are arranged on the front side of the set; they are, on the outside, provided with swivel-pipes *f'*, which, when turned up, prevent the liquor from running out. By turning the branches *f'* downwards at the same time as the plugs are taken out, the strong liquor runs into the shoot *i*, and from this into the well, from which it is pumped into the settlers.

At some works there are cocks instead of the swivel-pipes *f'*; at others the strong liquor pipes *ff* are omitted, and the strong liquor is run off by means of the bottom-cocks *gg*, which must be provided in any case; but neither of these plans can be recommended. The bottom cocks *gg* serve for running away the weak liquor previously to casting out the solid waste. This liquor passes on to a separate well, from which it may be pumped into the water-conduit *k*, from which the tanks are supplied by a separate branch each. A special set of pipes serves for supplying either steam or hot water, as the case may be.

The working of the lixiviation vats is carried on as follows:—

Let us consider we have a set of four vats working in series, and that the spent black-ash waste has just been thrown out ('cast') from one of them. The empty vat is filled to about 1 ft. from the top with lumps of black ash obtained by roughly breaking the black ash balls with a sledge hammer into pieces a man can readily handle. The other three vats of the set during this time are working. The last of the series in which the black ash is nearly exhausted is fed with fresh water and maintained at a temperature not exceeding 35°C. The weak liquor so obtained is run to the weak liquor store tank. When the liquor leaving the weak vat has in this way been washed down until it shows no strength to the Twaddell hydrometer, the vat is allowed to drain by opening the bottom run-off tap *g*, after which the spent waste is thrown out and the vat is ready for filling again, or 'setting' with fresh black ash. The other two vats meantime have been working as follows: Weak liquor from the weak liquor store tank is run on to the partially exhausted or intermediate vat, and from it overflows by the pipe *e*, on to the strong vat. In this way a constant stream of partially-concentrated liquor, gradually dropping in strength from 36° to 0°Tw., is run through the strong vat where its strength is raised to 56°–36°Tw., or an average strength throughout the run of about 46°Tw. When the strength of the liquor leaving the strong vat has fallen to 36°Tw., it is no longer fit to remain a strong vat.

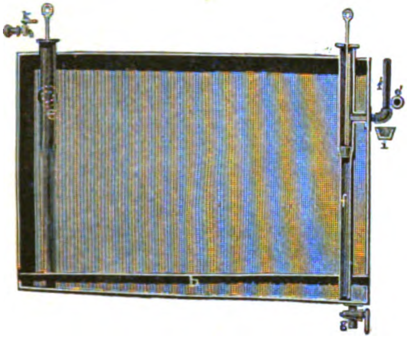

FIG. 38.

By this time also the intermediate vat is low enough in soda to become the weak vat and thus to take the place of the one just exhausted.

The freshly-charged vat mentioned above is then connected, the old strong vat becomes the intermediate vat, the old intermediate vat taking the place of the weak vat which has just been cast, and the whole series of operations starts again.

The great points to be observed are:—

1st. That the black ash should be as uniform as possible, so as all to lixiviate equally and rapidly.

2nd. That the lixiviation process should be conducted as quickly as possible with complete exhaustion.

3rd. That the temperature of the weak vats should not be allowed to exceed 35°C., and the strong vats 60°C.

4th. That the vat waste should be as completely exhausted as possible.

Testing methods for black ash, vat liquor, and tank waste. In order to test *black ash*, a sample consisting of several pieces of the ball (which unfortunately can never be a real average sample) is finely powdered, and 50 grms. of it are digested with tepid water, free from oxygen and carbonic acid; the solution is made up to 500 c.c., and is now tested just like the tank liquor obtained on the large scale. 1st, for *total available alkali*, by means of standard hydrochloric acid and methyl orange; 2nd, for *caustic*, by addition of barium chloride and titrating with hydrochloric or oxalic acid (in the last case without filtration); 3rd, for *sulphide*, by means of iodine; 4th, for *sulphate*, by means of barium chloride, either gravimetrically or volumetrically; 5th, for *total sulphur*, by oxidising with bleaching powder and estimating the sulphate formed; 6th, for *chloride*, by standard solution of silver nitrate, after having exactly neutralised the alkali by nitric acid and boiled away the H_2S; 7th, for *ferrocyanide*, by means of Hurter's copper sulphate solution. *Vat waste* is mostly only tested for *available soda* by treating a solution, obtained as previously described in the case of black ash, with CO_2, boiling, filtering, and titrating the clear portion; sometimes also for *total soda*, including the *insoluble* portion, which is a somewhat lengthy process. (Details of all these methods in Lunge's Technical Chemist's Handbook.)

The analyses by Jurisch, given in the first table on p. 46 (Chem. Ind. 1880, 441), show the composition of revolver vat liquors (abridging the three decimals to one).

A comparison between different systems of working is afforded by the figures in the second table on the next page, which give grms. of each constituent for each 100 grms. of available soda (as Na_2CO_3+NaOH) in tank liquor.

The vat liquor is always too muddy for immediate further treatment, and must be *settled* first. This will cause the vat waste mechanically carried away to subside; at the same time the action of the air will cause some of the ferro-sodium sulphide to be decomposed, and the FeS to be deposited along with alumina and silica, partly or entirely in the state of chemical combination.

THE MANUFACTURE OF CAUSTIC SODA FROM LEBLANC VAT LIQUOR.

Solutions of caustic soda have been made ever since soda was commercially used, especially by soap makers; later on by bleachers, paper makers, &c. Most of these prepared such solutions themselves; sometimes they bought them in the state of *caustic liquor*; but from the nature of things this could never be a large trade. Such a trade has only arisen since caustic soda has been manufactured in the *solid*

state, which was first done about 1845 in Tennant's works at St. Rollox, but only experimentally. The development of that large industry only dates from 1853, and is intimately connected with the names of Gossage, Dale, Ralston, Gamble, Muspratt, Pauli, Deacon, and other Lancashire manufacturers. It was introduced much later into the Tyne district and abroad.

Solid caustic was originally only made from the caustic mother-liquor ('red liquor') obtained in concentrating vat liquors for Leblanc soda ash as hereinafter described. This source of caustic soda is now of little importance, owing to the practically complete replacement of Leblanc soda ash by ammonia alkali.

Some caustic is made by dissolving and causticising ammonia alkali; but the bulk of it is made from *vat liquors*, obtained in the usual way.

The Leblanc vat liquors, as shown in the analyses given above, contain 70–80 p.c. of the total soda as Na_2CO_3, and have first to be causticised or converted as completely as possible into NaOH. The proper performance of this operation plays a very important part in the manufacture of caustic soda.

The method adopted for causticising the Leblanc liquors is always by treatment with quicklime:

$$Na_2CO_3+CaO+H_2O=2NaOH+CaCO_3.$$

This is a reversible reaction, and the conditions under which it is performed govern the proportion of NaOH to Na_2CO_3 in the causticised liquor. The apparatus used is usually a large wrought-iron vessel, fitted with either horizontal or vertical mechanical agitators and a basket (*see b* in Figs. 39 and 40), into which the lime required is placed.

Formerly the agitation was frequently effected by steam or air, but these have been shown to be less economical than the mechanical agitator. The strength of liquor used for the causticising operation is important, there being two facts to be considered.

1st. The lower the strength of the liquor causticised the higher the proportion of the total soda which can be converted into NaOH by the lime.

2nd. The higher the strength of the liquor causticised the less fuel is afterwards required for concentration. As a compromise between these two factors it is usual to causticise at a strength which gives a causticised liquor of 20°–26°Tw. or 1·1–1·13 sp.gr. With careful work such a liquor will contain 91–92 p.c. of its total soda as NaOH.

The operation is usually carried out as follows: Well-settled vat liquor is heated as far as possible by waste heat or exhaust steam, and run into the causticiser where it is diluted to a strength 1·1–1·13 sp.gr. with weak liquor obtained from a later stage of the process, and by water, both of which should also be preheated when possible by waste heat. The quantity of total liquor in the causticiser should be sufficient to just cover the bottom of the cage *b*. The liquor is then heated to boiling by steam through the steam pipe, and the quicklime thrown in gradually. Care is required to prevent the causticiser from boiling over. The steam can now usually be shut off, the heat of hydration supplying heat to make good losses by radiation.

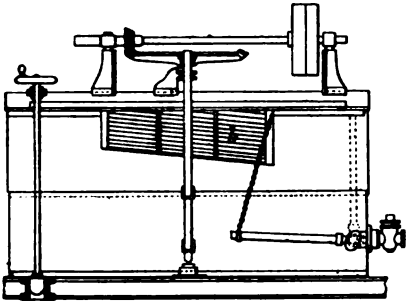

FIG. 39.

More vat liquor and weak liquor are gradually run in and the lime added until the causticiser is full and the calculated quantity of lime added. A sample should then be taken and tested to find the causticity per cent. obtained, and if this does not exceed 90 p.c. more lime is added.

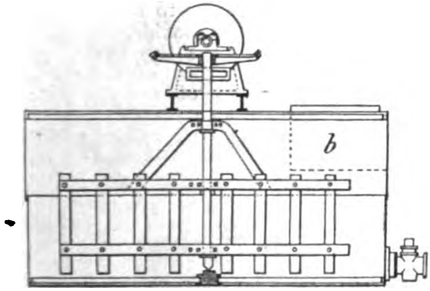

FIG. 40.

The agitator is then stopped and the liquor allowed to settle for about 1½ hours. The comparatively clear liquor is stripped off the top by a drop syphon and run to settlers. The causticiser then remains, perhaps, one-third full of caustic liquor and lime mud. This can either be run out direct on to a filter bed or the causticisers can be filled up with water, agitated and again settled. The weak liquor so obtained, together with washings from the filter, is used for diluting another batch of vat liquor. The washed mud is then run on to a filter bed and again washed with water.

It is by no means uncommon to work two or even three batches in a causticiser without running off the lime mud. This saves time and makes it possible to work each batch with a larger proportion of excess free lime than would be economical for the single batch. The increased quantity of free CaO slightly increases the causticity per cent. obtainable.

Many investigations have been made into the lime causticising operation, and several processes have been suggested with the object of increasing the proportion of causticised to uncausticised soda, *i.e.* of NaOH to Na_2CO_3 in the final liquor when working at higher strengths of solution.

Patents were taken out by Parnell (4144, 1877, and 2203, 1878), by Wells (3803, 1879), by Menzies (3804, 1879), and by Herberts (3577, 1882) for conducting the causticising operation under pressure, which was claimed to give increased causticity per cent. at strengths up to 1·2 sp.gr. The Parnell process was tried extensively on a large scale and failed.

The investigations of Lunge and Schmidt (Ber. 1885, 3286) showed that working under increased pressure did not increase the causticity per cent. obtained.

Herberts also, in a later patent (D. R. P. 43492), claimed that higher causticity could be obtained with liquors of 1·14–1·16 sp.gr. when working under diminished pressure. Later investigations on this subject are those of Bodländer (Zeitsch. angew. Chem. 1904, 1519), Leblanc and Novotny (Zeitsch. anorg. Chem. 11, 181), Wegscheider and Walter (Chem. Zentr. 1907; and Monatsh. 28).

At the present time, as mentioned above, however, the ordinary practice is to causticise at 1·1–1·13 sp.gr. and obtain about 91 p.c. of the total soda as NaOH.

The filters on to which the lime mud from the causticisers is run vary considerably in design and arrangement; Fig. 41, however, is representative of a large number of filters, and shows a thoroughly efficient and satisfactory apparatus.

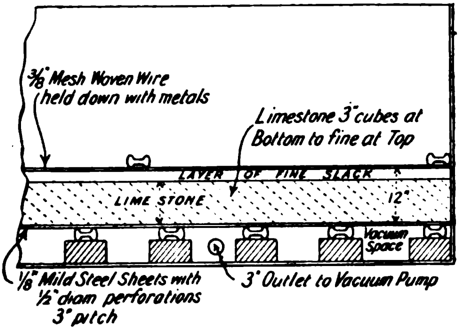

FIG. 41.

The lime mud is run from the causticiser through the 3- or 4-inch diameter pipe on to the filter bed and the vacuum pump started. As soon as the surface of the mud begins to dry cracks are likely to appear. These require raking over with a rake or patting with a spade to close them up. Hot water is then run on to the bed of mud to wash out the caustic liquor which is held up by and surrounds the particles of $CaCO_3$. Finally, the vacuum pump is kept going for some time to dry the mud as much as possible. Under the best circumstances, however, it will retain over 40 p.c., and usually nearly 50 p.c. of water.

On the care with which this washing process is conducted depends the quantity of soda left in the mud.

With careless washing, with cracks in the bed of lime or round the sides of the filter or holes and inequalities in the filter bed, there may be a heavy loss of soda.

With good work the soda loss can be reduced to well below 1 p.c. soda on the weight of lime mud; with bad work it may rise to 4 p.c., and even 6 p.c. on the mud.

As there are about 2 tons of lime mud to the ton of Leblanc 70 p.c. caustic soda, it is evident that this may be a very serious matter.

As mentioned above, the washings from the filters are used to dilute the vat liquor to the strength required for the causticisers.

Other forms of filter for caustic lime mud have been suggested of a more or less mechanical nature, but have not met with extended use, *see* patents by J. Brock and T. Martin, 2127, 1887; G. H. Bolton and T. A. Bullough, 14563, 1888; Hurter and Driffield; Solvay (Eng. Pat. 4725, 1896); and Houghton and the United Alkali Co. (Eng. Pats. 7957 and 28791, 1903).

The following analyses of caustic lime mud are given by Davis (Chem. News, 32, 187):—

$CaCO_3$	40·2	42·0
$Ca(OH)_2$	3·7	3·1
SiO_2	0·7	0·8
Al_2O_3	0·2	0·3
Fe_2O_3	—	0·7
MgO	0·1	0·1
Na_2O	1·8	1·6
H_2O	48·0	46·6
	99·6	99·6

Lime mud is frequently employed to replace part of the limestone required for the revolver charge. For this purpose it is used in the wet condition. The following shows a revolver mixing with and without lime mud:—

	1	2
Salt-cake	52·0	55 cwts.
Limestone	37·0	56 cwts.
Lime mud	45·0	
Mixing slack	21·0	22 cwts.

When used in this way the soda contained in the mud is probably recovered, and some limestone is saved. The output of the revolver is, however, reduced, and the labour and fuel charges increased per ton salt-cake decomposed. The advisability of utilising the lime mud in this way depends, therefore, on a balance in which the relative prices of limestone and fuel are the largest factors. In some works the attempt has been made to burn the calcium carbonate in the mud back again to quicklime, and it is reported that this has been economically done in the rotary kilns used in the manufacture of Portland cement. The lime mud is also used as a raw material for the manufacture of Portland cement (Rigby, J. Soc. Chem. Ind. 1888, 301).

A very important and increasing outlet for caustic lime mud is for liming the soil. For this purpose calcium carbonate is as useful as the oxide and the finely-divided condition of caustic lime mud renders it particularly suitable.

The lime improves the soil by opening up the land, this is especially valuable in the case of the heavier soils. It is in itself a plant food, and also helps to bring into action the insoluble reserves of nitrogen and potassium in the soil. It corrects acidity in the soil, and is the best remedy for the finger and toe disease in turnips and swedes. *See* leaflet No. 170 of the Board of Agriculture and Fisheries.

A totally different method of causticising is that of Löwig (Eng. Pat. 4364, 1882), who evaporated soda liquors with pure ferric oxide, and exposes the mixture to a bright-red heat. The mass is thus converted into sodium ferrate (or rather 'ferrite'), which is insoluble in cold water, so that it can be purified by washing with it: it is then treated with water at 80°C., which decomposes the compound into caustic soda and regenerates the ferric oxide. Thus concentrated liquors are obtained quite free from iron. In patent D. R. P. 41990 Löwig extends this plan to the sesquicarbonate or roaster ash of the ammonia soda process produced by the partial furnacing of the sodium bicarbonate first obtained to expel the NH_3, and part of the CO_2. This substance is then further treated with ferric oxide in a revolving furnace until the whole has been converted into a compound of soda, which is split up by the action of water into caustic soda and insoluble ferric oxide. The British patent of Mond and Hewitt (No. 1974, 1887) states that for the efficient conduct of the process it is necessary to use a pure sodium carbonate and oxide of iron, and to remove the liberated carbonic acid as it is formed. They also advocate the use of a revolving furnace similar to the black-ash revolver for the formation of the 'ferrite,' and the use of water gas as the source of heat in order to keep down the partial pressure of carbon dioxide.

The Löwig process has the advantage of yielding a stronger solution of caustic soda than the lime method of causticising. As mentioned above, the lime process produces a causticised liquor of 1·1–1·13 sp.gr., while the Löwig process produces one of 1·32–1·36 sp.gr., a difference which corresponds to a reduction in the quantity of water to be evaporated for the manufacture of solid caustic soda of about 6 tons water to the 1 ton 70 p.c. caustic soda.

For causticising liquors such as the Leblanc liquors above described, the process is out of the question, as before it can be worked those liquors have to be evaporated to dryness, and in addition there is the fuel required for the furnace and the other working costs which are heavier than in the lime process. The Löwig process is, however, used for causticising on a large scale the solid sodium carbonate obtained in the ammonia soda process, but it is doubtful even then if it is cheaper than the lime process.

Strontium hydroxide has been suggested as a substitute for lime in the causticising operation (Bacon, D. R. P. 99344), because the reaction is much more complete than in the case of lime, and can be carried out in stronger solution.

The process, however, has not been adopted, as far as is known, on the large scale.

The liquor from the causticisers at 1·1–1·13 sp.gr. contains 9–10 tons of water per ton of 70 p.c. caustic soda, and the economical evaporation of this large quantity of water has always been one of the technical problems of caustic soda manufacture. The usual custom is to do the first part of this evaporation by means of the waste heat of the black-ash revolvers as mentioned above. Fig. 36 shows a revolver with a series of the shallow wrought-iron bottom-heated pans *a, a, a, a, a* commonly used behind it.

The hot gases from the revolver dust stack pass under the series of pans, and the causticised liquor from the settlers is fed in a steady stream into the pan furthest from the revolver from which it overflows from pan to pan, until it leaves the front pan at, under good condition, 1·2 sp.gr. This means that the revolver waste heat has in this way evaporated 3–4 tons of water per ton 70 p.c. caustic soda out of the total 9–10 tons.

The further treatment of the caustic liquors to obtain solid caustic soda is divided into two stages, 'concentration' and 'finishing.'

The 'concentration' stage carries the liquor up to such a strength that the bulk of the Na_2CO_3 left in the causticised liquor (8–10 p.c. of the total Na_2O) and the Na_2SO_4 from the vat liquor (*see Analysis*) separate out, forming what are called 'caustic salts.'

The 'finishing' stage takes the liquor at 1·4–1·5 sp.gr., settled clear of 'salts,' evaporates the balance of the water, amounting to 1–2 tons per ton 70 p.c., and heats the fluxed anhydrous caustic soda to full redness.

The 'concentration' is usually now performed in large cast-iron self-fired vessels called caustic pots (*see* Fig. 42). These vessels are made of metal specially selected for the purpose, and vary in size in different works. A common size is 10 ft. diameter by 6 ft. deep.

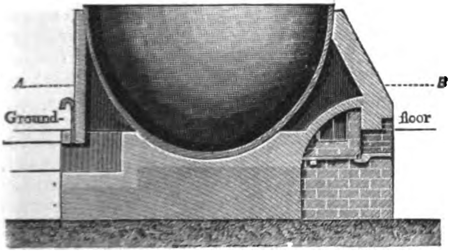

FIG. 42.

The setting of the caustic pot is a matter of importance, as the life of the pot, especially when used as a 'finishing pot' is largely dependent on the prevention of direct impact between a flame blast from the grate and the metal of the pot. It is usual, therefore, to protect the pot opposite the fireplace with a guard wall.

The pot is filled with liquor and fired. The loss by evaporation is made up by a constant slow stream of fresh liquor until the sp.gr. has risen to 1·4–1·5 as the case may be. The strength to which the liquor is taken in this stage depends on the strength of the caustic it is intended to pack. The fire is then drawn and the pot allowed to settle for some hours.

After settling the clear liquor is baled out with a large wrought-iron ladle cleverly balanced on the pot edge and worked with little exertion by an experienced man.

The clear liquor is either baled into an adjacent pot for the finishing operation or into a tank from which it is pumped to settlers where a further batch of salts settles out on standing and cooling.

The salts are fished out of the pot with a perforated ladle when all the clear liquor has been taken, and are drained as well as possible or jigged in a centrifugal machine.

The salts are a great source of trouble and expense.

The following analysis represents an average composition of the salts fished from the concentrating pots and jigged :—

	p.c.
Na_2CO_3	39
Na_2SO_4	20
NaOH	9

A small part of these salts is continually returned to the revolver to prevent too heavy an accumulation of Na_2SO_4 in the liquors, but the chief part is dissolved and mixed with the liquors feeding the causticiser and recausticised.

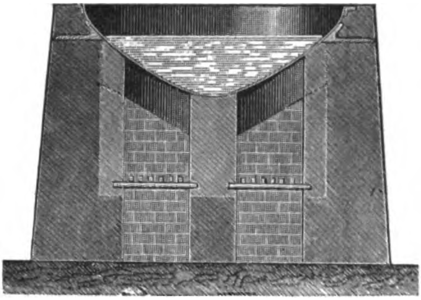

FIG. 43.

The total quantity of salts obtained per ton 70 p.c. caustic varies with the efficiency of the causticising operation between 5 and 7 cwts. Other methods of concentration have been suggested. One vessel frequently used, especially in former days, is the so-called boat pan, of which Fig. 43 is a cross section.

The boat pan is made of cast iron $1\frac{1}{8}$–$1\frac{3}{4}$ ins. thick, and its dimensions are about 12 ft. long, 8 ft. wide, 3 ft. 6 ins. deep.

Another method used for many years in some factories has been to concentrate the liquors up to a strength well short of the salting-point in Lancashire boilers, using the steam raised at low pressure for heating purposes. The difficulty is, however, that after a few years the boiler repairs become very heavy, and there is a great tendency for the rivet heads to shear off.

Recently multiple effect evaporation has been largely applied to caustic soda liquors with success.

Multiple effect evaporation consists in making use of the latent heat of the vapour evaporated from one liquid to generate vapour from a liquid with a lower boiling-point.

These liquors can either be really different liquids with different boiling-points, or, as in the case we are considering, the liquors can be the same, but by reduction of pressure the boiling-point of the second lot of liquor may be lowered sufficiently below the vapour temperature of the first lot to allow reasonable heat transference to take place.

The vapour raised from the second lot of liquor can be similarly used for evaporation of a third lot of liquor, whose boiling-point has been made still lower by a further reduction in pressure. The process can theoretically be repeated indefinitely, but actual multiple effect evaporators vary from two to six effects, *i.e.* the latent heat in the vapour originally evaporated is made use of from one to five times.

Fig. 44 shows a common form of an evaporator for use with caustic soda liquor in triple effect.

A. is the first effect.
B. is the second effect.
C. is the third effect.

The shells of these vessels are cast iron divided into three divisions by the tube plates *d*, *d'*.

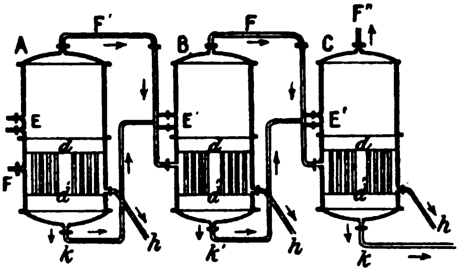

FIG. 44.

The tube plates themselves are connected by a number of wrought-iron tubes about 2 ins. diameter, and one central big tube all expanded into the tube plates top and bottom.

The space between the tube plates *d*, *d'*, through which the tubes pass, is the steam space and into it steam usually under pressure from boilers is admitted through F. In some cases the steam used in the first effect of an evaporator is exhaust steam.

In normal work the evaporator is filled with liquor through the inlet E to a few inches above the upper tube plate. The steam, therefore, is on the outside of the tubes, the liquor to be heated is inside them.

The weak caustic liquor is pumped into A by a pump not shown, and finally the concentrated liquor is drawn from C by a pump also not shown.

The steam raised from the liquor in A passes on through F' into the steam space of B, where it again raises steam from the liquor in B's liquor space. The steam raised in B passes similarly into C steam space, while the steam raised in C's liquor space passes away through F" to the condenser and vacuum pump not shown.

The speed at which work is done, *i.e.* the rate at which heat is transferred from the steam through the metal of the tubes to the liquor, depends first on the difference in temperature of the steam and liquors, and secondly on the circulation of the liquor in the liquor space. The liquor rises through ebullition in the small tubes from the bottom division of the evaporator to the top division, and then returns downwards through the big central tube. On the rapidity and uniformity in the different tubes of this circulation depends largely the heat transference per square foot of metal surface.

Another important type of evaporator is the Kestner so-called 'climbing film evaporator.' The essential point about this evaporator is that it contains a much smaller number of tubes than the type previously described, and that the liquor passes once only up the tubes in each effect. In this way the circulation is obtained by the direct action of the liquor-feed pump, and does not depend on the relative heating effects of small tubes and a large tube. The tubes in the Kestner evaporator are much longer, they are, however, about the same diameter, 2 ins., and are of wrought iron. In the older type the tubes are from 4 to 7 ft. in length, in the Kestner evaporator they are 23 ft. long.

Fig. 45 shows construction of a Kestner evaporator which explains itself.

Fig. 46 shows the arrangement of a Kestner four-effect evaporator, where A, B, C, D are the four effects, and E is the condenser. The general construction will be readily understood by comparison of Figs. 45 and 46.

The vessels *b*, *c*, *d*, *e* are save-alls or catch-boxes to collect any caustic liquor which escapes the baffles at the top of the evaporators and to prevent its loss.

The following is an example of the absolute pressure in the steam spaces of the four effects of such an evaporator, showing the gradual fall from effect to effect, on which the multiple evaporation depends.

Steam space	of	1st	effect	abs. press.	52 lbs.
„	„	2nd	„	„	35 lbs.
„	„	3rd	„	„	18⅛ lbs.
„	„	4th	„	„	7⅛ lbs.

Liquor space of the 4th effect abs. press. 1¾ lbs.

In such evaporators as have been described it is customary to concentrate the caustic liquors up to, but not beyond, the point at which salts begin to deposit, that is to about 1·3 sp.gr. For higher concentration an evaporator of the older type or the Kestner type, in either case with cast-iron tubes, is frequently used, either in single or double effect, more commonly in single effect. One way of working an evaporator of the older type is to fill it with the liquor at 1·3 sp.gr. and concentrate, adding more fresh liquor continuously to make good the loss by evaporation. Eventually when the evaporator is full of liquor at 1·4–1·5 sp.gr., as may be required, the bottom valve is opened and the whole contents, liquor and salts, allowed to fall into a settler or on to a filter bed. The salts are separated and the liquor is pumped to the store tanks feeding the finishing pots. With the Kestner type of evaporator, which holds practically no stock of liquor, the usual method of work is to start with 1·3 sp.gr. caustic liquor in a stock tank, and to circulate it round and round, through the evaporator and back to the stock tank, until the whole is up to 1·4–1·5 sp.gr.

Another method of work with the older type is to concentrate continuously, and not in batches, and to remove the salts from time to time from the bottom of the evaporator by means of a small closed vessel underneath it, which can be connected either with the atmosphere or the evaporator. Automatic arrangements have also been invented for continuous removal of the salts from the evaporators, and it is understood are used to some extent.

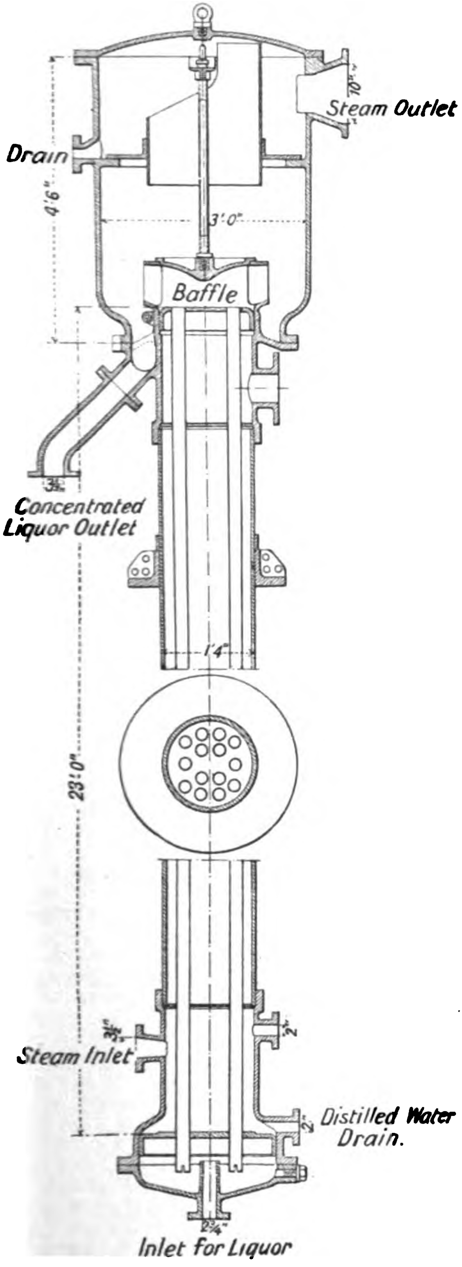

FIG. 45.

We have now the caustic soda solution as a settled liquor about 1·45–15· sp.gr. at 15°. This liquor is run into a caustic pot similar to that described above, for the concentration, and boiled.

A common way of working is to fill up two pots and concentrate until all the water is driven off, and then to bale the liquor from one into the other pot, and so make one full pot. The liquor, being of practically the same temperature in both pots, mixes without difficulty. At other times one pot is worked by itself and continuously fed with the 1·45 sp.gr. liquor. When the temperature of the pot increases and the flowing of this solution on to highly-heated, nearly anhydrous caustic becomes dangerous, it is usual either to sprinkle the liquor over the surface of the pot by running it through a perforated plate or ladle, or else to cover the pot with the loose wrought-iron lid which is, in any case, used as a cover during the last stage of the finishing. When all water is driven off, and the pot is full, the above-mentioned loose lid is put on and the pot gradually heated up until the molten NaOH in it is a just visible dull red colour.

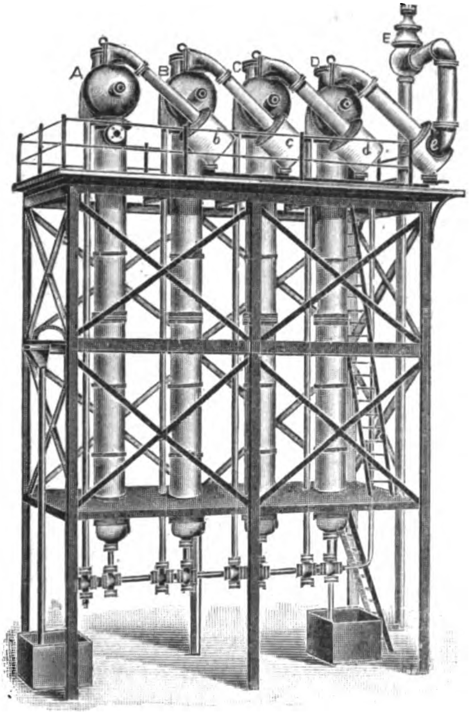

FIG. 46.

As caustic soda is usually sold at definite strengths, 60 p.c. Na_2O, 70 p.c. Na_2O, 76 p.c. Na_2O, &c., it is necessary to see how near the contents of the pot are to the required test.

A sample is, therefore, taken out on a spade or in a mould, allowed to set, and then tested in the laboratory. The caustic in the pot is usually found too high in test, and has to be reduced by the addition of a calculated and weighed quantity of well-dried salt (NaCl). The salt is added in small quantities through a lid in the sheet-iron cover mentioned above. The salt decrepitates badly when it comes in contact with the caustic soda, and causes considerable irritation to those near the pot by spreading finely-divided caustic through every outlet in the pot cover.

After addition of the salt the pot has to be again fired, as the fusion of the salt cools it considerably, and unless reheated it will not settle satisfactorily. The settling takes from 6 to 12 hours, and during this period the temperature gradually drops to about 330°. The quality of the caustic depends very largely on the settling of the impurities, which consist chiefly of ferric oxide, alumina, and silica. The clear settled caustic is then, after cooling to about 325°, ready for packing.

So far, one important point has not been dealt with, and that is the removal of the sulphide always present in Leblanc liquors. There has been much discussion as to the best way of doing this, and many expedients have been tried. Hargreaves proposed oxidation of the heated liquor by blowing air through it. In this case the oxidation was very slow and incomplete. Pauli advocated the addition of 'Weldon mud' (*see* art. CHLORINE, under heading *Weldon bleaching-powder process*) (Eng. Pats. 1306 and 1530, 1879). A detailed description of the oxidising process, both with air alone and by Pauli's process, has been given by Jurisch (Dingl. poly. J. 240, 55).

The removal of the sulphide by electrolysis was patented by Merle in 1875, and tried at Salindres; it was the subject of a later patent by Deacon, Hurter and Elmore (Eng. Pat. 800, 1885). Chance (Eng. Pat. 5920, 1885) decomposed the sulphides by a mixture of ferric and calcium hydroxides or carbonate, produced by precipitating ferric chloride with a large excess of lime or calcium carbonate.

The practically universal practice now is to remove the sulphide either by the addition of zinc oxide in the causticiser or by the addition of sodium nitrate to the finishing pots or both. The zinc oxide acts according to the equation:

$$ZnO+Na_2S+H_2O=ZnS+2NaOH.$$

Sodium nitrate probably acts in the finishing pot as follows:—

$$8NaNO_3+5Na_2S=5Na_2SO_4+4Na_2O+8N.$$

Metallic zinc readily dissolves in hot caustic soda liquor of about 1·13 sp.gr., and the solution so obtained is run into the causticiser during the causticising process.

The sodium nitrate is almost always now added in the finishing pot.

A common practice is to take out the greater part of the sulphide with zinc in the causticiser and then to finish the oxidation with sodium nitrate in the caustic pot.

It is important not to add the sodium nitrate until the pot temperature has become high, say between 420° and 470°. If the sodium nitrate is added before the pot is sufficiently heated, the caustic liquor has a great tendency to boil over.

The sodium nitrate is added until a small sample of caustic taken from the pot is only slightly blackened by a solution of lead acetate. When the whole of the sulphide is removed sodium manganate is formed in the caustic soda and colours the finished product green. If accidentally the limit is passed and on packing a blue or green colour is observed, it can be rectified by the addition of a small quantity of finely-divided sulphur.

By far the greater proportion of the caustic soda is packed solid in what are called caustic drums. The packing consists in ladling the molten caustic into the drums. It is usual to surround one side of the pot to be packed with a semicircle of drums into which the caustic is successively conveyed by a wrought-iron shute, which is moved from drum to drum.

The drums are cylindrical sheet-iron packages (*see* Fig. 47) with lap joints. The sheets are neither riveted nor welded, but rolled under pressure. In order to avoid leakage before packing it is necessary to cool the caustic down to a temperature near to the point of solidification.

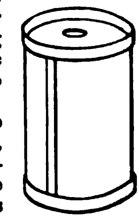

FIG. 47.

The clear liquid caustic in the upper part of the pot is packed, and then the residue called 'caustic bottoms,' which is a mixture of caustic soda, with the impurities settled out as above described, is baled similarly into drums.

The bottoms are of a deep-red colour, due to the ferric oxide they contain. The following is an analysis of a sample taken from a pot of 70 p.c. caustic:—

	p.c.
$NaOH$	63·2
Na_2CO_3	1·6
Na_2SO_4	2·0
$NaCl$	5·4
Na_2S	0·1
Na_2SiO_3	2·4
$Na_6Al_2O_6$	14·2
Fe_2O_3	10·9
	99·8

The 'bottoms' vary in strength between 53 and 63 p.c. Na_2O depending on the strength of the caustic from which they are made.

For many purposes the solution of 'caustic bottoms' after well settling is as efficient per unit of free Na_2O as that made from white caustic itself. The 'bottoms' are either sold at a reduced price as 'caustic bottoms,' or are dissolved, and the well-settled solution returned to the process.

As a package caustic drums are cheap, and from the fact that the caustic is a solid block, caustic in drums stows well for transit. On the other hand, caustic drums containing a solid lump of caustic weighing 6 cwts. are not readily handled by inexperienced hands. The best way to open a drum of caustic and break up the lumps is as follows: Lay the drum on its side with the seam upwards, and then crack the caustic by striking the drum along the seam once or twice for its full length with a sledge hammer. Insert a chisel under the seam and lever it open. The two ends should then fall off, and the caustic can easily be separated into pieces by simply inserting the chisel into the cracks and prizing them apart.

Caustic soda solution as such is sold to some extent usually in one of three strengths:—

90°Tw. containing	32·2 p.c. Na_2O
100°Tw. ,,	36·2 ,,
105°Tw. ,,	38·2 ,,

The solution is carried either in welded iron drums or in iron tank waggons.

Caustic soda is also sold in a form called 'detached,' that is thin sheets broken into small pieces and packed in casks.

The 'detached' caustic is usually made by baling a thin layer of the molten caustic on to heavy iron plates, where it almost immediately solidifies, and can be broken and packed. An apparatus to do this work was invented by Boulouvard (D. R. P. 34040).

Menzies (Eng. Pat. 4274, 1879) and Harned (Eng. Pat. 4677, 1883) described apparatus for grinding to a powder and sieving caustic soda. Caustic soda powder is produced to some extent for the market.

The commercial methods of analysis of caustic soda are given in Lunge's Technical Chemists' Handbook, p. 184.

Cream caustic. This is an inferior quality, formerly made, but now practically unknown. It was made by concentrating caustic liquor as described above until only about 12 p.c. water was left, and the caustic tested about 60 p.c. Na_2O.

The following are some analyses of commercial caustic soda of different strengths:—

		Huson and Hardwick		
	78 p.c.	77–78 p.c.	76 p.c.	70 p.c.
$NaOH$ . . .	98·1	96·92	95·4	86·6
Na_2CO_3 . . .	0·9	1·45	2·0	2·7
$NaCl$ . . .	0·4	0·58	1·5	6·9
Na_2SO_4 . . .	0·2	0·73	1·1	3·2
Na_2SiO_3 . . .	0·6	0·32	0·2	0·5
Fe_2O_3, Al_2O, and CaO	trace	trace	0·1	trace
Insol. . . .	—	—	—	0·2
	100·2	100·00	100·3	100·1

Production.—Of the total Na_2O charged into the revolver as salt-cake the average production in the form of finished caustic soda is about 85 p.c.

The greater part of the 15 p.c. loss is carried away in the black ash waste, partly as soluble soda through imperfect washing of the black ash in the lixiviating vats, and partly as insoluble compounds with the alumina and silica derived from the ash of the mixing fuel, the revolver lining, and the limestone.

Leblanc soda ash. As already mentioned, the original Leblanc process was introduced, and for many years worked primarily for the manufacture of sodium carbonate or soda ash.

For this purpose the same type of revolver was used, and black ash made as for the caustic soda manufacture just described.

The charge for the revolver was practically identical with the all-limestone charge given under caustic soda manufacture, viz.:

Salt-cake	55 cwts.
Limestone	56 ,,
Mixing slack . . .	22 ,,

The process of manufacture was the same as for caustic soda, up to and including the working of the lixiviating vats.

From the vats the liquor was pumped into settlers, where it was kept sufficiently warm to avoid crystallisation of the $Na_2CO_3,10H_2O$. A large amount of work was done on the purification of the vat liquor from iron in solution (chiefly as a double sulphide), from silica and alumina, and from ferrocyanides, but the usual practice was to take the well-settled vat liquor directly for concentration for ash. References to the papers and patents on the purification of vat liquor are as follows:—

Hurter (Chem. News, 39, 25), Carey, Gaskell and Hurter (Eng. Pats. 1161, 1881; 2939, 1879; and 5310. 1882), Newall and Sisson (J. Soc. Chem. Ind. 1887, 349), Mathieson and Hawliczek (D. R. P. 40987, 1887), Pauli (Eng. Pats. 1306 and 1530, 1879).

Figs. 34 and 35 (p. 41) show a black-ash revolver fitted with the top-heated pans adopted generally for the concentration of vat liquor for production of ash. In Fig. 34 *n*, *n'* are shallow open pans.

When properly settled, the vat liquor was run into the revolver pans *n*, *n'* (Fig. 34) until they were nearly full. The fire gases from the revolver passing over the pans concentrated the liquor, which was continually replaced by fresh liquor from the store tanks. Eventually the pans became full of a magma of crystals of Na_2CO_3,H_2O, which naturally formed first at the end nearest the revolver. It was the duty of the man in charge to work these salts to the back of the pans. When the operation was over the screw bolts were undone, the doors *p*, *p'* (Fig. 34) opened, and the salts raked out into the drainers *o*, *o'*.

The waste heat from the revolver passing over such a pan as is shown in Figs. 34 and 35, concentrated all the vat liquor made by the revolver separating the soda into crystals of fairly pure Na_2CO_3,H_2O in the drainer, and a liquor called red liquor, containing chiefly caustic soda, but also a little carbonate, and the main part of the impurities of the vat liquor. With a good vat liquor the mother or red liquor contained 20–30 p.c. of the total soda.

The composition of well-drained Leblanc pan salts was approximately as follows:—

Na_2CO_3	78·1
$NaOH$	0·3
$NaCl$	0·2
Na_2SO_4	0·4
Na_2SO_3	0·2
$Na_2S_2O_3$	0·3
Insol.	0·9
Water (by diff.) . . .	19·6

The salts after well draining were heated to redness in a reverberatory furnace when the non-carbonated liquor left in the salts was carbonated (sometimes sawdust was added to the salts to aid the carbonation), the water was driven off, and the small quantity of organic material present destroyed.

The soda ash then produced had a test varying in accordance with the draining of the salts from 50 to 57 p.c. Na_2O.

The following is an analysis of Leblanc soda ash made from well-drained salts:—

	p.c.
Na_2CO_3	96·5
$NaOH$	0·1
Na_2SO_4	1·1
$NaCl$	0·5
SiO_2	1·1
$Fe_2O_3+Al_2O_3$	0·5
MgO	0·2
	100·0

The operation of finishing soda ash is mechanical, but required continuous attention and work from the furnace man. In 1876 Mactear invented his mechanical finishing furnace, which was largely adopted. It consisted of a horizontal circular revolving hearth 20 ft. in diameter, made of boiler plate lined with firebrick. The following sketch indicates the general construction.

A purer form of sodium carbonate used to be made by dissolving the ash produced as above described in water—frequently with the addition of a little bleaching powder. The solution was well settled, and boiled down until it became a magma of crystals of monohydrate. The crystals were drained and furnaced, as in the case of the pan salts described above. The product so obtained was placed on the market as refined alkali.

RECOVERY OF SULPHUR FROM THE VAT WASTE.

The alkali waste was for many years a great nuisance, not only to the manufacturers, but to the neighbourhood of the factories producing it. The waste, under the influence of moisture and the oxygen and carbonic acid of the atmosphere, decomposed on the waste tips on which it was deposited, giving off a strong smell of H_2S, and contaminating all drainage of surface water which passed through it. As is evident from the description of the Leblanc soda process, this waste contains the sulphur originally burnt in the pyrites, and formed into sulphuric acid, and which then passed by decomposition with common salt into the sodium sulphate charged into the black-ash revolvers.

The obvious remedy for the nuisance as well as to avoid the loss of sulphur was to recover the sulphur from the waste, and for many years work was done and processes were invented to this end.

As the difficulty was finally solved by the Chance-Claus process, it will suffice to do little more than mention the principal processes previously invented and tried.

J. L. Bell in 1852, Ward 1862, Hewitt 1877, Kynaston 1885, Parnell and Simpson, Schaffner 1862, Mond 1862, Schaffner and Helbig 1878, proposed processes for this purpose.

The processes of Mond and Schaffner were both worked for some time on the large scale, and both depended on the partial oxidation of the CaS in the waste by the oxygen of the atmosphere which rendered a considerable proportion of the sulphur soluble in the form of CaS_2H_2, CaS_2O_3, and polysulphides. The solution so obtained on addition of hydrochloric acid deposited sulphur.

The Schaffner and Helbig process depended on the power of $MgCl_2$ to decompose CaS at the boiling-point, and the process was expressed by the following equations:—

1. $CaS+MgCl_2+H_2O=CaCl_2+MgO+H_2S$.
2. $CaCl_2+MgO+CO_2=CaCO_3+MgCl_2$.

A good account of this process is given by Chance in J. Soc. Chem. Ind. 1882, 266.

Other processes were those of Kraushaar, Dingl. poly. J. 226, 412, and Alkali Inspectors' Report, 1877–1878, 15 and 35; Opl's process, D. R. P. 23142; Miller and Opl process, Eng. Pat. 2334, 1884. The last-mentioned process was tried at the Rhenania Chemical Works (*see* Hasenclever, Chem. Ind. 1889, 434).

The Chance-Claus process depends on a reaction originally observed by Gossage, who, in 1837, patented (Eng. Pat. 7416, 1837) a process in which the calcium sulphide of the alkali waste was decomposed by carbon dioxide.

Gossage himself failed to make the process technically successful.

Since his time others, viz. Opl, Rawes (Eng. Pat. 1393, 1882), Claus (Eng. Pat. 5958, 1883), proposed processes depending on this decomposition.

The reaction is

$$CaS+CO_2+H_2O=CaCO_3+H_2S.$$

The difficulty was to find an outlet for the sulphuretted hydrogen. The earlier efforts to utilise fuel gases or gases from inefficiently-worked lime-kilns with a low percentage of carbon dioxide gave a gas too weak in sulphuretted hydrogen to burn by itself.

Chance made use of lime-kiln gas from a more efficiently-worked lime kiln, and also showed the way to get a gas richer in sulphuretted hydrogen by taking advantage of the fact that the first reaction on carbonating a slurry of alkali waste is

$$CO_2+2CaS+H_2O=CaCO_3+CaS_2H_2.$$

This means that at first a portion of the carbon dioxide is absorbed, but no sulphuretted hydrogen is given off. By allowing the inert gases present with the CO_2 to pass away during this stage of the process a double equivalent of sulphuretted hydrogen is liberated in the final stage for each equivalent of carbon dioxide.

$CaS_2H_2+CO_2+H_2O=CaCO_3+2H_2S$.

The Chance process is described in Eng. Pat. 8666, 1887, and in a lecture by Mr. A. M. Chance (J. Soc. Chem. Ind. 1888, 162).

The process was worked by Chance at Oldbury, and the gases enriched as above described contained about 33 p.c., or even 38 p.c. of sulphuretted hydrogen.

At first it was attempted to utilise the sulphuretted hydrogen as a source of sulphuric acid. The dilution and varying strength of the gas obtained, and a material drop in the price of sulphur in pyrites prevented this plan from succeeding economically. It was not until C. F. Claus published his patent 3608 of 1882 that Chance was able to develop his process on successful lines. Claus showed that it was technically possible to burn sulphuretted hydrogen under such conditions that the oxygen combined with the hydrogen only, and the bulk of the sulphur could be obtained at once in a marketable form.

The reaction utilised by Claus is represented by the following equation: $H_2S+O=H_2O+S$.

Further Claus patents are Eng. Pats. 5070, 5958, 5959, and 5960, 1883).

The following is a description of the plant and method of work usually employed at present in carrying out the Chance-Claus process.

Alkali waste as fresh as possible is mixed with water into a cream of 1·2–1·25 sp.gr. in an iron vessel fitted with a mechanical agitator. From the mixer the waste is usually run into another similar vessel passing on the way through a coarse mesh sieve to remove cinders and lumps. The second vessel acts as a store, and is also fitted with a mechanical agitator to keep the waste from settling.

From this store tank the cream of waste is pumped by a large ram pump into a shute which feeds the series of carbonators in which the waste is treated with carbon dioxide.

The carbonators are strong cast-iron vessels, arranged usually seven in a series. Fig. 49 shows a carbonator.

The carbonators are cast in two parts, as shown above, and are usually about 7 ft. in diameter by 15 ft. high. The fresh lime-kiln gas is pumped first into the nearly spent carbonator, and then on through the series to the freshly-charged cylinder at the other end.

The somewhat elaborate pipe connections necessary to enable any one cylinder to act as a leading cylinder are shown in diagram in the patent specification of Chance and Chance (Eng. Pat. 8666, 1887) and described in Chance's paper above referred to.

From the carbonators the issuing gas passes into a gas holder of considerable size. Chance's own gas holder was 50 ft. diameter with a 14-ft. lift and held about 30,000 cu. ft. of gas. The gas holder plays an important part in neutralising the fluctuations in the strength of the sulphuretted gas produced.

The working of the carbonators when the Chance enrichment process is used was described by Chance as follows:—

'At 7 P.M. Nos. 7 and 1 vessels (Fig. 50, where the discs represent the 7 carbonators of a series) were charged with fresh waste. The lime-kiln gases were pumped direct into No. 3 vessel, and then through vessels 4, 5, 6, 7, and 1 by opening all the intermediate taps; the useless gases escaped from No. 1 vessel into the exit main, and thence through a purifier into the air for a period of 1 hour 40 min.

'At 8.40 P.M. the sulphuretted hydrogen gases from No. 5 vessel were sufficiently strong for use, the calcium sulphide having mostly been converted into calcium sulphydrate; the sulphuretted hydrogen gases taken from No. 5 tested over 30 p.c. H_2S, while the useless gases from No. 1 tested only 1 p.c., thus showing that vat waste is a very efficient absorber of sulphuretted hydrogen.

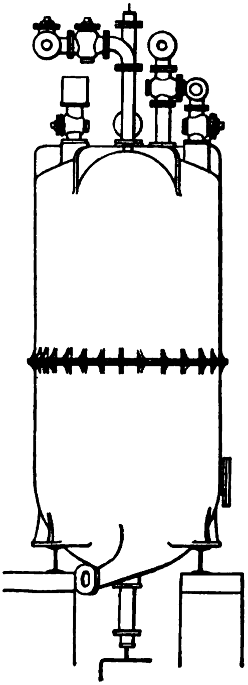

FIG. 49.

'The connections were then altered so that the H_2S gases could be taken from No. 5 to the gas holder. No. 2 vessel containing the partially carbonated waste was put into series, and the lime-kiln gases were now pumped through Nos. 2, 3, 4, 5, the sulphuretted hydrogen gases from No. 5 continuing to be taken to the gas holder for a period of 2 hours 25 mins., till 11.5 P.M. It was then found that the sulphuretted hydrogen gases were under 30 p.c., and that Nos. 2 and 3 were carbonated so thoroughly that water filtered from the mud did not tinge lead paper; Nos. 2 and 3 were, therefore, emptied and recharged.'

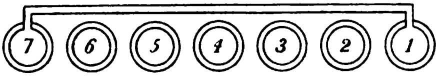

FIG. 50.

Much difficulty was experienced in working the enrichment process when the Chance plants were started, and it has been in most cases abandoned.

The following description shows, with the aid of the diagram Fig. 50, the method of working without enrichment.

No. 3 vessel is the leading carbonator into which the lime-kiln gases are first pumped, and is, therefore, the most nearly finished.

The gases pass from No. 3 through Nos. 4, 5, 6, 7, and 1 carbonators, No. 1 being the last charged, and from No. 1 to the gas holder.

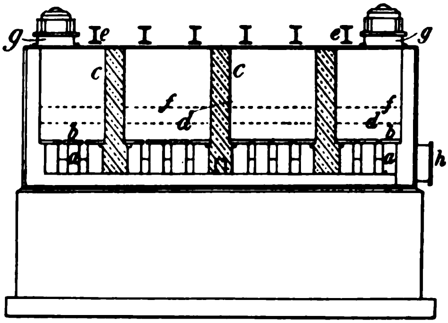

Fig. 51.

No. 2 carbonator is empty and ready for recharging.

The lime-kiln gases are pumped into No. 3 carbonator until the liquor in it no longer blackens lead paper. No. 3 is then finished, and is disconnected, No. 4 becoming the leading cylinder. No. 2, which has in the meantime been refilled, is connected up to the series, and becomes the final cylinder from which the gases pass to the gas holder under sufficient pressure (about 8 ins. water) to maintain the weight of the holder, and thus supply the pressure necessary to drive the gases on through the remainder of the plant.

It is usual to work the carbonators in 2, 3, or 4 sets of 7 vessels each in parallel, the number depending on the quantity of waste to be treated. By this means also the effects of the inevitable fluctuations in strength of the gas are materially reduced. Two such sets will deal with the waste from 300 tons salt-cake a week. It is obvious that the strength of the sulphuretted hydrogen produced, as well as the power consumed in pumping the lime-kiln gas through the carbonators, depends on the steady composition and percentage of carbon dioxide in the lime-kiln gases themselves.

Chance, in his lecture already referred to, gives great credit to Mond for his improvements in the working of lime kilns, and acknowledges the assistance received from him in this part of the process. Chance goes on to say, 'from the best-worked lime kiln, however, the escaping gases never contain on an average more than 30 p.c. CO_2.'

Further experience in working has somewhat increased the amount of carbon dioxide in lime-kiln gas.

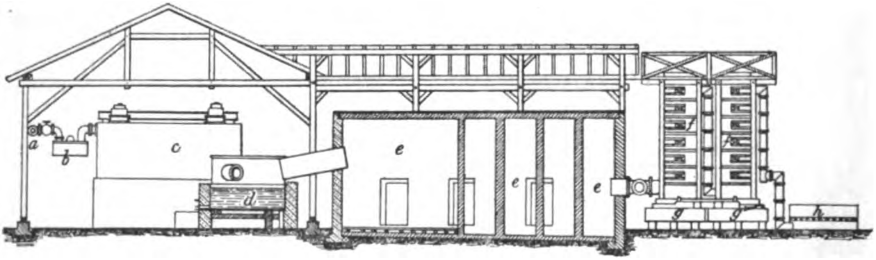

Fig. 52.

Two points about the lime-kiln gas in addition to its content of carbon dioxide are of great importance for this process.

1st. It is essential the gas should be practically free from oxygen, as oxygen in the gases pumped through the carbonators oxidises part of the sulphur in the waste to sulphite and thiosulphate, and prevents its recovery.

2nd. It is also important that the kiln gases should be practically free from carbon monoxide because the combustion of this gas together with the sulphuretted hydrogen in the Claus kiln liberates additional heat, which, as will be seen later, reduces the efficiency of the Claus kiln.

We have now in the gas holder when working with a lime-kiln gas containing 30 p.c. CO_2, a gas which :—

1st. When enriched by Chance's nitrogen elimination process contains 30–33 p.c. H_2S.

2nd. When not so enriched contains about 25 p.c. H_2S. These figures, of course, depend on the valves that regulate the distribution of the gases to the carbonators being in good condition and not leaking.

The gas from the gas holder then passes through a small vessel called a mixer, into which a carefully regulated supply of air is pumped by a blower or fan, and then through a water lute into the Claus kiln.

Fig. 51 shows a section of an average-sized Claus kiln.

The kiln is made of wrought-iron plates, and is 25 ft. in diameter by 9 ft. deep. It is brick-lined, and has a table of perforated tiles on which the packing is placed.

1st. About 12 ins. of broken fire brick.

2nd. 12 to 24 ins. of bog iron ore. Water lutes act as safety valves in case explosion takes place.

The mixed gases, *i.e.* the gas from the holder and the air, pass through the water lute *b*, into the top of the kiln above the packing. The gases pass downwards and out through the exit pipe *h* into a cast-iron receiver *d*, Fig. 52, which collects the bulk of the sulphur in a liquid form. The gases pass on from *d* into the brick chamber *e*, which contains several baffle walls, and in which almost all the remainder of the recoverable sulphur is collected as a coarse powder. The towers *f f* are very openly packed wooden scrubbers, which serve to collect an additional quantity of powdered sulphur. The Claus-kiln reaction is not complete, and always an appreciable proportion of the total sulphur passes away as sulphuretted hydrogen and sulphur dioxide with the exit gases.

From the exit *f f* it is usual to pass the gases through a furnace to burn the undecomposed sulphuretted hydrogen to sulphur dioxide before passing them on to the chimney.

Lunge states (Sulphuric Acid and Alkali, vol. iii. 11, 975) that of every 100 parts of sulphur entering the Claus kiln, 85 parts are recovered as refined sulphur and 15 p.c. is lost as sulphur dioxide and sulphuretted hydrogen, and polythionic acids.

This figure agrees very closely with the loss to be expected when the exit contains about 16 grns. S per cubic foot of gas, and the initial strength of the holder gas is 25 p.c. H_2S.

The bog-iron ore does not require renewal for many years, and has, in some cases, remained unchanged for over 20 years.

The working of the process is controlled by frequent tests of the exit gases from the Claus kiln for SO_2 and H_2S.

The method adopted is to obtain the total sulphur present, as SO_2 and H_2S, by drawing the gases through a known volume of standard iodine solution containing a little starch solution until the blue colour disappears, and noting the volume of gas aspirated.

The actual sulphur dioxide in the gases is determined by drawing a known volume of the exit gases through water containing hydrogen peroxide and then titrating the sulphuric acid formed with standard soda solution, using methyl orange as indicator. The difference between the total sulphur per cubic foot and the sulphur present as sulphur dioxide is taken as the sulphur present as sulphuretted hydrogen. The result in this country is usually expressed as grains total sulphur per cubic foot, and as grains sulphur as H_2S, and grains sulphur as SO_2 per cubic foot.

The air supply is adjusted in accordance with the relative proportion of sulphur as H_2S and SO_2. If the mixture of gases is thoeretically correct there should be obviously 2 H_2S to 1 SO_2, that is to say, if the total exit is 15 grns. sulphur per cubic foot the sulphur as H_2S should be 10 grns., and as SO_2 5 grns. per cubic foot.

In practice it is usual to work with as nearly equal quantities of sulphur as H_2S and SO_2 per cubic foot as possible in the exit gases.

The efficiency of the sulphur recovery depends entirely on the regularity of these tests, and the care with which the air supply is regulated. The completeness of the reaction is largely affected by temperature. An increase in the Claus-kiln temperature is always followed by an increase in the exit tests, and in the proportion, therefore, of sulphur not recovered.

A Claus kiln, as above described, will make 15–20 tons of sulphur per week, but with 30 tons per week the temperatures are too high, and the exit tests materially raised.

With 15 tons sulphur per week the temperature of the exit gases taken 1 ft. from the kiln outlet is about 290°C., which may be considered a good working temperature.

A number of attempts have been made to improve the Claus-kiln action by substituting other materials for bog-iron ore. Bauxite is recommended by the Chemische Fabrik Rhenania and Projahn (Eng. Pat. 3122, 1906), and is now largely used. The Rhenania in Chem. Zeit. 1908, 249, states as the result of several years' trial of this substance that there is a material reduction in the Claus-kiln exit tests.

Titaniferous iron ore (Eng. Pat. 25976, 1907) and manganese dioxide have both been tried, but so far as is known have not been successful.

Many efforts have been made to utilise the sulphur in the Claus-kiln exit gases, and it has been suggested :

1st. To burn the exit gases completely to sulphur dioxide and pass them along with pyrites gases into vitriol chambers (*see* Alkali Inspectors' 28th Report) and also through the Hargreaves' salt-cake plant (*see* Alkali Inspectors' 29th and 30th Reports). The 38th Alkali Inspectors' Report states that all attempts to deal with Claus-kiln exits in vitriol chambers have been unsuccessful.

2nd. To burn the sulphur completely to sulphur dioxide and utilise it for production of sulphur trioxide by the contact process (Carey and Heslop, Eng. Pat. 10317, 1900).

This process has not been adopted.

3rd. By absorption in milk of lime and by the slurry from the carbonators, *see* Alkali Inspectors' Reports for 1903 and 1904, and Heaton, Eng. Pat. 21217, 1890.

With the improved exits obtained by careful working, especially when the bauxite packing is used in the Claus kilns, no difficulty is experienced in turning the exit gases, after complete burning in a furnace, into the atmosphere through a chimney without raising the SO_3 test of the chimney gases above the statutory limit.

We have still to deal with the contents of the carbonators after removal of the sulphur. These are calcium carbonate and a weak solution of soda salts, chiefly sodium bicarbonate.

The following analyses of the calcium carbonate and the carbonator liquor are given by Chance.

Recovered calcium carbonate on dry	
Calcium carbonate	87·16
„ sulphate .	0·49
„ chloride .	—
„ silicate .	2·3
Magnesium carbonate	1·03
Sodium carbonate .	0·55
„ sulphate .	0·21
„ silicate .	1·42
Al_2O_3 . . .	1·47
FeS . . .	0·71
Coke . . .	2·06
Sand . . .	0·56

Water filtered from carbonator mud in grns. per gallon	
Soda (present as $NaHCO_3$) .	476·3
$CaCO_3$ . .	124·3
Total S . .	25·9
S as SO_4 . .	1·0
as hyposulphites	12·85
as sulphides .	Nil

The recovered calcium carbonate contains all the $CaCO_3$ used in the revolver mixing, and Chance originally suggested its use in the revolver over again. Mason (Eng. Pat. 21314, 1901) proposes to mould the Chance process waste into blocks before use in the revolver.

As far as is known, however, the carbonator mud is not used in the revolvers at present.

Another proposition has been to utilise the Chance waste for the manufacture of Portland cement.

Chance waste has been actually used for this purpose by Rigby (J. Soc. Chem. Ind. 1890, 254), and for many years by Chance himself.

The Chance waste is also an excellent form of calcium carbonate for agricultural purposes, and is largely used in the districts surrounding the Chance sulphur recovery plants (*see* remarks on this subject under *Caustic lime mud*, p. 48).

Chance also drew attention in his original paper to the value of the water filtered from the Chance waste for use on the black-ash vats, to which it would return quite an appreciable part of the total soda loss on the Leblanc process (*cf.* Eng. Pat. by Carey and United Alkali Co., Ltd., 7404, 1911).

With the discovery and practical success of the Chance sulphur recovery process the Leblanc process was materially cheapened, and a complete cycle of processes created.

The sulphur in pyrites passes through the following series of steps, finally emerging as a very pure form of commercial sulphur. The sulphur starts in the pyrites, passes into sulphuric acid, into sodium sulphate, into black ash as calcium sulphide, into sulphuretted hydrogen, and finally into pure sulphur. The production, of course, varies with the efficiency of the plant, but the sulphur recovered represents 65–80 p.c. of the sulphur in the salt-cake charged into the revolver.

2. The Manufacture of Soda by the Ammonia Soda Process.

The first germ of this process, which has quite revolutionised the alkali trade, is, as usual, found to have originated in various quarters. A German chemist, Vogel, is said to have known the reaction as early as 1822, and a Scotch chemist, John Thom, seems to have actually made some soda, in a crude way, by that process in 1836. Mond has definitively disposed of the attempt made by several French *savants* to claim the merit of the invention of this process for their countrymen, Schloesing and Rolland. Quite recently a claim has been set up for Fresnel, who is said to have made soda from common salt and ammonium carbonate in 1811, according to some hints found in recently-discovered private letters; evidently he did not meet with much success, as nothing came of his attempts. It is beyond doubt that the real history of the ammonia process dates from June 30, 1838, on which day Harrison Grey Dyar and John Hemming, both chemists residing in London, patented a process embodying all the principal reactions now carried out. This was done even more clearly in an additional patent, taken out in France on May 18, 1840, on their behalf, by Delaunay, where the use of a current of carbonic acid is first mentioned. A number of patents by other inventors followed, among which that of Gossage (1852) is remarkable, and those of Schloesing and Rolland (1854 and 1858) have become best known by the detailed description they gave in 1868 of their process.[1] Although their apparatus was very ingenious, it must have been deficient in important portions, for they could not make their works pay, and the reasons given for their abandoning the process are quite inconclusive.

In many other places works had been erected for making ammonia soda: by Dyar and Hemming, in Whitechapel; by Muspratt, at Newton; by Gossage and Deacon, at Widnes; and by a number of French and German manufacturers. But although we find every feature of the now-successful processes in these older establishments, there was always something or other wanting, and especially the loss of ammonia seems to have been too great, so that at that time the ammonia soda could not compete with the Leblanc soda even in localities where the loss of the hydrochloric acid would not have been of much consequence at that time. Apparently, about 1860, nobody manufactured ammonia soda, and the failure of all previous attempts in that direction had evidently discouraged nearly all chemists.

It was reserved to Ernest Solvay, of Brussels, to find the solution of that long-pursued problem. His first patent dates from 1861, but the process as we know it now is first described in his English patent of September 12, 1863, followed by many others in 1872, 1876, 1879, and later on. His works at Couillet, in Belgium, were started in 1863, and soda made there was exhibited in Paris in 1867 without exciting much attention. But since 1872 his triumph was assured, and has given rise to a host of other inventions, most of which have again passed into oblivion, while a few have stood the test of practice; so that ammonia soda is now manufactured not merely by Solvay's processes (which certainly furnish the largest share), but by several other independent and partly secret processes.

The reactions on which the ammonia soda process is based are the following:

(1) $NaCl+NH_3+CO_2+H_2O=NaHCO_3+NH_4Cl$;
(2) $2NH_4Cl+Ca(OH)_2=2NH_3+CaCl_2+2H_2O$;

that is, sodium chloride is treated with ammonium bicarbonate, either directly or indirectly, in successive stages—namely, first by ammonia and then by carbonic acid. If this treatment takes place at a low temperature, it leads to the precipitation of sodium bicarbonate, this salt being sparingly soluble in a solution of ammonium chloride. From sodium bicarbonate the normal carbonate can be obtained by heating. The mother-liquor, containing ammonium chloride, is treated with caustic lime, and the ammonia is thus recovered, calcium chloride remaining behind as a waste, but inoffensive, product.

Simple as this statement appears, a great amount of research has been devoted to working out the theory of the reactions.

From the nature of the case much of this work has not been made generally known, and is not, therefore, available, but the following names and references indicate a large part of what has been published. Alex. Bauer, Ber. 1874, 292; Grünsburg, *ibid.* 1874, 644; Honigman, quoted by Landolt in A. W. Hofmann's Vienna Exhibition Report, 1875, 1, 452; Schreib, Zeitsch. angew. ---

[1] Ann. Chim. Phys. 1868, 64, 1.

The work done has practically all been from the point of view of the physical chemist, and consists in attempts partly experimental and partly in purely theoretical applications of the so-called 'Phase Rule,' to determine the conditions of concentration and of temperature under which the reversible reaction

$$NaCl+NH_4HCO_3 \rightleftarrows NaHCO_3+NH_4Cl$$

is most complete.

These conditions are in practice liable to modification from the practical necessity of obtaining the precipitate of sodium bicarbonate in such physical condition that it leaves the carbonators readily and can be efficiently washed.

The reactions of the process are as follows :—

1. The manufacture of caustic lime

$$CaCO_3=CaO+CO_2.$$

2. The production of ammoniacal brine by solution of ammonia in saturated brine.

3. The carbonation of ammoniacal brine

$$2NaCl+2NH_3+2H_2O+2CO_2 =2NaHCO_3+2NH_4Cl.$$

4. The calcination of bicarbonate

$$2NaHCO_3=Na_2CO_3+H_2O+CO_2.$$

5. The regeneration of ammonia

$$2NH_4Cl+CaO=CaCl_2+H_2O+2NH_3.$$

The total cycle of operations is the resultant, *i.e.* the algebraic sum of all the foregoing reactions, and it can be summed up in the following equation :—

$$\underset{\text{(Solid)}}{CaCO_3}+\underset{\text{(Dissolved)}}{2NaCl}=\underset{\text{(Solid)}}{Na_2CO_3}+\underset{\text{(Dissolved)}}{CaCl_2}-5200 \text{ Cal.}$$

Practically, however, the whole cycle of operations cannot be considered together, but each of the five stages or reactions has thermally to stand alone, and not one can be technically performed without consumption of fuel.

Equation 3, representing the actual central reaction of the ammonia soda process, is thermally almost a balance.

$$\begin{array}{ccc} (NaCl)+(NH_4HCO_3) & = & (NaHCO_3)+(NH_4Cl) \\ 96{\cdot}2+205{\cdot}6 & & 227+72{\cdot}7 \\ 301{\cdot}8 & & 299{\cdot}7 \end{array}$$

The equation represents, therefore, a typical case of a reversible reaction, and the amount of change of sodium chloride into sodium bicarbonate depends on the relative quantities or active masses of the four salts.

For instance, Bradburn (J. Soc. Chem. Ind. 1896, 882) succeeded by a ten-hours' treatment with a current of air at 21°C. in clearing a sample of 'Tower liquor' filled with suspended sodium bicarbonate, *i.e.* the sodium bicarbonate had been completely reconverted into sodium chloride by the ammonium chloride in the liquor, and the ammonium carbonate formed had been carried away by the air. This demonstrates the importance of the presence of excess of ammonium carbonate to protect by 'mass' action the sodium bicarbonate from decomposition by ammonium chloride.

Another determining factor in directing the course of interaction between the four salts $NaCl$, NH_4HCO_3, $NaHCO_3$, and NH_4Cl, is temperature. A moderate reduction of temperature, by favouring the precipitation of sodium bicarbonate, and therefore its removal from reaction, increases, in accordance with the theory of mass action, the formation of sodium bicarbonate.

A rise in temperature or a reduction of pressure by increasing the volatilisation of the only volatile member of the group, ammonium bicarbonate, tends to decrease the amount of sodium chloride converted in sodium bicarbonate.

The situation is, however, complicated by the phenomenon that by too great a reduction in temperature ammonium bicarbonate is thrown down with the sodium bicarbonate, and also that too low a temperature produces an unfavourable physical condition of the sodium bicarbonate precipitate, which makes the subsequent washing process in extreme cases practically unworkable. These facts limit the possible reduction of temperature within a small range, and nothing remains but to promote the conversion of sodium chloride into sodium bicarbonate by influence of mass action, which is in practice effected by working with a considerable excess of sodium chloride and ammonium bicarbonate, assisted by the sparing solubility of sodium bicarbonate in strong solution of sodium chloride.

This fact emphasises the importance of working the process with a sodium chloride solution as concentrated as possible.

The process.—The general nature of the ammonia soda process, and such theoretical considerations as are given above, are well known, and have been public knowledge for a considerable time. The actual working conditions in the successful ammonia soda works have, however, been kept to a large extent secret. A great number of patents, almost entirely for apparatus, have been taken out, but which are actually used, and with what modifications on the patent specification description, it is impossible to say.

Generally speaking, success in this process depends, subject to careful working in accordance with the theory of the reaction outlined above, on absolute regularity in work, and on the perfection of, and accurate interworking of the mechanical arrangements used, for the different stages of the process.

It is, in fact, the development of the mechanical and apparatus side of the ammonia soda process which converted the failure of the older workers and the pioneers of the process into the success of to-day's great industry.

We give below, however, as far as is public knowledge, the working details and apparatus used.

The raw materials required are, of course, salt (NaCl), limestone, ammonia, and fuel.

Salt. From the considerations detailed above it is clear that more than the theoretical quantity of sodium chloride is required. The actual excess of sodium chloride over that theoretically equivalent to the sodium carbonate produced is 30–40 p.c. If the sodium chloride has to be used as rock-salt, and conveyed any considerable distance, the charge for salt per ton of ash produced becomes an extremely serious item.

In practice, therefore, the chief factories for producing ammonia alkali have been established on sites where the factory can pump its own salt as a saturated brine from salt beds in its neighbourhood, or can receive its supplies of brine through a pipe line.

When the brine is pumped direct by the factory itself the actual cost per ton of salt so raised may be as low as 6*d*. per ton (*see* Lunge, Sulphuric Acid and Alkali, iii. 35).

Brines vary in composition within wide limits, but according to Bradburn (J. Soc. Chem. Ind. 1896, 880), 'A good brine for the ammonia soda process should contain about 300 grms. sodium chloride per litre, and as little as possible of lime and magnesia. Of these the magnesia is the more troublesome.'

Bradburn gives the following analyses:—

—	A good brine. Grms. per litre	Cheshire brine. Grms. per litre	New York brine. Grms. per litre
$NaCl$ . .	298·0	295·0	298·0
$CaSO_4$ . .	4·0	5·0	4·4
$CaCl_2$ . .	1·0	0·93	2·35
$MgCl_2$ . .	0·3	2·6	0·65

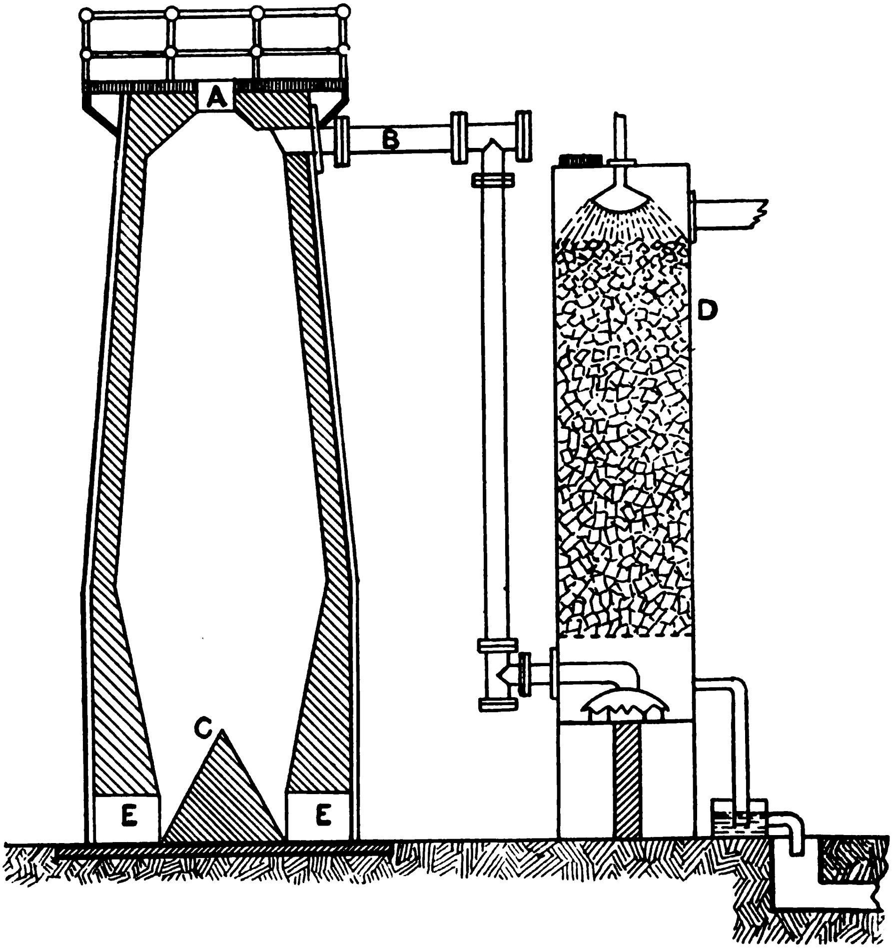

FIG. 53.

Limestone. The quantity of limestone used by the process is in considerable excess of that theoretically required and amounts to 20–24 cwts. per ton of soda ash. It is therefore of considerable importance that the ammonia soda factory should, if possible, be within a short distance of quarries of a clean limestone free from clay and low in magnesium carbonate.

We will take the actual processes in the order of the equations given in the early part of this article.

Process 1. The manufacture of caustic lime: $CaCO_3 = CaO + CO_2$.

The limestone is invariably burnt by heating with coke in tall vertical kilns.

The limestone, usually broken into comparatively small pieces, together with the necessary quantity of coke, is charged into the top of the kiln, and the burnt lime is drawn out from the bottom.

Figs. 53 and 54 represent types of lime kilns.

The kilns vary considerably in size, but are usually 30–40 ft. high and 7–10 ft. diameter.

In Fig. 53 A is the charging hole through which the limestone and coke are dropped into the kiln. The evenness with which the comparatively small quantity of coke is mixed with the larger quantity of limestone plays a very important part in determining the extent to which the quantity of coke can be reduced, and consequently the strength of the carbon dioxide obtainable in the gases.

It is necessary, therefore, to pay continual attention to this important point.

The burnt lime is drawn out through a number of openings at the base of the kiln, of which E, E are two, and through which the air required for the combustion of the coke enters the kiln.

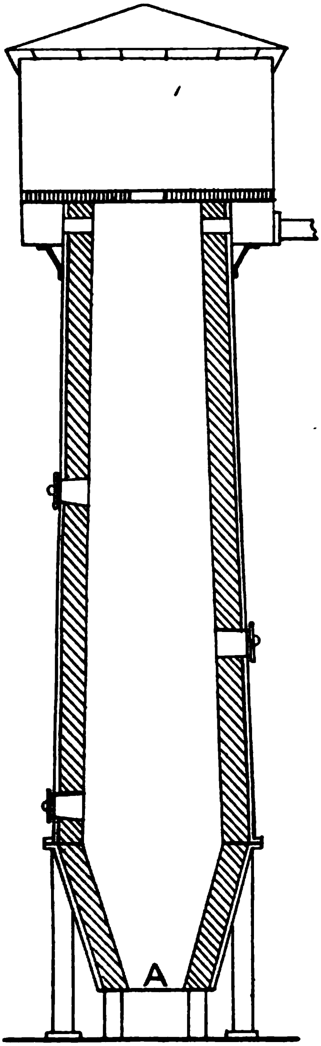

Fig. 54.

C is a brickwork cone called a 'dumpling,' which serves to prevent the accumulation of dust in the centre of the kiln, where it could not be got at for removal, and which assists in the distribution of the air to the centre of the kiln.

B is the gas exit pipe connecting the kiln to the coke packed scrubber D, of which there are usually at least two in series to each lime kiln.

Fig. 54 represents another type of kiln in which the charge is usually supported by iron bars at A, and from which the burnt lime is allowed to fall from time to time either on to the ground or into a bogie placed underneath to receive it.

According to Lunge such kilns as those described above will burn 200–300 tons of limestone a week.

The important point in lime kiln work for the ammonia soda process is to obtain as high a percentage of carbon dioxide in the gases leaving the kiln as possible, combined with a reasonably well burnt lime.

The percentage of carbon dioxide depends on the quantity of coke used, because the carbon dioxide evolved by the limestone on heating is mixed with the products of combustion from the coke, which contain only 20 p.c. carbon dioxide. Hence the smaller the quantity of coke the higher the strength of the kiln gas. The following calculated figures show approximately the relation between the coke used and the percentage of carbon dioxide.

Kiln gas strength	Cwts. coke per ton lime
31 p.c. . .	6 cwts. coke
35 p.c. . .	4·5 ,, ,,
40 p.c. . .	3·0 ,, ,,

These figures assume that the limestone is completely burnt, and the gases contain neither oxygen nor carbon monoxide, which is never the case in actual work.

The great object being to conserve heat the kiln is worked as far as possible on the regenerative principle. The cold air entering the bottom of the kiln is heated by the burnt lime as it drops from the zone of maximum temperature to the bottom of the kiln, and the hot gases, as they rise above the combustion zone, yield their heat to the cold limestone and coke freshly charged into the top of the kiln.

Radiation losses are kept within reasonable limits by the thickness and construction of the kiln walls, and are materially reduced, of course, by a high speed of work.

The actual figures published for the strength of the carbon dioxide obtained in various factories vary within wide limits.

Chance (J. Soc. Chem. Ind.) gives for good work an average test of 30 p.c. carbon dioxide. Jurisch in Chemische Industrie, 1910, 392, gives the average strength as 30–31 p.c. Again in other factories for many years an average strength of 32–33 p.c. has been obtained. Lunge describes in Sulphuric Acid and Alkali, vol. iii. 65, the Khern lime kiln, improved by Faber, which is much used in the German sugar works (Centr. für Zucker fabr. 1901, 532), and which is stated to require 5 to 7 p.c. only of coke on the weight of limestone, and to give a gas containing 40 p.c. carbon dioxide. This is a high test, but, as no aid is afforded by theory to tell us what is the highest percentage of carbon dioxide obtainable in lime kiln gases, still higher tests may be possible.

The lime kiln gases after leaving the lime kiln require to be cooled and well scrubbed to remove dust, tarry material, and sulphurous acid, as completely as possible.

A common form of scrubbing plant is two or more coke-packed wrought- or cast-iron towers, about 30 ft. high by 5–8 ft. diameter, connected in series and down which a stream of water is run.

The lime drawn from the bottom of the kilns should be well burnt. Whatever calcium carbonate is left unburnt is, however, recovered in the lime pot, and is returned and charged a second time into the kiln with the fresh limestone. A factory producing 500 tons ammonia soda a week would require three such kilns as those described.

2. *The production of ammoniacal brine.* As mentioned above, the impurities in the brine, viz. the lime and magnesia salts, are a source of trouble in the pipes and connections unless previously removed. In practically all cases now this purification takes place simultaneously with the absorption of ammonium carbonate which throws down the lime salts. The purification has been done as a separate process by the addition of sodium carbonate and lime, but that is not the general practice. Occasionally the soda crusts from the cleaning of the towers and sweeping of dirty soda from the floors are used, but as a rule the purification is done as stated above by the ammonium carbonate in the ammonia used for ammoniating the brine, and the scales produced by the hard crystalline magnesium salts are mechanically cleaned from the pipes and connections at intervals.

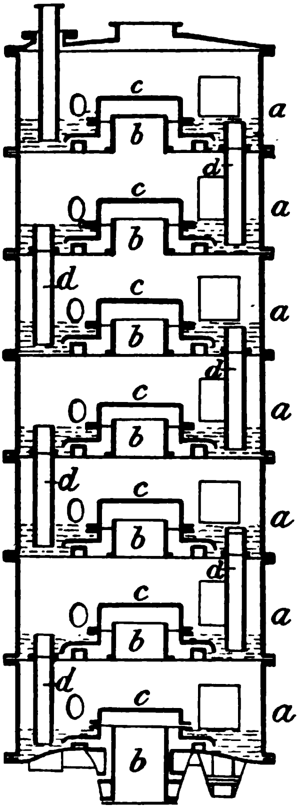

FIG. 55.

The fresh brine entering the works goes into a vessel called a tower washer where it serves to scrub the ammonium carbonate mechanically carried over from a battery of Solvay towers.

A common type of tower washer is shown in Fig. 55 which consists of a series of cast-iron rings *a, a,* &c., divided by plates with central holes *b, b,* &c., covered with a cup or mushroom *c, c, c,* &c., which has serrated edges and often is perforated with small holes. The brine running down the tower accumulates on each plate until it is sufficiently deep to run down the overflow pipe *d, d, d,* &c., to the shelf below. The gases travelling upwards pass through the central hole of each shelf under the mushroom, and then bubble out round the serrated edge through the brine. The fresh brine entering the top of the tower naturally meets the gases from which the ammonia has practically all been absorbed. This system of bringing gases and liquids into contact in towers divided into compartments by a number of shelves with a central hole for the passage of the gases covered with a mushroom, the serrated edges of which are luted with the liquor, is characteristic of the Solvay ammonia soda process, and is used in various parts of the process. It is the same idea as that in the Coffey's still for the distillation of alcohol. The lime in the brine is to a large extent precipitated in the tower washer by the ammonium carbonate absorbed. The calcium carbonate does not, however, settle out, but remains in suspension in the liquor agitated by the current of gas and travels on with the brine through the ammonia absorber or ammoniating vat to the vats or store tanks where it settles out.

In consequence of the calcium carbonate remaining in suspension the tower washer runs for many months without necessity for cleaning. From the tower washer the brine runs into the ammonia absorber or ammoniating vat, in which the brine is saturated with ammonia from the stills.

The ammonia absorber is usually a cast-iron vessel made up of three or more cast-iron rings similar in principle to the tower washer just described. Fig. 56 shows one type of absorber: *a, a, a,* are the shelves, *b, b, b,* mushrooms, as described in the case of the tower washer, *c, c, c,* the pipes through which the liquor overflows from each shelf to the one below.

The bottom of the absorber is conical and is fitted with a discharge pipe and tap through which the sludge that settles out may from time to time be drawn. Another type of absorber is shown in Fig. 57, and is a vessel built up of several cast-iron rings, frequently about 8 ft. diameter, but without the shelves shown in Fig. 56. In this case the gases enter by the pipe A, and are distributed by the single mushroom B. The bottom of the vessel again is conical to permit the occasional blowing off of slurry. The ammoniacal gases from the stills are drawn through the absorber by a vacuum pump, which, as a check on ammonia escape, sends on the gases it has exhausted through an additional small tower or washer generally called the vat washer. The vat washer usually receives the brine coming from the tower washer and only in very exceptional cases is fed by fresh brine. By using the tower washer brine a natural and continuous circuit is established for the flow of the brine through the process.

Heat is generated in considerable quantities in the absorber by the solution of ammonia and cooling is necessary. This is done either by an external spraying with water or preferably by internal cooling pipes.

The ammoniacal brine should be cooled in the absorbers, and should not at any rate exceed 30°C.

The gases, however, entering the absorbers from the stills should be maintained at about 70° in order to prevent blockages of the ammonia main by the formation of ammonium carbonate crystals.

Deposits of ammonium carbonate and of carbamide are thrown down and block up the pipes and connections. It is, therefore, a very difficult matter to reduce the steam in these gases to a low enough point to avoid excessive dilution of the brine. At the best these gases can only enter the brine saturated with moisture at 70°–75°.

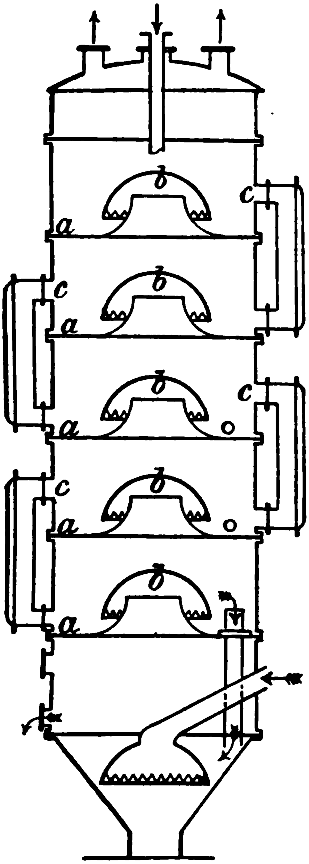

Fig. 56.

Naturally the strength of the brine solution is a very important point. The output of the plant depends on it.

A good saturated ammoniacal brine should contain 27–28 p.c. sodium chloride and 6–7·5 p.c. ammonia. The theoretical equivalent of 27 sodium chloride is 7·8 ammonia, so that nearly equal equivalents are used. The following figures, determined experimentally by Schreib, indicate the variation in the completeness of the carbonation reaction with the variation in the proportion of $NH_3 : NaCl$.

Original solution		Carbonated solution				
P.c. NH_3	P.c. NaCl	P.c. NH_3	P.c. NaCl	P.c. NH_4Cl	P.c. decomposition	Grams Na_2CO_3 per litre
3·4	29·6	0·6	20·1	9·1	33·1	90
6·6	27·3	1·3	10·2	16·1	63·1	146
7·2	27·2	1·3	9·3	17·9	67·8	154
8·9	25·8	1·3	7·4	18·8	73·6	168
13·2	23·5	2·9	9·5	14·2	62·0	132

The large scale results are not identical with the laboratory results, which are comparative only between themselves.

The large scale decomposition with the normal ammoniacal brine given above should exceed the maximum figures given by Schrieb, and is stated to vary between 73 and 78 p.c.

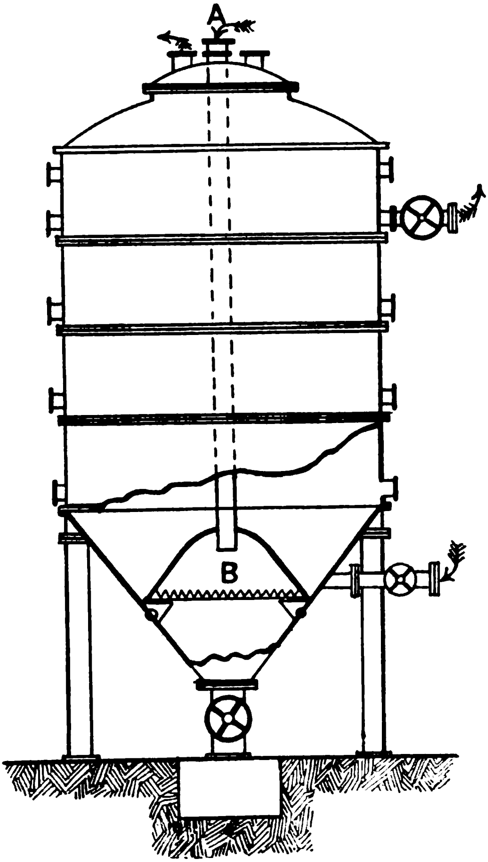

Fig. 57.

The presence of ammonia and ammonium carbonate decreases the solubility of sodium chloride in water.

Lunge gives the following figures for the solubility of sodium chloride in water in the presence of ammonia at 15°.

P.c. NH_3 by vol.	P.c. NaCl by vol.
—	31·78
3·5	29·5
5·0	28·6
6·0	28·0
6·5	27·7
7·0	27·4
7·5	27·1
8·0	26·8
10·0	25·4
12·0	24·1

The bulk of a brine solution on addition of the 6–7½ p.c. ammonia required for the carbonation process increases by 9 p.c.

From the absorber the ammoniacal brine runs in a continuous stream into the 'vats.'

The vats are frequently cast-iron vessels built up in four rings on a cone-shaped bottom piece supported on columns exactly similar to the vessel shown in Fig. 57 without the gas delivery pipe A and mushroom B. A common arrangement is for the ammoniacal brine to run in a continuous stream through two of these vessels in series and from there into one or other of two more similar vessels which act as measuring tanks, one being emptied while the other is filling. The mud, consisting chiefly of calcium carbonate mixed with a considerable proportion of ferrous carbonate and hydrate, settles out mainly in the two leading vats and is drawn off through the discharge pipes at the bottom of the cones at regular intervals. A further but small quantity of mud settles out in the measuring vats.

The mud is usually mixed with other liquors (from the filters, for instance), and pumped to the ammonia stills where the ammonia carried away with the liquid in the mud is recovered.

The 'tower washer,' ammoniating plant, 'absorber' and vats are usually erected at such heights that the brine from the 'tower washer' will flow by gravity into the 'absorber' and then on to the 'vats.' In this way the brine is only pumped once. The absorber, vats and ammonia still are usually all included in the same vacuum circuit, the exhaust gases from which pass through the vat washer or final small scrubber mentioned above to ensure recovery of all ammonia.

As has been mentioned, dilution of the brine is bound to take place to some extent through the uncondensed steam entering the absorbers with the gases from the stills.

It was formerly the custom to make good this dilution by the addition of solid sodium chloride in the carbonating tower itself. This, however, is generally discontinued and either the cooled ammoniated brine is strengthened by passing through a separate closed vessel containing salt, on its way from the coolers to the carbonating towers, or it is pumped direct to the carbonating towers at the strength at which it leaves the absorbers.

The well-settled ammoniacal brine has now to be cooled as far as possible before being carbonated, and this is generally done in a series of 6-inch cast-iron pipes arranged in tiers one above the other. The pipes are either submerged in a water tank or cooled by a stream of cold water flowing down and over them. The coolers are arranged in pairs or trios so as to permit of cutting out a cooler for cleaning. For instance, if there is a set of three coolers, two of them will at any time be working, the third will be disconnected for cleaning. Very troublesome crusts are formed in these coolers, which have first to be steamed to soften them and then chipped out.

Reinitzer (Zeitsch. angew. Chem. 1893, 446) gives the composition of these crusts as Na_2CO_3, $MgCO_3$, NaCl. Pennoch, Chem. Trade Journal, 1893, 191, found crusts in the coolers of the composition $MgCO_3$, Na_2CO_3.

In the great majority of the ammonia soda works the central reaction of the process, viz. the carbonation of the settled cooled ammoniated brine is carried out in a tower originally designed by Solvay (patented in 1872), and which is therefore called the 'Solvay Tower,' and is the most important apparatus in the process.

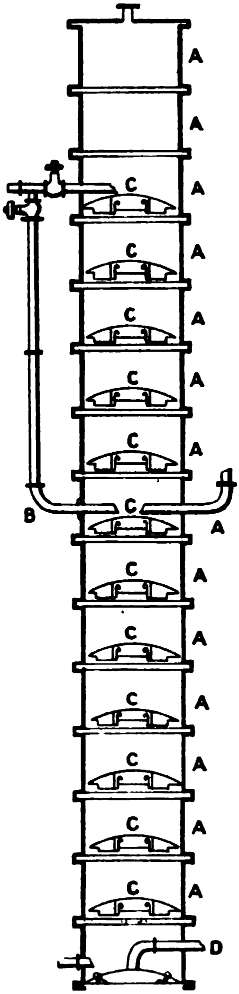

FIG. 58.

Fig. 58 represents a Solvay tower, which consists of a number of cast-iron cylinders A, A, &c., approximately 3 ft. 4 ins. deep by 5 ft. to 8 ft. diameter. The bottom of each cylinder is formed by a cast-iron disc with a central opening not shown in the drawing, about 1 ft. 4 in. diameter. Over the opening is supported a perforated cover C, C, &c. (shown in detail, Fig. 59), about 6 inches less in diameter than the cylinder itself. The actual number of these cylinders in a tower varies usually between 15 to 25 with the practice of the different factories.

The ammoniated brine enters the tower by the pipe B under pressure, and is maintained at a level 6 ft. to 10 ft. from the top of the tower. The object of feeding the fresh liquor part way down the tower, to which Solvay attaches great importance, is to avoid excessive volatilisation of ammonia, which if driven out of the tower is, of course, useless for the reaction.

The carbon dioxide gases from the lime kiln, enriched, as will be described later, by the carbon dioxide obtained from the first roasting of the bicarbonate, are compressed to sufficient pressure (varying with the height of the towers from 1½ to 2½ atmospheres) to overcome the resistance of the Solvay tower and the subsequent washers, and enter the tower through the pipe D. A constant feed of ammoniated brine is pumped into the tower at B, and a constant stream of carbon dioxide is pumped into the bottom of the tower at D.

The gases travelling up through the openings in the bottom plates of the cylinders are split up by the perforated covers, and, part passing through the perforation in the mushrooms, and part bubbling round the edges of the mushrooms, come in a comparatively fine state of division in contact with the liquid in the tower. With the assistance of the constant agitation the stream of ammoniated brine carries down with it practically all the bicarbonate precipitated from it.

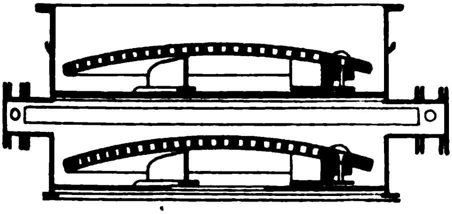

FIG. 59.

The increased partial pressure of carbon dioxide in the gases at the bottom of the tower, due to the pressure, increases the speed of the reaction.

One of the most important technical points in the working of the Solvay towers is, as indicated above, the regulation of temperature. The absorption of carbon dioxide by aqueous ammonia liberates considerable quantities of heat, the larger part of which is produced in the formation of the mono-carbonate $(NH_4)_2CO_3$.

To avoid this, in some cases a supplementary Solvay tower has been added in which the greater part of the mono-carbonate is produced.

In other cases part, or the whole of the ammonia (NH_3) is mono-carbonated in an intermediate vessel of the type of a tower washer placed between the ammonia vats and the feed pump to the Solvay towers, and which is supplied independently with carbon dioxide from the lime kiln.

Bradburn thus describes the working of a Solvay tower.

'It was stated that the carbonating of the vat liquor is made only nearly complete: this is of course completed in the carbonating tower. In the upper rings, where the liquor is warmer, the crystals of bicarbonate of soda begin to form; if the tower is cooled too much a small, fine-grained, muddy bicarbonate is made which is very difficult to wash free from salt, and which is very difficult to dry. On the other hand, if the liquor is not cooled enough the production is diminished. But at a certain temperature and point in the tower for this temperature, both found by experience, a coarse-grained bicarbonate is obtained, which washes quickly and well, and which when taken from the filters and crushed in the hand no water is squeezed out of it; this kind dries in calciners without forming balls the outside of which is ash and the core bicarbonate. The temperature of the gas going to the tower runs about 28°. The pressure on the gas runs about 55 inches of mercury at the bottom, and about 9 inches at the top; the top pressure is due to the liquor in the tower washer. When ordinary vat liquor of 39 to 40 grms. CO_2 per litre is fed into a tower there is more ammonia carried off by the unabsorbed gas than when liquor of 69 to 70 grms. CO_2 is used.

'Each cubic metre of waste gas carries away about 112 grms. of NH_3 when 40 grms. CO_2 liquor is used, against 58 grms. carried off when using 70 grm. CO_2 liquor. The quantity of bicarbonate suspended in the liquor increases, of course, as the liquor travels down the tower. If a sample of liquor be taken from the bottom it will be found after standing about half an hour that the volume of the bicarbonate is from a quarter to a third of the total volume of the sample.'

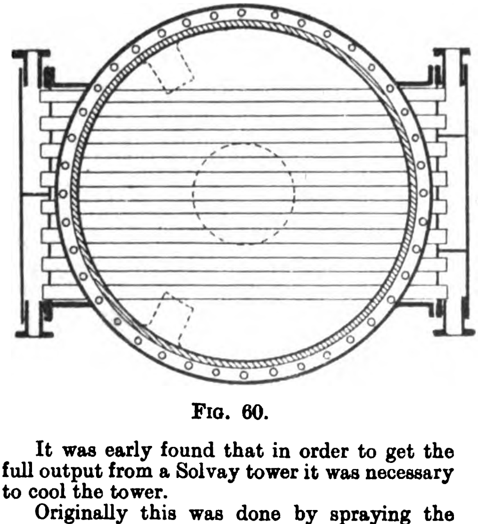

FIG. 60.

It was early found that in order to get the full output from a Solvay tower it was necessary to cool the tower.

Originally this was done by spraying the exterior of the tower with water. This is naturally an inefficient method, and is not capable of satisfactory regulation. Cogswell (Eng. Pat. 1973 of 1887) applied a system of internal cooling pipes, Figs. 59 and 60, in the tower cylinders;

cooling water is circulated through the pipes and enables the temperature to be regulated in the different parts of the tower.

The top of the tower should be kept as cool as possible to avoid volatilisation of ammonia, and the middle and lower parts should be maintained at a temperature of about 20°, as steadily as possible.

Cleaning the Solvay tower. The Solvay tower normally runs two to three months without blocking up and requiring cleaning.

The tower is cleaned by first of all emptying out the liquor in it, maintaining the usual agitation by pumping in kiln gas while the liquor runs out. Water is then run into the tower, and the whole boiled up with steam. This dissolves out the soda crusts that have been formed.

Other forms of carbonators. Numerous other forms of carbonators have been suggested, and some are worked on the large scale.

As, however, the Solvay tower is, with a few exceptions, the apparatus universally employed, only a list of the more important alternatives are given here.

Of the vertical type. Schreib, D. R. P. 70169; Honigmann, D. R. P. 13782; Schreib, Chem. Zeit. 1890, 492.

Of the horizontal type. One of the oldest apparatus is that of Gossage (Eng. Pat. 422, 1854; Young, Eng. Pat. 2558, 1871).

The Boulouvard apparatus, which has been employed successfully in France, is described in Fr. Pat. 125625, 1878; Pechiney, Eng. Pats. 2098 and 5394, 1880, describes a modification of the Boulouvard apparatus.

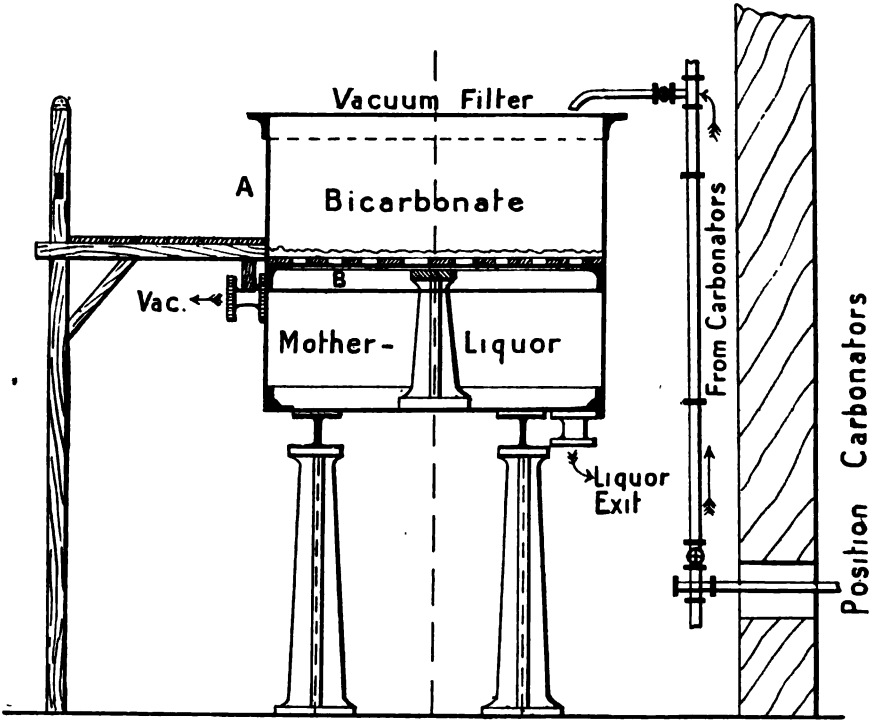

FIG. 61.

Filtering the precipitated bicarbonate from the Solvay tower liquor. Fig. 61 represents a common form of filter. The shell A is of steel plates, varying in size up to 12 ft. diameter. The filter bed B usually consists of a perforated cast-iron plate on which rests a coarse flannel filter cloth, over which is a wire mesh grid to protect the flannel from the spade used to empty the bicarbonate from the filter. A series of five such filters are connected to a battery of four Solvay towers, and are alternately filled with the liquor and salts flowing from it.

While filling, the space below the filter bed is placed under vacuum, and receives the filtered liquor. When the bed of bicarbonate on the filter has become about 24–28 ins. thick, the stream of liquor is turned on to another filter. As soon as the mother liquor has been drawn through the salts, the surface of the salt is smoothed over and any cracks, especially round the edges of the vessel, made good. The salts are then washed with water, delivered by a spray, until the chloride in the bicarbonate has been reduced to 0·1–0·2 p.c. NaCl.

When this is done the spray of wash water is stopped, and the vacuum maintained until the bicarbonate is drained as dry as possible. The usual rough test with a normal good grain bicarbonate is that a ball of the salts when pressed in the hand does not yield water.

Bradburn gives the following analysis of the washed bicarbonate:—

$NaHCO_3$	70–75	p.c.
Na_2CO_3	3–5	,,
NaCl	0·2–0·7	,,
NH_3	0·56	,,
H_2O	24–25	,,

It is practically impossible to wash the precipitated bicarbonate free from ammonia or sodium chloride without an altogether extravagant loss of bicarbonate.

As it is, the washing results in a material loss of bicarbonate.

The efficiency of the washing operation depends more upon the physical condition of the bicarbonate itself than upon apparatus. This physical condition, as described above, depends on the temperature conditions of the Solvay tower.

At low temperatures in the tower not only is the precipitate in a very fine state of division, and practically impossible to wash, but it contains ammonium chloride in the solid state, which experience has shown is with the utmost difficulty taken up by the wash water.

The mother liquor and wash liquor after the removal of the vacuum under the filter are run off into the store tanks or wells, from which they are afterwards pumped to the ammonia stills.

Several mechanical filters have been devised which permit of continuous and automatic filtering, washing, drying, and removal from the filter bed, thus effecting a material saving in labour.

Figs. 62 and 63 represent the filter patented by Solvay (4725, 1896), in which A is a drum revolving in the vessel B into which the liquor and salts from the towers are fed, and in which they are kept agitated.

The drum A revolves about a horizontal hollow axle C connected with a vacuum pump. The periphery of the drum A is formed of a perforated metal sheet, covered with a fine metallic cloth in which a piece of flannel is secured. As the drum revolves the internal suction draws in liquor and forms a coating of bicarbonate on the surface.

In order to prevent the pores of the filtering bed becoming clogged, internal pressure is substituted for the vacuum from time to time.

The cake of bicarbonate as it travels round is sprayed with water and is effectively washed at a later stage of the revolution, the vacuum drys the thin cake of bicarbonate, after which it is continuously removed by a scraper.

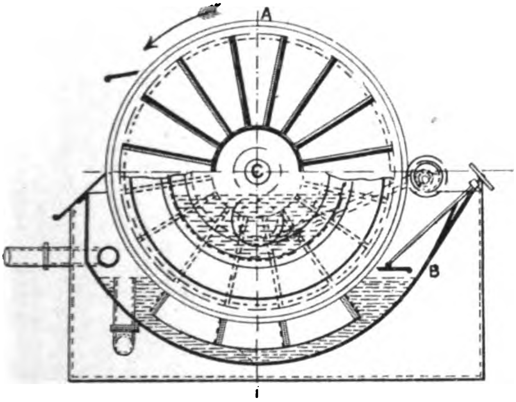

FIG. 62.

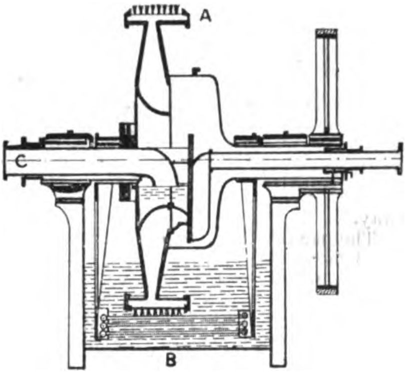

FIG. 63.

Another mechanical filter is described in Eng. Pats. 7957 and 28791, 1903, taken out by Houghton and the United Alkali Co., Ltd.

This filter consists of an inclined rotating dish provided with a false bottom of filtering material. The dish is divided into compartments below the filter bed, which are alternately in communication with the suction device to carry away filtrate, and with a supply of mother liquor or water to wash the solid matter from the pores of the filtering material. A stream of liquor and salts from tower is run on to the rotating filter bed, the liquor passes through, drawn by the suction, and the bicarbonate is left as a comparatively thin layer, which in the course of revolution of the dish is washed by a water spray and then automatically removed by a scraper or plough.

From the filters the washed and drained bicarbonate is taken to the roasters or furnaces to be converted into the monocarbonate or soda-ash. From the ordinary filters of the type shown in Fig. 61 the bicarbonate is discharged by hand into barrows or trollies, in which it is conveyed to the roasters.

From the mechanical filters the bicarbonate, as it is continuously removed by the plough, is carried away by a conveyor and fed continuously into the roaster.

The roasting and furnacing operation. From the readiness with which sodium bicarbonate decomposes it would be anticipated that the roasting and furnacing operation would be an easy matter. Practically it has been found that the economical performance of this operation is one of the most difficult problems in the process.

The difficulty is indicated by the large number of patents on this part of the process taken out by Solvay and others.

The practice in the various works is understood to vary widely, and the details of the apparatus in actual use are, as is the case with so much of this process, kept secret.

Below are given short descriptions of some of the furnaces which have been used.

It is usual to divide the calcining operation into two stages. In the first, the bicarbonate is dried and the ammonia contained is driven off together with about 75 p.c. of the second molecule of carbon dioxide. The product, called 'roaster ash,' is then subjected to a second calcination at a higher temperature to complete the decomposition of the bicarbonate. Fig. 64 represents a form of roaster which has been much used. It consists of a cast-iron pan A closed by a cover B through which passes a vertical shaft, carrying an arm with scrapers. The pan is heated by the fireplace C, and is provided with an exit pipe D, through which the gases evolved —steam, ammonia, and carbon dioxide—pass away.

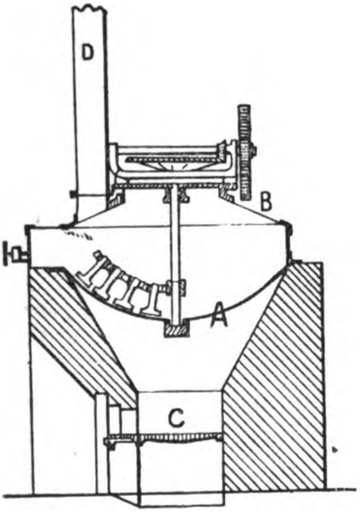

FIG. 64.

The pan of such a roaster varies in size from 10–14 feet.

Fig. 65 represents an apparatus modelled on the Thelen pan described in Die Chemische Industrie, 1878, 7, and which has been very largely used for the finishing operation where a light quality ash is wanted.

The Thelen pan consists of a cast-iron dish 7–8 ft. diameter by 30 ft. long, hooded with a sheet iron cover. The pan is heated by an external fire and rests on brick walls. The roaster ash is fed continuously at the firing end, and slowly moved by the oscillating movement of the scrapers, which rock through an angle of about 90°, to the other end of the pan, where it is delivered to a conveyor, or to an elevator, which lifts it to the so-called cooling conveyor, usually placed in the roof of the building, and from which the ash is afterwards conveyed to the store or to the dressing and packing plant.

The cooling conveyor is sometimes an atmospherically cooled revolving shell, having an inside screw fastened to the shell, and sometimes a water-cooled conveyor.

The Thelen pan as shown above, but fitted with an exit pipe near the fire end, is also used for the whole operation of drying and furnacing.

The wet bicarbonate is fed in at the fire end, and the monocarbonate delivered, as described above, from the end further from the fire into the elevator feeding the cooling conveyor. The water vapour, ammonia, and carbon dioxide escape by the exit pipe.

Bradburn (J. Soc. Chem. Ind. 1896, 884) states that in the United States the form of dryer shown in Fig. 64 is in use, but is being replaced by the calciner described in U.S.A. Pat. 386664, 1888. This calciner consists of a cast-iron cylinder about 60 ft. long by 5 ft. diameter, supported at the ends and in the middle on roller bearings, and revolved by gear fixed in the middle. A furnace chamber is built round each half of the calciner, connected together by flues. The ash is moved by means of a heavy chain lying along the length of the cylinder.

The apparatus described above yields the sodium carbonate in the form of a light powdery ash requiring very little grinding before packing, but occupying, when compared with Leblanc ash, materially more package space.

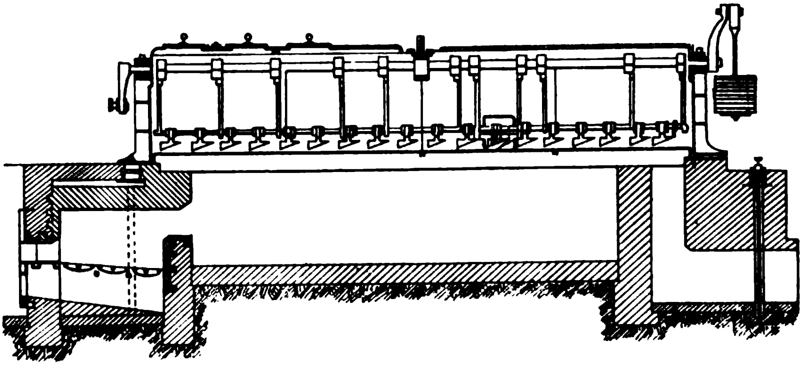

FIG. 65.

For many purposes this light, somewhat dusty ash is not liked, and a denser form has to be made by subjecting it to direct fire.

When this is done the 'roaster ash,' that is the not completely decomposed bicarbonate or sesquicarbonate, taken from either the dish roaster shown in Fig. 64 or produced in a lightly fired Thelen pan, is finished in a furnace of the type of the Mactear furnace shown in Fig. 48, p. 54, or in a rotating furnace of the type of the black ash revolver, where the ash is brought into direct contact with the fire gases, and therefore raised to a much higher temperature than in the Thelen or other similar pan.

Bradburn gives the difference between the light and heavily-finished ash as follows :—

A 1000 c.c. jar filled and well shaken down with light ash, will hold 900 to 1000 grms. weight of ash. If the ash is heavily finished, the jar will hold about 1550 grms.

As mentioned above, whatever apparatus is used for drying and roasting the bicarbonate, arrangements are made to draw off the gases (NH_3, CO_2 and H_2O) evolved.

The gases are drawn by means of a pump, first through a series of water-cooled cast-iron pipes, similar to the cooler for the ammoniacal brine, to cool them and condense the bulk of the water vapour which carries with it a part of the ammonia.

They are then usually drawn through one or more coke-packed towers, down which water is running, and in which the remainder of the ammonia is condensed as ammonium bicarbonate. The ammonia liquor both from the cooler and the scrubber is run to the store tank for ammoniacal liquor, from which the ammonia still is fed.

The gases leaving these scrubbers consist of carbon dioxide diluted by the air drawn into the roaster.

Great care is taken to reduce this air leakage to a minimum, because with absolute freedom from leakage the carbon dioxide from the roaster would, of course, test 100 p.c. CO_2, and when mixed with the lime kiln gases pumped into the Solvay towers or carbonators would materially increase their strength.

In the early days the roaster carbon dioxide tested as low as 25 p.c. With the dish roasters (Fig. 64) the carbon dioxide is stated to test about 50 p.c. With great care and the more modern roaster, such as those of the Thelen type, it is stated that a gas containing 60–80 p.c. carbon dioxide is obtained.

Ammonia recovery. The ammonia used in the process, with the exception of the unavoidable losses, is recovered by the distillation of the various ammoniacal liquors collected as described above.

The larger part of the ammonia is contained in the mother liquors from the filters, and is present mainly as ammonium chloride. Of the total ammonia going to the stills, about 15–20 p.c. is, however, present as bicarbonate, and is therefore volatile. Again, the ammonia losses are made good by the addition of fresh ammonia liquor from gas works and recovery coke ovens, which is chiefly in the form of oxide with some carbonate and sulphide. This fresh liquor is added to the general stock of filter liquor, and is fed with it into the still.

The liquors also contain, of course, the excess of sodium chloride which has passed through the Solvay towers.

Fig. 66 shows the form of still in general use. A, A, A, are compartments made of steel plates or cast-iron rings, separated by cast-iron plates, each with a large-sized hole in the centre covered by an umbrella-shaped mushroom.

B is the chamber into which the milk of lime necessary to decompose the fixed ammonia, *i.e.* such salts as the chloride which are not decomposed by heat, is run.

C, C, C, C, are a number of compartments, each consisting usually of a cast-iron ring. The bottom plate of each ring has a central hole covered with a plate.

The filter liquors are fed in at the top of the still through the pipe E, and passing down the upper part of the still or 'heater' are heated by the steam rising from the lower half, and the ammonium carbonate and bicarbonate are decomposed and driven off.

The liquor then passes into the chamber B, where it is mixed with the milk of lime pumped in through the inlet G.

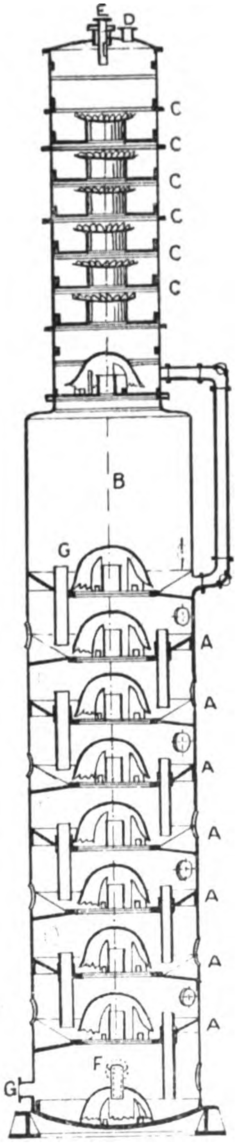

Fig. 66.

The lime decomposes the fixed ammonia, namely ammonium chloride, and any sulphate present, and in passing down through the compartments A, A, &c., the liberated ammonia is driven off by the steam which enters at F.

From the top of the still ammonia, steam, an carbon dioxide pass away through the outlet D, at a temperature of 80°–85°.

As has been stated previously, it is very important before the ammonia is brought in contact with the brine, that as much steam as possible should be condensed, and that it has been found that the gases should be cooled so that they enter the absorbers at 70°–75°.

The distiller cooler or condenser may be of various forms, but is usually a vessel built up of cast-iron rings. Near the top of the vessel, and also near the bottom, is a cast-iron tube plate, into which are expanded a number of tubes. Cooling water is circulated through these tubes, entering below the bottom tube plate and flowing away from the top. By regulating the cooling water supply, the temperature of ammoniacal gases leaving the cooler or entering the absorber is controlled. The ammoniacal liquor condensed in the cooler is either run back into the filter liquor store or into the still itself at some point in the upper or heater part of the still depending on the levels.

For the efficient working of the still itself, and for the smooth interworking of the still and the absorber, regularity is required—

1. In the test of the ammonia in the filter liquor feed. It is therefore a matter of importance to watch carefully the average strength of the liquors collected in the filter liquor store tanks.

2. In the supply of the milk of lime, which should always be in slight excess. If there is a deficiency of lime there is incomplete decomposition of the ammonium chloride, and loss of ammonia.

3. In the supply of steam, because if there is a deficiency of steam there is incomplete distillation of the ammonia, and loss in the exit liquors. If, on the other hand, there is an excess of steam, the cooler will be overworked, and the gases entering the absorber will contain an excess of water, and thus dilute the brine.

The lower parts of the stills gradually become blocked up with scale which adheres to the shell, the mushroom, and all parts of each compartment, sometimes to the thickness of three inches.

From time to time this has to be cleaned away, and the only method available is, after well steaming out the still and allowing it to cool, to chip off the scale by hand.

The scaling requires to be done every one to two months, depending on the speed of work.

The loss of ammonia in the whole process varies between ½ and 2 p.c., estimated as ammonium sulphate on the ton of soda ash made. Good ammonia results are, of course, dependent on the careful carrying out of the precautions indicated above, and have been effected only by the gradual accumulation of experience and improvement of apparatus. Bradburn says that an ammonia soda works requires to carry a stock equal to two tons of ammonium sulphate per ton of ash made per day. Of this 25 cwts. are in the form of working liquors.

The waste liquor leaving the still is a solution of calcium and sodium chlorides, containing the excess of lime mentioned above, and also calcium carbonate, due to the unburnt calcium carbonate in the lime which gets past the filters of the lime slaker, and also due to any carbon dioxide not driven off in the upper part of the still. The liquor also carries away any other impurities which may have been in the limestone.

It is the usual custom to run this liquor through settling ponds, where the lime, calcium carbonate, and other solids separate out, after which the solution of chlorides is run away.

It will be noted that the calcium chloride thus run away contains all the chlorine combined with the sodium which has been converted into sodium carbonate, and, in addition, the liquor carries away unused about 20–40 p.c. of the total salt brought into the process.

A very great amount of work has been done to try and utilise the chlorine thus lost by the ammonia soda process, but without success. See article CHLORINE, p. 43, vol. ii.

It is necessary to reiterate that success in the working of the ammonia soda process depends on the balance of the different sections of the plant, so that by careful supervision a mechanical interworking of the different parts of the process may be attained.

Application of the ammonia soda process to sodium sulphate. As the ammonia soda process starting from sodium chloride does not economically yield hydrochloric acid, attempts have been made to work the process using sodium sulphate as the starting-point.

In this case the hydrochloric acid is evolved in the production of the sodium sulphate. The process is first mentioned by Bower (Eng. Pat. 8413, 1840), and was afterwards considered by Gerlach and by Weldon (see Eng. Pat. 5605, 1883). Gaskell and Hurter were, however, the first to seriously attack the difficulties of the process (see Eng. Pats. 5712, 1883; 8804, 1884; and 9208, 1886). The great difficulty was how to deal with the ammonium sulphate formed in the reaction. Gaskell and Hurter's scheme was to heat the ammonium sulphate with sodium sulphate in a current of steam, when the ammonia is liberated and acid sodium sulphate left behind. The process then followed the three reactions—

$$(1)\ Na_2SO_4+2NH_3+2CO_2+2H_2O =2NaHCO_3+(NH_4)_2SO_4.$$

$$(2)\ (NH_4)_2SO_4+Na_2SO_4=2NH_3+2NaHSO_4.$$

$$(3)\ NaHSO_4+NaCl=Na_2SO_4+HCl.$$

The second stage of the process was, however, always the stumbling block, and, owing largely to its cost, this interesting process was not persevered with.

Application of the ammonia soda process to sodium nitrate. This was suggested in 1876 by Gerlach and patented in 1877 by Lesage & Co., and again by Chance (Eng. Pat. 5919, 1885). Colson (J. Soc. Chem. Ind. 1910, 190), again, recommends this process as being theoretically more favourable than the sodium chloride process.

Caustic soda from ammonia soda. In competition with Leblanc process, caustic soda is manufactured on a considerable scale by the makers of ammonia soda. As has been stated before, although the ammonia soda process has proved itself much the cheaper process for the manufacture of sodium carbonate, the Leblanc process, owing to the numerous bye-products produced, and to the fact that the Leblanc vat liquors are already a solution of partially causticised soda, is the better adapted for the production of caustic soda.

The manufacturers of caustic from ammonia soda either make use of Löwig's ferrite process described on p. 48, and thus produce a solution of 1·32–1·36 sp.gr. at once, or dissolve the ash in water and causticise by lime in exactly the same way, and using the same apparatus as is described above for the Leblanc vat liquors, p. 45.

Although the Löwig process has been adopted by some of the largest makers of caustic from ammonia soda, and although it possesses the double advantage of producing a stronger solution of caustic, and of avoiding the very serious trouble of finding an outlet, or depositing ground, for the large quantities of caustic lime mud produced by the lime process, it is doubtful if there is much difference in cost between the processes.

In either case the later stages of the concentration and finishing are carried on in the same way, and in the same apparatus, viz. cast-iron caustic pots, sometimes supplemented by multiple effect evaporators, such as have been already described under the Leblanc process.

To some extent ammonia ash is also causticised by consumers such as paper makers, textile bleachers, and soap makers, who require a solution of comparatively low strength caustic soda liquor in their manufacture. When actual costs are obtained, however, it is very rarely found that the production of their own caustic liquor pays when compared with price of already made caustic.

Local conditions as to prices of fuel, lime, and facilities for waste deposit vary too much to enable a standard comparison to be made, applicable to every case, but it is necessary to remember that to produce caustic liquor of 1·1–1·13 sp.gr., equivalent to 1 ton 70 p.c. caustic soda, requires from actual results in such works, 29–30 cwts. 58 p.c. soda ash, 17–18 cwts. lime, 20 cwts. fuel.

In addition to this there have to be deposited 2¼–2½ tons of caustic lime mud, and the wages, repair and capital charges to be met. The soda liquor obtained in this way contains about 90 p.c. of its total soda only as hydroxide, the remainder as carbonate, and if great care is not exercised in the washing of the lime mud on the filters before sending to the tip, the soda losses may be largely increased.

Soda crystals. For some purposes soda is required not in the calcined form, as soda ash, but in the crystalline form, in which it contains 10 molecules of water. Although soda crystals, if chemically pure, contain only 37·08 p.c. of anhydrous sodium carbonate, or 21·71 p.c. of available soda (Na_2O), and thus cost much more than their equivalent of soda ash for packages and carriage, they are preferred to the latter in some cases, for the following reasons: while soda ash is a more or less white powder, whose value cannot be recognised at a glance, and which may contain more or less useless, or even injurious, impurities, soda crystals by their very appearance seem to guarantee to the buyer a product of sufficient purity and of uniform strength. Their greatest recommendation for household use, as well as for the scouring of wool and some other purposes, is their absolute freedom from caustic, which is very injurious both to the skin and to the fabrics to be washed or scoured. For all manufacturing purposes soda crystals are now advantageously replaced by ammonia-soda, which is equally free from caustic; but for household purposes the ordinary soda crystals are likely to retain their hold, and are consumed in very large quantities as 'washing soda,' and under various fancy names.

Originally, of course, all soda crystals were made from Leblanc soda, and the great effort of the crystal makers was to find out how to obtain a good crystal from the vat or tank liquor direct. The bulk of the crystals made and probably all those of good quality were, however, produced from Leblanc ash by the same method as is adopted for their manufacture from the ammonia alkali which is now always used.

The ammonia alkali is dissolved in any suitable dissolver fitted with a mechanical agitator and fed with hot water. In a vessel 8 ft. diameter by 6 ft. high, 40 tons of 58 p.c. ash can be dissolved in 16 hours.

The solution is made to 1·3 sp.gr. hot, and is then pumped to settlers in which a small quantity of sodium sulphate is added, as commercial crystals require anything up to 1 p.c. sodium sulphate to give them the desired crystalline form. While settling the temperature of the liquor has to be maintained above 34°, the temperature of maximum solubility. If the settlers are large and sheltered there is usually little difficulty in this.

The liquor is run from the settlers into the crystallisers, which are iron vessels varying in different factories between the widest limits of shape and size. These vessels have in all cases a hole in the bottom stopped up with a long wooden plug. This hole is to permit the mother liquor from the crystallisers at the end of the crystallising operation to drain into shutes below, which convey it to collecting tanks or wells in the floor, from which it is pumped into the dissolver again to assist in making up the next batch. Across the top of the crystallisers from side to side is usually placed a number of bars or strips of metal, in order to support the crystals formed near the top of the liquor, and in this way to obtain fine large crystals.

The crystallisers are usually placed in double rows, with a mother liquor shute between them, in large, airy, lattice-sided sheds.

Crystallisers yielding 1 to 1½ tons of crystals usually finish in about one week in winter and a fortnight in summer.

After the mother liquor has been run off and the crystals allowed to drain well in the crystalliser, the crystals are taken out and placed in blocks on wooden shelves to drain for at least 24 hours, after which they are ready to pack.

Other crystals are crushed to comparatively small pieces in a crusher frequently of the Blake type and 'whizzed' in a centrifugal machine.

Soda crystals are either packed in wooden casks or kegs or in bags. When the casks or kegs are used it is usual to take the crystals from the draining shelf. When bags are used the better dried crystals from the centrifugal are taken, because the presence of any liquor in that case discolours the bag and the crystals.

The following is an analysis of a good brand of commercial soda crystals.:—

Na_2CO_3	36·60
$NaHCO_3$	0·25
Na_2SO_4	0·14
NaCl	0·15
Water (by diff.)	62·86
	100·00

The mother liquor eventually contains too much sodium chloride to be used again. It is therefore evaporated to dryness and the residue, which will contain about 29 p.c. Na_2O and 34 p.c. NaCl, is sold for what it will fetch. This necessity recurs at such long intervals that if the residue is thrown away the debit on the soda crystals made is negligible.

Commercial soda crystals are sometimes adulterated with Glauber's salts, specially manufactured in 'soda-fashion,' and it is said that now and then Glauber's salts are vended as 'best Scotch soda,' but it is hardly credible that such an easily discoverable fraud is frequently committed.

Mactear (Eng. Pat. 10651, 1884) has constructed an apparatus for obtaining soda crystals in a granular form, by subjecting the solution during crystallisation to the combined action of cooling by cold-water action from the outside, and mechanical agitation.

In another patent (Eng. Pat. 1989, 1886) he describes compressing those granular crystals into the shape of tablets, cakes, or blocks, most conveniently of a rectangular form, so that they can be packed without waste of space.

Crystal carbonate. This is the name given originally by Messrs. Gaskell, Deacon & Co. to a very pure monohydrated sodium carbonate, Na_2CO_3,H_2O, obtained by direct evaporation from tank liquors, thoroughly carbonated with addition of bauxite, and afterwards purified from ferrocyanide by superheating to 180° (Carey, Gaskell and Hürter, Eng. Pats. 1161, 1881; 2939, 1879; 5310, 1882). This substance was absolutely free from caustic, silica, and alumina, and was altogether far superior to ordinary soda crystals, not merely in strength, but also in purity.

As in the case of soda crystals, however, the Leblanc vat liquor has been replaced by ammonia alkali, and the crystal carbonate is now obtained in a still purer state from this source.

The following is an analysis of crystal carbonate, made from ammonia alkali:—

Na_2CO_3	82·0
NaOH	0·0
Na_2SO_4	trace
NaCl	0·25
Water	17·5
	99·75

Crystal carbonate dissolves in water much more easily than ordinary soda crystals, because, instead of lowering the temperature, it slightly raises it in the act of solution, and because its grainy texture offers a much larger surface to the water than soda crystals do.

One ton of crystal carbonate contains as much alkali as 48 cwt. of soda crystals, and occupies only 65 cubic feet against 150 cubic feet occupied by 48 cwt. of soda crystals

Bicarbonate of Soda. Bicarbonate of soda was formerly made by the action of carbonic acid usually obtained by decomposing $CaCO_3$ with hydrochloric acid, on soda crystals.

The soda commonly employed was in the state of ordinary crystals; those of yellow colour or otherwise inferior quality could be utilised quite well. They were exposed to the action of the gas in apparatus of various shapes, made of brickwork, wood, or preferably of iron, holding up to 60 tons of crystals. They were connected in such way that the gas passed from one chamber to another. Large doors served for charging and emptying. A false bottom, made of laths, was laid down inside, below which the gas entered and above which the crystals were put up in regular layers. The space below served for holding the abundant drainage of mother-liquor caused by the fact that nine of the ten molecules of water of crystallisation were set free: $Na_2CO_3,10H_2O+CO_2=2NaHCO_3+9H_2O$. This liquor dissolved the small quantity of foreign salts and other impurities contained in the crystal soda, and ran off through a U-tube fixed in the chamber bottom. The end of the process was indicated by the stoppage of this flow, which generally occurred in from 6 to 9 days.

On opening the chambers the bicarbonate was found apparently in the shape of the crystals originally charged, but in reality only as a loose powder. It was very damp, and had to be dried in stoves heated to a temperature not exceeding 45°. Dry and warm carbonic acid, if not too expensive, would have greatly expedited the drying, which generally lasted 8 or 10 days.

Mathieson and Hawliczek (Eng. Pat. 150, 1886) prepared pure sodium bicarbonate from black ash, crude sodium sulphide, or crude bicarbonate, as obtained in the ammonia-soda process, by dissolving those products in a solution of sodium chloride of from 16 to 19 p.c., and treating the solution with carbon dioxide, whereby nearly all the bicarbonate was precipitated in a crystalline form. The bicarbonate is said to be obtained nearly in a chemically pure state. With impure materials, as black ash or crude sodium sulphide, the CO_2 first precipitates iron, alumina, and silica, and these are separated by filtration before precipitating the bicarbonate itself.

A totally different process from that formerly employed is that of Carey, Gaskell and Hürter (1881 and 1882). It is principally based on the employment of the 'crystal carbonate' previously described, which is exposed in a revolving cylinder to the action of pure carbon dioxide, entering at one end and escaping out of the other; after being passed in a pipe upwards, say 30 ft., and down again, it is sufficiently deprived of moisture, and is re-introduced into the first cylinder, or else into another cylinder. A cylinder of 8 ft. length and 5 ft. 6 in. wide contains a charge of 1½ tons, and produces 2 tons of bicarbonate. It is supported on hollow trunnions; gas-pipes pass through these, and upwards inside the cylinder, so that they are not stopped up by the salt. By taking the exit pipe upwards for about 30 ft. and down again, and thus cooling the gas, a difference of temperature is produced which effects a sufficient circulation of the gas, while at the same time the excess of moisture is condensed, and the water is run off before the gas passes again into the cylinder. This circulation is in practice best promoted by mechanically pumping the gas back again. The temperature rises very much during the absorption, but the cooling action of the air keeps it down; practically, the bicarbonate made in this way—that is, under a certain pressure—is very strong, containing about 97 p.c. real $NaHCO_3$, against 87–90 p.c. in the old process. The moisture must be regulated; if the mass becomes too dry, the carbonic acid introduced must be moistened by means of a small coke tower. With the progress of absorption the temperature falls again, and it is finished in 5 or 6 hours.

The patent contains also provision for employing impure carbon dioxide, by passing the gas through a series of absorbing cylinders; but this process does not seem to be in practical use. Anhydrous monocarbonate can also be used (Eng. Pat. 2876, 1882) by introducing steam together with carbonic acid.

The bicarbonate made by this process had almost superseded that made by the old process, when it was itself displaced by the bicarbonate made in the ammonia-soda process. This formerly could not be immediately employed for use as baking powder, &c., owing to the ammonium compounds it contains. Mond and Jarmay (Eng. Pat. 2996, 1884) found that on dissolving the crude bicarbonate in warm water and cooling pure bicarbonate of soda crystallises out and the ammonia salts remain in solution.

They dissolve the crude salt at 65°, filter off the insoluble impurities and allow the solution to cool. The bicarbonate separates out in granular crystals, which are drained, dried and ground. The solution can be made at a higher temperature in an atmosphere of carbon dioxide under pressure, but it must be cooled down to 65° before removing the pressure. The mother liquors can be used many times over until they get too rich in ammonia.

Jarmay (Eng. Pat. 23890, 1893) describes improvements made in this process, and states the crude bicarbonate is dissolved in a closed vessel provided with an agitator in which the temperature is maintained by a closed steam coil between 85° to 90°.

The escaping vapours containing NH_3, some CO_2 and steam, are passed through a multitubular cooler, where they are surrounded by mother liquor from a former operation.

The solution in the dissolver containing bicarbonate and some sesquicarbonate is passed through a filter press and then pumped into an iron tower containing many compartments and water cooled. Here the temperature of the solution is reduced to 72°. Lime kiln gas is pumped into the bottom of the tower and causes constant agitation. The carbonated liquor and precipitated bicarbonate runs from the bottom of the tower on to a filter and the mother liquor flows back to the dissolver through the cooler mentioned above.

Jarmay (Eng. Pat. 3889, 1893) describes the drying of the moist bicarbonate obtained as above in a long covered trough through which the bicarbonate is carried on a conveyor and through which also air, preferably mixed with carbon dioxide and heated to 95°, is blown.

Brock and Hawlicek (Eng. Pat. 8314, 1896) treat the ammonia soda roasted ash or the crude bicarbonate, after removal of the ammonia and part of the carbon dioxide, with steam and carbon dioxide, either in rotation or simultaneously, in order to obtain a pure bicarbonate.

The composition of commercial refined bicarbonate is given as—

$NaHCO_3$	97·2
Na_2CO_3	1·9
Na_2SO_4	trace
NaCl	0·35
H_2O	0·82
Insol.	0

(See Lunge's Alkali, vol. iii. p. 211.)

Sodium bicarbonate is chiefly used for the following purposes: as a chief ingredient of baking powder; as the carrier in the washing blue used in laundries; as the source of carbonic acid in the manufacture of mineral waters, for which it has the advantage over $CaCO_3$—which was formerly used for the purpose—of yielding double the quantity of CO_2 gas per unit of sulphuric acid and of leaving a soluble salt in the generator, viz. Na_2SO_4 instead of $CaSO_4$.

Sodium sesquicarbonate

$Na_2CO_3,NaHCO_3,2H_2O$

is made by Watts and Richards (Eng. Pat. 13001, 1886) by preparing a solution containing the above proportions and allowing it to crystallise not below 35°, keeping it agitated all the time. Such a solution can be prepared by heating sodium bicarbonate so as to deprive it of about one-third of its carbonic acid and dissolving the residue, or by adding to a hot solution of 84 parts of sodium bicarbonate 106 parts of sodium carbonate. This salt, which crystallises in fine needles, does not effloresce or deliquesce, and is readily soluble in water. Its principal employment is for wool washing.

The composition of sesquicarbonate is given as—

Na_2CO_3	46·57
$NaHCO_3$	37·0
Water of crystallisation	16·24
NaCl	0·18
Insol.	0·02

(See Lunge's Alkali, vol. iii. 212.)

THE MANUFACTURE OF SODA BY ELECTROLYSIS.

Practically all soda manufactured by electrolysis is produced by the electrolysis of sodium chloride.

The electrolysis of sodium chloride is described, together with the chief types of apparatus in use, under the article CHLORINE, vol. ii. p. 21.

The types of cell in that article are classified under four heads:—

I. The cells in which the electrolyte consists of fused sodium chloride.

II. The cells in which the electrolyte is a NaCl solution and in which the cathode and anode are separated by a porous partition.

III. The cells in which the electrolyte is a NaCl solution, but in which a moving cathode of mercury is used to remove the sodium produced from the action of the chlorine.

IV. The cells in which the electrolyte is a NaCl solution and which depend on specific gravity to keep apart the alkali and the chlorine.

Class I. The cells of this class, described p. 22, vol. ii., are the Vautin and Acker cells, in both of which the sodium is obtained as a lead sodium alloy. The sodium was obtained by Acker in the form of caustic soda by treating the molten alloy with steam in the absence of air, as described in his Eng. Pat. 14269, 1898.

Class II. With the exception of the Hargreaves Bird cell, all cells of this class yield a solution of caustic soda mixed with varying but always large quantities of sodium chloride. These solutions are concentrated and finished in apparatus similar to that described under the manufacture of soda by the Leblanc process, p. 49. Instead of the comparatively small quantities of salts which are deposited during concentration of Leblanc soda, much larger quantities of NaCl are thrown down and have to be fished out. This large quantity of salt is, after draining, usually washed with fresh cathode liquor from the cell, redissolved, and returned to the process.

Constitution of the cathode liquors from the various cells mentioned has been given approximately as—

The Griesheim cell, 8 p.c. NaOH, 20 p.c. NaCl;

The Townsend cell, 150 grms. NaOH and 213 grms. NaCl per litre;

The Finley cell, 7 p.c. NaOH.

In the case of the Hargreaves Bird cell, the liquor from the cathode compartment is, as described vol. ii. p. 23, a solution of carbonate mixed with sodium chloride.

Hargreaves (Eng. Pat. 21178, 1897) describes a method of separating the sodium carbonate from the salt. The sodium carbonate is generally produced in the form of soda crystals (washing soda).

Kershaw (Electrician, 1898, 547) gives the following analyses of two samples of the soda liquor flowing from this cell:—

	Sp.gr.	Na_2CO_3	NaCl	Molecules NaCl on 100 mol. Na_2CO_3
(1)	1·125	10·9 p.c.	0·94	15·6
(2)	1·094	10·44 „	0·1	1·73

Class III. The soda solution obtained from the decomposition of the sodium amalgam produced by cells of this class is very pure and free from NaCl. Its concentration, therefore, is not complicated by the production of 'salts.'

The solutions obtained are usually of about 45°Tw. (Lepsius, Ber., 1909). There is, therefore, about 4 tons of water to be evaporated before the solid caustic soda is obtained. The apparatus used for the concentration is similar to that described under Leblanc caustic soda, p. 49.

Class IV. As in the case of the cells with the porous diaphragm, the soda solution yielded by such cells as the Glocken cell contains large quantities of undecomposed sodium chloride, which has to be separated during concentration, drained, washed, and returned to process.

The constitution of the solution obtained is given in Chem. Zeit. 1901, 1171, as alkali, 6–12 p.c.; sodium chloride, 16–30 p.c.

A modification of the Glocken cell has been patented by the Society of Chemical Industry of Bale, 25118, 1909, the main point of which is the continuous saturation of the brine by causing the fresh electrolyte to flow from an upper to a lower electrode in order to drive backwards the ions of the newly formed products. The mode of operation consists in causing the electrolyte which has been partially impoverished at the upper electrode to be enriched again between the two electrodes by solid salt fed in a special manner. The advantage consists in obtaining a higher strength caustic soda with a good current efficiency. The theoretical considerations involved are dealt with in the patent.

4. Manufacture of Soda by other Processes.

ENUMERATION OF PROCESSES PROPOSED FOR MANUFACTURING SODA.

A. From common salt without converting it into sodium sulphate.

Potash (potassium carbonate) was used in the infancy of the manufacture of soda by Bergman, Hahnemann, Losh, and others, at a time when the former alkali was less valuable than the latter, the reaction being

$$K_2CO_3+2NaCl=2KCl+Na_2CO_3.$$

Lime slightly decomposes common salt, as first noticed by Scheele. In 1782 Guyton de Morveau and Carny obtained a French patent for this process, which they actually worked for some time, of course with very little success.

Lead oxide. Scheele, in 1773, noticed that common salt is (partially) decomposed by lead oxide, caustic soda and lead oxychloride being formed:

$$2NaCl+2PbO+H_2O=2NaOH+PbO,PbCl_2.$$

This process was at first considered one of the most favourable for the manufacturing of soda, and was worked both in France and England, where many patents were taken for it. It was the process first employed by Losh at Walker-on-Tyne, at the same works where also one of the later patents belonging to this class, Bachet's, received a serious trial in 1870, but with hardly more success than formerly. The incompleteness of the reaction is the principal obstacle to this process. A new patent for it is Knab's (Eng. Pat. 3082, 1877). The Société Anonyme Lorraine Industrielle (D. R. P. 23791) separates the caustic from the lead oxide by alcohol.

Romiquières (Eng. Pat. 14977, 1888) dissolves finely-divided lead in caustic soda by means of a current of air. The solution of Na_2PbO_2 thus obtained is treated with NaCl, and thus two molecules of NaOH for each molecule previously employed are formed, $PbCl_2$ being precipitated.

Berl and Austerweil (Zeitsch. Elektrochem. 1907, 165) describe the reaction as reversible, and give two equations:

1. For 'normal concentration'—

$$5PbO+H_2O+2NaCl+ \rightleftarrows 4PbO,PbCl_2+2NaOH.$$

2. For higher concentrations—

$$2NaCl+4PbO+H_2O \rightleftarrows 3PbO,PbCl_2+2NaOH.$$

The conversion of NaCl to NaOH being—

18°C.	50 p.c.
48°C.	43 „
74°C.	37 „

Vournassos (Eng. Pat. 23689, 1908) decomposes NaCl in a fused state by means of PbO.

Magnesia has been patented by W. Weldon

(March 1, 1866) for the following reaction: $2NaCl+MgCO_3+CO_2+H_2O=2NaHCO_3+MgCl_2$. The inventor expected to obtain all the soda as bi-carbonate, and to decompose the $MgCl_2$ into MgO and HCl. It is hardly necessary to point out that both of these reactions are far too incomplete for practical use.

Sulphide of iron is used by Reynaud (Eng. Pat. 14483, 1890), who heats it with NaCl, with the production of chlorine, sodium sulphate, and ferric oxide. This residue is mixed with coal and heated, producing a ferro-sodium-sulphide, which is treated by Blythe and Kopp's process (*see* below).

Oxalic acid and oxalates of ammonium and magnesium have been employed by various inventors. Their action is based on the slight solubility of the monosodium oxalate. None of these agents seems ever to have been tried on a large scale.

Hydrofluoric acid was proposed by Weldon (in 1866), and

Hydrofluosilicic acid by many inventors, these acids forming very slightly soluble sodium salts. A factory, working on a patent by Karcher and Tessié du Motay, existed for some years up to 1870, near Saargemünd, and the process seems to have given better results than might have been anticipated; but the various reactions on which it is based are too incomplete for practical use.

Calcium fluoride is employed by Brochon (Fr. Pat. 208754).

Alumina decomposes sodium chloride, in the presence of steam, at a very high temperature; this was utilised by Tilghman in 1847, and it has been taken up more vigorously since the discovery of native alumina in the mineral bauxite. Sodium aluminate is formed, and is decomposed as in the manufacture of soda from cryolite (*see* below). But the temperature required for the above-mentioned decomposition is too high, and the vessels employed cannot be made to last. On this account the attempts of Gossage (1862), of Grüneberg and Vorster (1876), and of Lieber (1878) have had no practical results.

Peniakoff (Fr. Pat. 405611, 1908) concentrates the impure liquors containing sodium carbonate, which are obtained in making pure alumina from bauxite to about 1·3 sp.gr., and then treats them with carbon dioxide, which precipitates sodium bicarbonate.

Clay, common salt, and water are employed by Kayser, Williams, and Young (Eng. Pat. 11492, 1887).

Silica and steam were employed as early as 1809 for decomposing common salt by Gay-Lussac and Thénard. This reaction was afterwards tried on a practical scale by Blanc and Bazille (1840), Fritzsche (1858) and others, especially by Gossage (1862), who brought sodium chloride in the state of vapour, along with steam, into contact with intensely heated quartz. The sodium silicate formed runs down in a fluid state. It is either used as such, or converted by CaO into NaOH, or by CO_2 into Na_2CO_3. This process was worked for some time, but the decomposition was too incomplete, the HCl was too difficult to condense, and the apparatus could not resist the intense heat.

Chromium oxide and steam has been patented by Swindells (1851), and Kessler (1687), but the reaction is quite incomplete.

Boric acid and steam have been patented by Margueritte (1855); boric acid alone by Garroway (Eng. Pat. 17395, 1889).

Steam alone decomposes NaCl at a very high temperature, and this reaction has been the subject of many patents, but unfortunately the reaction $NaCl+H_2O=NaOH+HCl$ proceeds only a very little way, otherwise this would be undoubtedly the simplest way of decomposing NaCl.

Magnesium sulphate (kieserite) is heated with sodium chloride and silica or clay in a current of air to 500° or 700°C. Chlorine is given off; sodium sulphate and magnesia remain behind (Townsend, D. R. P. 10641).

SODA FROM SODIUM SULPHATE.

Without converting it into Sulphide.

Lime. In 1789 Delius proposed this agent, and many other chemists followed him; in 1865 Hunter added the action of pressure. But the change is extremely imperfect as proved by Hill (Chem. News, 27, 165), and experiments made by Lunge (Dingl. poly. J. 238, 69), and by Cross and Bevan (*ibid.* 213, 137), confirm this.

Caustic baryta easily and completely decomposes sodium sulphate, but it is much too dear for practical use, in spite of several patents having been taken out for this process.

Caustic strontia was proposed for a very ingenious cycle of reactions by Ungerer (*ibid.* 188, 140). But as this process is very complicated, and includes the intervention of ammonia, it is far simpler and cheaper to employ Dyar and Hemming's process. There is also an American patent for strontium compounds (454136) by G. H. Gray.

Another process is suggested by Eichstädt (Eng. Pat. 15136, 1891), which depends for recovery of the $Sr(OH)_2$ on the following reactions—

(*a*) $SrSO_4+Na_2SO_4+8C=SrS+Na_2S+8CO$.
(*b*) $SrS+Na_2S+2H_2O=Sr(OH)_2+2NaSH$.

Calcium bicarbonate was patented in France by Pongowski (1872). Lunge (Dingl. poly. J. 243, 157) found that this causes no formation of sodium carbonate whatever.

Strontium carbonate is nearly always mentioned at the same time as

Barium carbonate. This has been tried in the dry way, by Kastner (1826) and Anthon (1840); in the wet way by many inventors, beginning with Kölreuter, in 1828. The reaction: $Na_2SO_4+BaCO_3=Na_2CO_3+BaSO_4$ is, however, incomplete, whatever temperature may be employed, even with excess of $BaCO_3$. But the decomposition is quite complete when barium bicarbonate is employed, or much more simply and cheaply by passing a current of CO_2 into an agitated mixture of $BaCO_3$ and solution of Na_2SO_4, as patented by Lunge in 1866. This process would be practicable, if a cheap method of recovering the $BaCO_3$ from the $BaSO_4$ could be found. At present it cannot compete with the ammonia soda process. Bramley (Eng. Pat. 1050, 1866) regenerates the barium carbonate from the sulphate, formed from the carbonate, by reducing the sulphate to BaS, then dissolving this in HCl, and treating the solution of $BaCl_2$

with hydrated magnesia and carbonic acid (a very hopeless process !).

In 1892 Nauhardt took a French patent (223339) for manufacturing sodium carbonate by digesting sodium sulphate with $BaCO_3$, prepared by treating BaS with CO_2.

Ammonium carbonates have been several times proposed for decomposing Na_2SO_4, first by Bower (1840). After the analogous process with NaCl had attained such complete success, the above has been again proposed, principally in order to recover the chlorine, as well as the soda, by interposing the manufacture of sodium sulphate and hydrogen chloride.

Alumina decomposes Na_2SO_4 in the presence of steam. This reaction, first proposed by Tilghman in 1847, furnishes sodium aluminate, which is easily decomposed by CO_2, Na_2CO_3 being formed and alumina being regenerated. In lieu of pure alumina, the mineral bauxite, found at Baux in the South of France, and in several other places, also at Irish Hill and Straid, County Antrim, can be employed. Several German patents by Löwig Brothers (93 and 1650, 1877) describe this process, in which, however, the manufacture of hydrated alumina is the principal feature. A modification of the alumina process was proposed by Vogt and Figge (D. R. P. 31675), another by Behnke (D. R. P. 7256).

Ph. B. and S. P. Sadtler (U. S. Pat. 877376, 1908; and Eng. Pat. 273, 1908) decompose alkaline sulphates by heating with excess of bauxite. Peniakoff (D. R. P. 80063) ignites bauxite or aluminium sulphate with sodium sulphate in the presence of alkaline sulphides or pyrites to produce sodium aluminate and sulphur dioxide. Projahn (D. R. P. 112173; Eng. Pat. 6790, 1899) heats salt-cake by itself, or with aluminous substances with exclusion of air, and with metallic iron at a dark red heat, and then lixiviates.

Silica decomposes Na_2SO_4, especially in the presence of coal, sodium silicate being formed, which is, indeed, one of the ways in which this compound is manufactured. It has been proposed to employ this as a soda-manufacturing process, by subsequently converting the sodium silicate into carbonate or hydroxide.

Hydrofluoric acid is mentioned in Weldon's patents of March 1, 1866, which are quite impracticable.

Calcium bisulphite and sodium sulphate yield calcium sulphate and sodium bisulphite. By heating the latter SO_2 is given off; the residual Na_2SO_3 is converted by lime into NaOH and calcium sulphite (Gutzkow's U. S. Pat. 198293, 1877).

A mixture of carbon dioxide and monoxide is supposed to decompose sodium sulphate at a red heat into carbonate and sulphur dioxide (Kayser, Young and Williams, Eng. Pat. 7355, 1885). This process is entirely useless, according to the investigation of Watson Smith, and Hart (J. Soc. Chem. Ind. 1886, 643). It has been tried on a practical scale at the Hautmont works, in France, in an apparatus similar to that of Hargreaves and Robinson for the manufacture of sodium sulphate, as the reaction is a very slow one. The drawbacks found there were: that the mass crumbles to powder, which stops the passage of the gas; that it is very difficult to keep the temperature at the proper point; and that all the sulphur escapes in the shape of sulphur dioxide, too dilute for utilisation (Lunge, Pariser Ausstellungsbericht, 1889, 15).

Crude phenol from coal-tar was proposed by Staveley (Eng. Pat. 17657, 1887). He agitates it with milk of lime and treats the resulting solution of calcium phenate with sodium sulphate. Calcium sulphate is precipitated; the solution of sodium phenate is decomposed by CO_2 into sodium carbonate and free phenol, which is used over again. *Cp.* also Staveley's paper, J. Soc. Chem. Ind. 1888, 807. This process is ingenious, but no doubt impracticable, especially owing to the hardly avoidable loss of phenol.

Calcium hydrosulphide is employed by Haddock and Leith (*cf. infra*, sub. *Soda waste*); also by Simpson (Eng. Pat. 17765, 1890) in the following way: Saltcake, nitre-cake, or the like are converted by $Ca(SH)_2$ into $CaSO_4$ and NaHS; this is carried on in closed vessels under a pressure of 60–80 lbs. per square inch. The clear liquor is decomposed by CO_2, and the H_2S set free is passed into milk of lime, in order to re-form the original calcium hydrosulphide. The soda is precipitated as $NaHCO_3$. A special application of this process is made upon low-class phosphatic minerals, which are suspended in water and treated with H_2S, the $Ca(SH)_2$ in solution being employed as above, whilst the enriched phosphatic mineral remains behind.

Calcium phosphates are employed in another patent of Simpson's (Eng. Pat. 18835, 1890). They are made to react with sodium sulphate; the sodium phosphate thus formed is converted by lime into caustic soda and calcium phosphate.

Soda from Sulphate, after converting it into Sulphide.

By heating sodium sulphate with coal a mixture of sulphide and carbonate is obtained, and this process has been proposed from a very early period down to 1839, among others by Berzelius, Gay-Lussac, Graham, and Liebig. It is, however, quite impracticable for soda-making, except as an intermediary for other processes, in the first instance.

By adding calcium carbonate, which is Leblanc's process, and has already been described.

Barium carbonate has been proposed by Reinar (1858), in lieu of calcium carbonate, but there is no advantage in this, and the cost is much too great.

Carbonic acid. In 1819 Atwood obtained an English patent for the decomposition of Na_2S by CO_2.

Since that date many inventors have tried to develop processes for the manufacture of carbonate of soda by this reaction, among others: Gossage (1838), Hunt (1861), Theissig, Verstract and Oliver, Claus Gomeg, Weldon, Thompson (1887), Chance (1888), Parnell and Simpson (1888), Mathieson and Hawlicek (1886), Gossage and Williamson (1888).

Na_2S requires more than one equivalent of CO_2 for complete decomposition, in fact it is necessary to convert nearly all the soda into bicarbonate

$$Na_2S+2CO_2+2H_2O=2NaHCO_3+H_2S.$$

The bicarbonate of soda separating out in fine crystals. Most of the processes suggested differed only in the apparatus used to bring the carbon dioxide and sulphide into contact.

Hunt, however, suggested treating the solid sulphide with carbon dioxide and steam. Mathieson and Hawlicek suggested the use of a brine solution instead of water to dissolve the Na_2S in order to take advantage of the lower solubility of $NaHCO_3$ in brine than in water.

Gossage and Williamson for some years made determined efforts to succeed with this process, but as far as is known, the sulphide process is not in use to-day. The difficulties were: (1) The technical difficulty of making the sodium sulphide itself, owing to its rapid action in the fused state on silicious material; (2) the fall in price of carbonate of soda owing to the development and cheapening of the ammonia soda process.

Sodium bicarbonate decomposes Na_2S thus: $Na_2S+2NaHCO_3=2Na_2CO_3+H_2S$. This reaction has been several times patented as a soda-making process (first by Wilson in 1840), but it seems to have a chance of success only as a means of purifying the liquor of the Leblanc process from the Na_2S always contained therein, and even there the action is not instantaneous.

On the contrary, sodium sulphide cannot be completely decomposed by CO_2, until about 1·6 equivalents of CO_2 are present to 1 equivalent of soda.

Alumina mixed with sodium sulphide is treated in a current of hot air by Liermann (1878); sodium aluminate is formed, and the gaseous products which escape are passed into a vitriol chamber.

Metallic oxides—such as copper, zinc, lead, iron or manganese oxide—have been very frequently proposed for decomposing Na_2S into a metallic sulphide and caustic soda. These proposals have hitherto mostly failed, first, on account of the difficulty of preparing Na_2S on a manufacturing scale; second, because in practice much more than an equivalent of the metallic oxide is required for effecting a complete decomposition of Na_2S; third, because the recovery of the metallic oxide from the sulphide is too costly, always entailing a loss of some of the metal, and never effecting a thorough utilisation of the sulphur. Such processes have been found more useful for purifying Leblanc's liquors from Na_2S. Still, attempts are continually made in this way—*e.g.* by Lalande (D. R. P. 41991, 1887). Lalande's process (which employs zinc oxide) has been found to effect the desulphurisation very well when tried at the St. Gobain works, but the separation of the ZnS and the regeneration of ZnO were found to be too troublesome.

Another form of this type of process has been invented by Ellershausen (Eng. Pats. 1015, 9112, 16676, 1890). He first forms a 'ferrate of soda,' similar to Löwig's (p. 48), by heating sodium carbonate with ferric oxide; on filtering a solution of sodium sulphide through a layer of ferrate of soda, the sodium sulphide is entirely converted into sodium hydroxide, which can be easily manufactured into commercial caustic soda. The sulphur is retained in the form of an insoluble ferrosodium-sulphide, to which Ellershausen gives the formula $Fe_2Na_2S_4$, and which retains one-sixth of the total soda.

Iron or **iron oxides** decompose Na_2S also at a red heat. Malherbe in 1778 proposed iron which was oxidised by the fire gases. Blythe and Kopp, in 1855, patented the use of iron oxides. Their process was tried on a large scale, but given up as useless; and this result has been confirmed by very extensive experiments on a manufacturing scale made by Lunge in 1865. There is a double sulphide formed in this process, the formula of which is stated by Stromeyer (Annalen, 107, 233) to be $Fe_2Na_2S_3$; this must be decomposed by CO_2 in order to yield Na_2CO_3 and FeS; but much H_2S escapes, and the FeS is much too impure to be burned for SO_2, as had been intended by Blythe and Kopp. The mass, moreover, contains much sodium thiosulphate and re-formed sulphate, and the furnace bottoms are very strongly acted upon, whatever material may be used for them.

Manufacture of Soda from Sodium Nitrate.

A very large quantity of sodium nitrate is indirectly converted into carbonate, inasmuch as it is first worked for nitric acid, and the residual acid sulphate ('nitre-cake') is worked up along with common salt in the ordinary decomposing pans. A considerable number of proposals have been made for making soda purposely from sodium nitrate, always, of course, with the condition of fully utilising the nitric acid as well. For some time artificial potassium nitrate was made by decomposing native sodium nitrate by *potassium carbonate*, chiefly in the impure form of carbonised 'vinasse,' from the manufacture of beet-root sugar; but this process has long been superseded by the use of Stassfurt potassium chloride.

Silica or *alumina* expel nitric acid from $NaNO_3$; so does *calcium carbonate*; in all cases the reaction takes place at such high temperatures that the nitric acid is decomposed, and although its re-composition can be effected by an excess of air and water, this costs too much to compete with the ordinary manufacture of nitric acid. The vessels employed are also corroded to an enormous extent. The advantage of obtaining the sodium in the shape of silicate, aluminate, or even hydroxide cannot compensate for these drawbacks.

Ferric oxide is used by Bradburn (Eng. Pat. 6710, 1889) to convert sodium nitrate (being the residue of Dunlop's chlorine process) into hydroxide.

Manufacture of Soda from Felspar.

Soda felspar has been several times proposed for manufacturing soda—*e.g.* by Ward and Wynants (1857 and 1864), who heated it with fluorspar, chalk, and lime; but this process has been found far too costly even for potash, and is not likely ever to answer for soda.

Manufacture of Soda from Cryolite.

This mineral is found mainly in one locality—namely, the bay of Evigtok, in South Greenland, where it was discovered by whalers, and again by Giesecké (1806–1813). Since 1849 it has become of some importance, because Julius Thomsen, of Copenhagen, proved it to be easily decomposable by lime, and to yield very pure soda and alumina. It was first worked upon a large scale in 1854, and several factories were erected for this purpose in various parts of Europe, but since 1865 the Pennsylvania Salt Manufacturing Company at Natrona, near Pittsburg, has obtained the control of nearly all the available mineral, so that no soda is made from it elsewhere.

Cryolite is a double fluoride of aluminium and sodium, of the formula $Al_2F_6,6NaF$; in the pure state it contains 12·85 Al, 32·78 Na, 54·37 F, corresponding to 24·23 Al_2O_3 and 44·17 Na_2O, but as it comes into trade it usually contains about 15 p.c. of impurities (galena, pyrites, fluorspar, limespar). It is a snow-white mineral, easily fusible, and soluble in concentrated sulphuric acid, but insoluble in hydrochloric acid.

Thomsen's process for working it up (which is the only one carried out in practice) consists in igniting it with calcium carbonate, when CO_2 escapes and soluble sodium aluminate, with insoluble calcium fluoride, remain behind:

$$Al_2F_6 \cdot 6NaF+6CaCO_3=Al_2O_3,3Na_2O+6CaF_2+6CO_2.$$

Finely-ground cryolite (100 parts) is intimately mixed with 150 parts of ground chalk, and some of the impure CaF_2 obtained in the process itself is added to the mixture, which causes it to decompose more completely and greatly increases the yield of valuable products. The mass must be spread in a thin layer, and must be heated to a red heat, but short of being fluxed, which would cause an imperfect decomposition. This is done in furnaces specially constructed by Thomsen for this purpose, which finish each charge of 9½ cwt. in 2 hours (*cf.* Lunge's Sulphuric Acid and Alkali, iii. p. 220).

The furnace charge is put, while hot, into the lixiviating tanks, and is methodically washed. The residue from this operation is an impure calcium fluoride (containing 62 p.c. CaF_2, 12 p.c. $CaCO_3$, 5·6 p.c. CaO, &c.). It is used for making bottle glass, for enamelling stone ware, as a metallurgical flux, &c. The solution of sodium aluminate obtained, which tests from 48°–60° Tw., is decomposed in revolving cylinders, or in vessels provided with agitators, by the carbon dioxide from a lime kiln.

The final result of the decomposition is stated thus:

$$Al_2O_3,3Na_2O+3CO_2+3H_2O=Al_2(OH)_6+3Na_2CO_3;$$

but in reality a compound of 45 p.c. alumina, 20 p.c. sodium carbonate, and 35 p.c. water is precipitated in a granular state, and must be freed from soda by long washing with hot water. This is carried on until the aluminium hydroxide contains only 2 p.c. of soda. Most of it is converted into aluminium sulphate by dissolving it in dilute sulphuric acid at 90°C., and boiling down the solution in copper pans to the consistency of treacle; it is then poured into moulds and solidifies on cooling. The richest commercial article contains 20 p.c. Al_2O_3.

The solution produced in the precipitating vessels is boiled down to 66°Tw., and on cooling yields a crop of extremely pure soda crystals, containing hardly more than ½ p.c. of foreign salts. The mother-liquors are so pure that they can always be taken back again into the process.

THE COMMERCIAL SODA TEST.

The commercial soda test used for trade purposes for both caustic soda and soda ash does not agree with the real percentage of Na_2O in the product. This is well known to the trade and is universally accepted under the name of the Liverpool test.

The discrepancy between real soda and the commercial test originated in the early days of the manufacture, when the equivalent of Na_2O was considered to be 32 and of Na_2CO_3 54.

The percentage of Na_2O in Na_2CO_3 was therefore considered to be 59·26 p.c. Na_2O. With the modern equivalents of 31 : 53, the actual percentage of Na_2O in Na_2CO_3 is of course 58·49 p.c. Na_2O.

In the same way, a caustic soda with an actual test of 70 p.c. Na_2O would, by the commercial test, be said to contain 70·92 p.c. Na_2O. A. C.

Sodamide $NaNH_2$ was discovered by Gay Lussac and Thénard. It is produced when a solution of sodium in liquid ammonia is allowed to stand at the ordinary temperature:

$$2Na+2NH_3=2NaNH_2+H_2$$

The reaction is considerably accelerated by the presence of a catalyst, such as platinised asbestos.

The usual method of preparation, and the one employed technically, consists in passing a stream of dry ammonia gas over metallic sodium heated to 300°–400° in an iron retort, when it is obtained as a waxy mass which is white when perfectly pure, but usually possesses a brownish or greenish tint due to the presence of traces of other substances.

When heated, sodamide softens at 149° and melts at 155°, forming a bright green liquid. At a red heat it decomposes slowly into its elements, but it may be distilled under ordinary pressure at about 400° with only slight decomposition. On exposure to air it absorbs moisture and carbon dioxide and becomes converted into a mixture of sodium nitrite, carbonate and hydroxide. Sodamide is an exceedingly reactive substance; heated in a current of carbon dioxide it glows, and is converted into cyanamide:

$$2NaNH_2+CO_2=2NaOH+CN \cdot NH_2$$

with nitrous oxide it yields sodium azide:

$$NaNH_2+N_2O=N_3Na+H_2O$$

It is decomposed by water with explosive violence, producing ammonia and caustic soda, and acts as an extremely powerful dehydrating agent. On this account it has of late years been manufactured on the large scale for use in the artificial indigo industry to replace the caustic soda formerly employed to remove water in the conversion of phenylglycocoll into indigo blue (*vide* INDIGO, ARTIFICIAL).

It has also found application in many other organic syntheses, and in the preparation of pure hydrazine, which it yields when heated with hydrazine hydrate.

Sodamide is an intermediate product in the manufacture of sodium cyanide. In this process, ammonia is led into a fused mixture of sodium cyanide, metallic sodium and carbon, when the sodamide first produced reacts with the cyanide to form disodiumcyanamide:

$$NaNH_2+NaCN=CN \cdot NNa_2+H_2$$

At a somewhat higher temperature, this compound is decomposed by the carbon present, being converted quantitatively into sodium cyanide.

Sodium nitroprusside $Na_2[Fe(NO)(CN)_5],2H_2O$ was discovered by Playfair in 1850. In order to prepare it, powdered potassium ferrocyanide is treated with twice its weight of concentrated nitric acid, previously diluted with its own volume of water. The mixture turns brown, and carbon dioxide, cyanogen, nitrogen, and hydrocyanic acid are evolved. As soon as solution is complete the liquid is warmed on a water-bath until a few drops give a slate-coloured precipitate on the addition of ferrous sulphate. It is then allowed to cool, when crystals of potassium nitrate separate out. The solution separated from the crystals is neutralised with sodium carbonate, filtered, and evaporated, when ruby-red crystals of sodium nitroprusside are obtained, which must be recrystallised to free them from admixed nitrate.

Another method of preparation consists in mixing a concentrated aqueous solution of ferrous sulphate with a solution containing equal parts of potassium cyanide and sodium nitrite, and allowing the mixture to remain at the ordinary temperature for five hours. Ferric hydroxide is deposited, and nitrogen and nitric oxide evolved. The liquid is then heated to 25° for a short time, made slightly alkaline with caustic soda, filtered, and the sodium nitroprusside obtained by evaporation and crystallisation.

Sodium nitroprusside forms ruby-red rhombic crystals, which contain two molecules of water of crystallisation. It dissolves in 2½ parts of water at 15°, and in a smaller quantity of hot water. The solution decomposes on exposure to light with separation of Prussian blue and evolution of nitric oxide. A concentrated solution is used as a reagent for the detection of small amounts of sulphur existing in the form of alkaline sulphide, a deep violet colour being produced. The colour is sufficiently intense to be noticeable in a solution containing only 0·0000018 grms. of H_2S in the form of ammonium sulphide, and by employing a capillary tube when applying the test one-tenth of this amount can be detected. The solution to be tested must be as concentrated as possible, and an excess of caustic soda in the liquid should be avoided, as this tends to prevent the development of the colour. The most suitable alkali to employ is ammonia, an excess of which has no such retarding action (Reichard, Zeitsch. anal. Chem. 1904, 43, 222).

The nature of the coloured compound produced is at present a matter of uncertainty, but it is probably represented by the formula $Na_4[Fe(NO{\cdot}SNa)(CN)_5]$ as the action of thiourea on sodium nitroprusside yields a compound $Na_3[Fe(NO{\cdot}NH{\cdot}CS{\cdot}NH_2)(CN)_5]$ which is a carmine red powder, closely resembling the substance formed from nitroprussides and sulphides.

SOFT CEMENTS *v.* LUTES.

SOILS. (1) *Classification.* Various classifications of soils have been proposed, the most general may be described as 'Genetic,' in which the position of the soil is determined by its origin, and the factors of climate and vegetation which have given rise to it. Tulaikoff (J. Agric. Sci. 1908, 3, 80) distinguishes:

1. Laterite soils developed in humid tropical climates and marked by a large proportion of hydrated ferric oxide and alumina.
2. Wind blown loess soils.
3. Soils of the dry steppes, distinguished by their richness in soluble salts, often alkaline.
4. Black soils (Tchernozem), containing large quantities of neutral humus.
5. Gray forest soils containing less humus.
6. Peat and ashy soils (Podzol). In this group are included all the soils of Great Britain.
7. Tundra soils.

Under British conditions we may distinguish between sedentary soils which have arisen *in situ* through the weathering of the underlying rock, and drift soils (soils of transport or alluvial soils) which have reached their present position through the action of running water or ice. The mixed soils of steep slopes which have either been washed or rolled down from above and containing angular fragments of diverse origin are sometimes separated as colluvial soils.

The farmer is accustomed to classify soils according to the ease or otherwise with which they can be worked, as sand, loams, and clays, with suitable subdivisions, *e.g.* sandy loams. These terms possess, however, widely different meanings according to the amount of rainfall which prevails, and can only be given any scientific value by correlating them with the mechanical analysis of the soil.

(2) *Proximate composition of the soil: mechanical analysis.* The texture of the soil and the manner in which it will behave under cultivation are determined by the relative proportions of sand, clay, calcium carbonate, and humus or organic matter which it contains. By sand is meant the coarser particles generally consisting of silica. As it is convenient to take an arbitrary limit of size, sand may be defined as consisting of particles smaller than 1 and coarser than 0·04 mm. in diameter. Such material is distinguished by the small amount of water it will contain and by its lack of coherence when dry. Clay consists of the finest particles present in the soil and is distinguished by the large amount of water that it will retain, by its plasticity and impermeability to water when wet, and by its power of shrinking and cracking when dry and swelling again on wetting. When diffused through water, the clay particles can be flocculated or coagulated by small quantities of various soluble salts (Hall and Morison, J. Agric. Sci. 1907, 2, 244). The properties of clay have been attributed to the presence of a small proportion of colloidal material, but it is doubtful if any such distinction can be drawn. If we take 0·002 mm. as the superior limit of size for the clay particles they run down without any break to particles of ultra-microscopic size which remain indefinitely in suspension in a neutral liquid, forming what might be described as a 'colloidal solution.' While clay mainly consists of hydrated silicates of alumina (kaolinite) there are also present notable proportions of zeolites—double silicates of alumina with soda, potash, lime and magnesia, also ferric hydrates and an admixture of very finely divided silica. For the purposes of analysis, the clay particles are divided by their size and not by their chemical composition. It is generally convenient to distinguish the groups of particles intermediate between sand and clay as silts.

All fertile soils contain some proportion of calcium carbonate finely disseminated throughout the soil. The proportion may vary from 60 p.c. or more in purely calcareous soils down to an inappreciable amount. Soils in which calcium carbonate and clay predominate are usually distinguished as marls.

The organic matter of soils consists in the main of the débris of previous vegetation. It is a mixture of various complex substances, some of them containing nitrogen, and from it a few distinct compounds have been isolated (*see* Schreiner, U.S. Bureau of Soils, Bull. 53 and 74). In fertile soils the organic matter usually possesses a neutral reaction and largely consists of calcium salts of the so-called 'humic acid.' Humic acid does not possess any distinct composition and though it may in part be identical with the humic acid that can be prepared by the decomposition of sugar, it cannot be obtained from soil in a state free from nitrogen. Humic acid is soluble in ammonia and other alkalis and may be extracted from soil, peat, &c., by first treating the material with hydrochloric acid to decompose the calcium humate, washing, and then extracting with an alkali solution from which it may be precipitated by acid. Soils in which the organic matter predominates are always black in colour, retentive of water and possessed of a very friable texture when dry. These peaty or boggy soils may be either acid in reaction, *e.g.* peaty and moorland soils, or neutral like the soils of the Fens.

The separation of the soil into its proximate constituents is known as a mechanical analysis, and the process consists in grading the particles (*a*) according to the velocity of the stream of water by which they can be carried, or (*b*) according to the time in which they will remain suspended in a column of water of a given height. The two methods are identical in principle and may be made to give similar results, but in most laboratories it is convenient to adopt the beaker method of separation by suspension.

A. *Sampling.* In Great Britain, the layer down to a depth of 9 ins. is usually considered to represent the soil. Probably a depth of 20 cm. would have been more satisfactory, since it represents more nearly the layer which is usually stirred by the plough, but so many analyses have now been made on the 9 in. basis that it is desirable to retain the convention. In certain cases of very shallow soils the soil changes suddenly at a smaller depth than 9 ins. into something which can hardly be regarded as sub-soil, as for instance, into pure chalk rock. In these cases, the sampling must be stopped at the line of division, which should be recorded. To obtain a sample two methods are commonly employed. In the first, a steel box, 6 ins. in section, is driven into the ground to a depth of 9 ins. and its contents removed. In the second case, an auger of not more than 2 ins. in diameter is employed. It is always necessary to take a number of samples on the same piece of land and mix them before analysis, and the advantage of the auger method lies in the number of samples that can be quickly obtained without unduly increasing the bulk of material to be handled. The first sampling is usually followed by a second one, taking the second 9 ins. to represent the subsoil. Small samples for examination, and even for approximate analyses, may be rapidly obtained down to a considerable depth by means of an auger such as is used by shipwrights. For details of sampling, Hall's 'The Soil' (Murray, 1908), p. 47, may be consulted.

The samples, on reaching the laboratory, should be spread out on shallow trays to dry at a temperature not exceeding 40°. The process is much accelerated by occasionally stirring and by crumbling down the lumps of the stiffer soils with the fingers before they become quite dry. The dried soil is passed through a brass sieve with holes 3 mm. in diameter, the lumps being gently worked down in a mortar with a wooden pestle. The material passing through the sieve is approximately weighed and also the material remaining on the sieve, which is then thoroughly washed on the sieve under a stream of running water. After drying, the stones which remain on the sieve are weighed to obtain the proportion of stones in the total sample as brought from the field. The material which passes the 3 mm. sieve is regarded as the fine earth for analysis.

B. *Mechanical analysis.* Two portions of 10 grms. and one of 50 grms. of the fine earth are weighed out. One 10 grm. portion is dried for 24 hours at 100°, and then ignited in an open basin over an Argand at a dull red heat with occasional stirring to obtain (1) hygroscopic moisture, (2) loss on ignition. The second 10 grm. lot is placed in a basin and covered with 100 c.c. of N/5 hydrochloric acid to dissolve out the carbonates and break up the calcium humate. The soil is rubbed up into a fine paste with a rubber pestle made by fixing a small solid rubber bung on a stout glass rod. After standing for an hour the soil is thrown upon a tared filter and washed until all acid is removed. The filter and its contents are then dried, the loss representing the hygroscopic moisture plus soluble salts. The soil is now washed off the filter with water containing about 1 c.c. of ammonia in 500 c.c. water on to a small sieve made with No. 100 brass wire cloth, the portion passing through being collected in a beaker 7 or 8 c.c. in diameter with a mark on the side 8·5 c.c. from the bottom. The material on the sieve is dried and weighed to represent the coarse sand and fine gravel. As the proportion of this coarse material is likely to be affected by irregular sampling when determined on 10 grms. only, it is advisable to repeat these operations on the 50 grm. sample without, however, preserving the material passing through the sieve. The residue after drying and weighing is then divided into 'fine gravel' and 'coarse sand' by means of a sieve with round holes 1 mm. in diameter. The beaker containing the portion of the 10 grm. sample which passed through the wire cloth sieve is now well stirred up with the rubber pestle, filled to the 8·5 mark with ammoniacal water and put aside to stand for 24 hours. The turbid supernatant liquid is then rapidly poured off into a large jar, and the deposit at the bottom of the beaker is rubbed up with a rubber pestle and more ammoniacal water as before. The operations of filling up to the mark, standing for 24 hours, and pouring off the turbid liquid are gone through as before and repeated every day as long as any material remains in suspension for the 24 hour period. Generally, 7 to 10 decantations will be sufficient, after which the bulk of turbid liquid is evaporated down and finally brought into a tared basin, dried and weighed. This fraction consists of clay particles less than 0·002 mm. in diameter, together with a certain amount of humus. After drying it is ignited as before and reweighed to obtain the weight of the 'clay.' The sediment from which the clay has been removed is worked up as before in the beaker, which, however, is only filled to the depth of 7·5 cm. The contents are allowed to stand for 12½ minutes only, when the liquid is poured off into a large jar as before. The operations are repeated until all the sediment settles in 12½ minutes and the liquid above is left quite clear. The contents of the second jar are now evaporated to dryness and weighed as in operation 3, before and after ignition; this fraction is designated 'fine silt' and consists of particles between 0·010 and 0·002 mm. in diameter.

The sediment remaining in the beaker is worked up afresh just as in the previous operations, the mark being now placed 10 cm. from the bottom of the beaker, and the time of settlement fixed at one hundred seconds. The sediment is dried and weighed as 'fine sand' while the portion that is poured off is obtained by evaporation as in the previous operations and is designated as 'silt.' The soil has thus been divided into the following series—

	Diameter in millimetres		
	Max.	Min.	
1. Stones and gravel	—	3·0	Separated by sifting.
2. Fine gravel . .	3·0	1·0	
3. Coarse sand . .	1·0	0·2	
4. Fine sand . .	0·2	0·04	Separated by subsidence.
5. Silt . . .	0·04	0·01	
6. Fine silt . .	0·01	0·002	
7. Clay . . .	0·002	—	

The sizes of the particles in the above groups, which is determined by the depth of the liquid and the time of settlement, are purely conventional and are those in use by agreement in the United Kingdom. For discussion of the method *see* Hall, Chem. Soc. Trans. 1904, 85, 950.

Chemical Analysis.

As in a mechanical analysis, certain conventions as to the sampling, nature of the solvent, and time of its action have to be adopted. The conventions followed below are general in the United Kingdom. The air-dried fine earth passing the 3 mm. sieve is taken and a portion of about 100 grms. is ground in a mill or broken in a steel mortar until it all passes through a sieve with round holes 1 mm. in diameter. Hygroscopic moisture and loss on ignition are determined as before.

C. Nitrogen is determined in 10 to 20 grms. of the ground material by Kjeldahl's process; no correction need be made for the nitrate that is present.

D. The determination of calcium and other earthy carbonates is of great importance, especially when the amount is low. It is not sufficient to determine the calcium, which may be present in considerable amounts as silicate, humate, &c., even when the soil is acid from lack of calcium carbonate. The earthy carbonates are best determined from the carbon dioxide evolved on treatment with acid, being calculated as though they consisted entirely of calcium carbonate. The most exact method, when the quantity involved is small, consists in liberating the carbon dioxide by treatment with dilute acid at low pressure, absorbing the carbon dioxide by dilute caustic soda in a Reiset tower and estimating the carbon dioxide by double titration, first with phenolphthalein and then with methyl orange as indicators (*see* Amos, J. Agric. Sci. 1905, 1, 322).

E. For the determinations of soluble constituents, 20 grms. of the powdered soil are placed in a flask of Jena glass, covered with about 70 c.c. of strong hydrochloric acid, and boiled for a short time over a naked flame to bring the acid to constant strength containing about 20·2 p.c. of pure hydrogen chloride. The flask is loosely stoppered, placed on the water-bath, and the contents allowed to digest for 48 hours. The solution is then cooled, diluted, and filtered. The washed residue is dried and weighed as the material insoluble in acids.

The solution is made up to a litre and aliquot portions are taken for the various determinations. The analytical operations are carried out in the usual manner, but special care must be taken to free the solution from silica and organic matter.

For determination of the potash and phosphoric acid, 50 c.c. of the solution is taken and evaporated to dryness, about half a gram of calcium carbonate being added during evaporation if the soil is poor in calcium. The contents of the dish are then ignited over an Argand or a Bunsen burner at a black or very dull red heat, the material being constantly stirred with a small glass pestle made by flattening out the end of a glass rod. After cooling, a few c.c. of water is added and the mass is worked up with the pestle, 50–80 c.c. of water is then added and the contents of the dish are boiled for half an hour. The solution is filtered off, the residue washed and the solution taken for determination of the potash by precipitation with platinic chloride in the usual way. The residue is washed back on to the dish, 50 c.c. of water and 10 c.c. of strong sulphuric acid are added and the whole boiled for half an hour. The solution is filtered and used for the determination of phosphoric acid by precipitation with ammonium molybdate, the molybdic acid precipitate being either weighed or estimated by titration. In some cases, finely divided ferric oxide comes through the filter paper in making up the solution, in which case 5 c.c. of hydrochloric acid is added and the whole evaporated nearly to dryness. This will bring the iron into solution, when it will not interfere with the determination.

Calcium, magnesium, iron, manganese, and sulphuric acid may also be determined in the hydrochloric acid extract.

The determinations just described give what is commonly called the total plant food in the soil. It will be seen that the quantities revealed are usually very great, if we consider that the layer of soil down to the depth of 9 ins. over an acre weighs from 2½ to 3 million pounds. As a rule, hydrochloric acid will extract something in the order of 0·1 p.c. of phosphoric acid and from 0·3 to 0·5 p.c. of potash, proportions which would correspond to about 3000 pounds of phosphoric acid and 10,000 lbs. of potash per acre, whereas the average crop will remove not more than 50 lbs. of phosphoric acid and 200 lbs. per acre of potash. It is clear that the quantities thus determined throw very little light upon the need, or otherwise, for the application of particular fertilisers to the soil, since the soil is shown to contain far more than is sufficient for a maximum crop. Even the extraction with hydrochloric acid does not measure the total amount of plant food in the soil; if, for example, the soil is completely brought into solution by fusion with ammonium fluoride as much as 2 p.c. of potash may be found in clay soils, and this quantity is in a sense the only absolute measurement that can be made.

In order to obtain by analysis some practical guidance as to the requirements of the soil, attempts have been made to discriminate between the total amount of plant food in the soil and that which may be regarded as readily available to the plant, *i.e.* that which is soluble in such weak solvents as may be at work under natural conditions. In the soil *in situ* there is every reason to suppose that the solvent action is carried on by water containing carbon dioxide in solution, partly by the natural soil water, and partly by the more concentrated solution of carbon dioxide which forms in contact with the plant roots that are always excreting carbon dioxide. As the gases entangled in the soil always contain more carbon dioxide than ordinary air (up to 5 p.c. by volume), the soil water contains a corresponding amount of carbon dioxide, and so becomes a more effective solvent of phosphoric acid and potash. Attempts have been made to use water saturated with carbon dioxide as an analytical agent to determine the available mineral constituents in the soil; but although this is the solvent with the best *à priori* justification, its use has not been general and there are not sufficient data obtained by its means for comparison. For the present, therefore, it must remain as a research method hardly available for general analytical purposes. It is customary to employ a solution containing 1 p.c. of citric acid to determine the phosphoric acid and potash that may be regarded as available. Other available constituents which may be taken to measure the fertility of a given soil are the nitrates and the ammonium compounds and also the humus compounds soluble in dilute alkali—the soluble humus or *matière noire*—which represents that part of the organic matter in the soil likely to be readily oxidised.

F. *Nitrates.* The soil sample must be rapidly dried in the steam oven, since slow drying at temperatures a little above the normal would result in the formation of nitrates. After drying the soil is roughly powdered and passed through a 3 mm. sieve as before. 200 grms. of the sample are then packed on a Buchner funnel, 6 ins. in diameter, connected with a filter pump. The soil is washed with successive portions of hot water, and if care is taken to avoid plastering the wet soil it is possible to wash all the nitrates through in the first 100 c.c. or so of the water that reaches the filtering flask. The nitrates in the solution thus obtained are estimated by the standard methods. In the Rothamsted laboratory, it has been found most convenient to proceed by reducing them to ammonia by the zinc-copper couple, as devised by Thorpe (Chem. Soc. Trans. 1873, 26, 541). Strips of thin sheet zinc about 6 ins. long and 1½ ins. broad are cleaned by immersion in dilute caustic soda, followed by very dilute sulphuric acid, and are then dipped in a dilute solution of copper sulphate until they have obtained a heavy black deposit of copper. After washing finally in ammonia-free water they are placed in a bottle with the soil extract and a crystal of oxalic acid. The bottle is kept in a warm place or an incubator at 25° for 24 hours, then the ammonia is distilled off and determined by titration or by 'Nesslerising.'

G. For determinations of the ammonium salts, 100 grms. of the soil are placed in a distillation flask with 2 grms. of magnesia and 100 c.c. of water. The tube from the flask is connected to a 100 c.c. pipette which leads into a filter flask serving as a receiver and containing 50 c.c. of standard acid. The distilling flask is placed in a water-bath kept at 30° and the filter flask is connected with a pump to maintain a partial vacuum. Distillation at this temperature proceeds for 6 hours, after which the pipette is disconnected and the acid titrated (*see* Russell, J. Agric. Sci. 1910, 3, 233).

H. *Available phosphoric acid and potash.* 200 grms. of air-dried soil are placed in a Winchester quart bottle with 20 grms. of citric acid and 2 litres of water. By the original method (*see* Dyer, Chem. Soc. Trans. 1894, 65, 115), the contents of the bottles are shaken up from time to time for 7 days and then filtered; but it has been shown that identical results can be obtained in 24 hours if the bottle is placed in an end-over-end shaker and kept in continuous agitation. After filtering, two portions, each of 500 c.c., are taken for the determination of phosphoric acid and potash by the methods previously described, after evaporation and incineration to get rid of the citric acid and dissolved silica.

I. *Soluble humus.* 10 grms. of the air-dried soil are treated with dilute hydrochloric acid in order to decompose the humus as in the method for mechanical analysis. After filtering and washing away the acid the soil is washed into a flask with 500 c.c. of 4 p.c. solution of ammonia. Flask and soil are then shaken for 24 hours, allowed to stand for several hours, and filtered until 200 c.c. of filtrate are obtained. This, representing 4 grms. of the original soil, is then evaporated to dryness in a tared basin and weighed. The basin and its contents are ignited to determine the ash and inorganic matter also present, the weight of which must be deducted from the weight of soluble humus previously obtained. Determinations are sometimes made of the nitrogen contained in the soluble humus; 50 c.c. of the extract are placed in a Kjeldahl distillation flask and evaporated nearly to dryness with the addition of 2 grms. of magnesia, after which the residue is digested with sulphuric acid and the nitrogen estimated in the usual way.

J. *Physical determinations.* In addition to the mechanical analysis of soils, several other physical constants of soil have, from time to time, been determined: for example, the maximum and minimum water capacity, the capillarity, the apparent and real density, the hygroscopic moisture, the heat evolved on wetting (Benetzung-wärme), specific heat, &c. The methods by which these determinations are made may be found in standard works on soil, but at the present time little value can be attached to the results. In many cases, the results are conditioned by the state into which the soil has been brought by the process of sampling, and as no satisfactory method exists of testing the soil *in situ* or bringing it in an unchanged condition into the laboratory, determinations made upon the usual samples possess no value. Further, in nearly all cases it is difficult to attach any interpretation to the results, *i.e.* to correlate them with the behaviour of the soil in the field. To two determinations, however, some practical value may be attached, viz. the hygroscopic moisture and the water content when the soil is in its optimum working condition and possesses a crumb structure. Hygroscopic moisture is usually determined by exposing the dried soil in a shallow tray to an atmosphere saturated with moisture at the ordinary room temperature. The dish containing the soil is placed under a bell jar over water and the interior of the bell jar is lined with filter paper which dips into the water below. It will be found almost impossible to obtain consistent results by this method because of the deposition of dew upon the dish or the soil. A better method is to place the soil in a shallow layer in a flat boat contained in a wide tube. The tube is immersed in a water-bath, maintained at a constant temperature of 25° by a thermostat, and a slow current of air is drawn over the soil, the air current being previously bubbled through a potash bulb containing water immersed in the same bath, so as to become saturated with vapour at the temperature of the experiment. Consistent and comparable results can in this way be obtained, and the hygroscopic moisture thus determines serves as a measure of the absorbing surface possessed by the soil. The water content of the soil in its optimum working condition is a conception introduced by F. K. Cameron (J. Phys. Chem. 1910, 14, 320) and represents that condition in which the soil can be cultivated and made to break down into small particles without puddling. Several pounds of the soil in a dried condition are placed in a large basin and slowly wetted with a fine spray of distilled water; the soil is carefully worked about with the hands to equalise the wetting, and it will be found that a point is eventually reached when the soil is distinctly moist and yet can be broken down to a crumb without getting into a pasty condition. If the moisture is increased beyond this point, the soil becomes obviously wet and gets sticky and puddled when any attempt to work it is made. The experimenter must use his judgment as to when the right point has been reached, then a sample of the soil is taken and its water content determined. With a little practice it will be found that successive results can be obtained with the same soil that agree within 1 or 2 p.c. The mean of several determinations may be taken as the optimum water content.

For further particulars, the following books may be consulted: Hall, The Soil, London, 1908; Hilgard, Soils, New York, 1906; Wiley, Principles and Practice of Agricultural Analysis, vol. i.; Ramann, Bodenkunde, Berlin, 1911.

Bacteria of the Soil.

A recognition of the importance of the biological factors at work in the soil is comparatively recent, indeed it can hardly be said to date further back than 1877, when Schloesing and Müntz showed that the formation of nitrates from the organic nitrogen compounds in the soil is a process brought about by a living agency. It is now agreed that as regards all the compounds of carbon and nitrogen present in the soil, their transformation into compounds capable of serving as food for plants is brought about by micro-organisms of one class and another, and that the fertility of the soil is very largely determined by the relative activity of the different groups. It is possible to show by the ordinary methods of plate culture that the soil contains bacteria in numbers of the order of 0·5 to 50 million per gram of soil, and there are several important groups of bacteria which do not grow on the usual gelatine media and therefore do not get included in this account. In addition to the bacteria, the soil possesses a micro-flora of yeasts, moulds, and other fungi, while latterly certain higher organisms—protozoa and amœbae, nematodes and the like, have been shown to play an important part in determining the activity of the lower organisms and therefore the fertility of the soil. A large amount of work has been done in the way of isolating and describing particular organisms present in the soil, but for practical purposes it is less important to identify species than to ascertain the collective activity of groups of organisms which possess the same function. Many efforts have been made to measure the activity of these various groups so as to obtain a quantitative estimate of the factors which determine the preparation or destruction of plant foods, but it cannot be said as yet that the methods devised are satisfactory, or have received general acceptance as leading to results which can be correlated with the fertility of the soil when determined by the yield of test plots.

The soil organisms may be conveniently grouped under the following heads:—

(*a*) Humus-making organisms which transform carbohydrates and other plant residues into humus.

(*b*) Nitrogen-fixing organisms which are capable of taking up free gaseous nitrogen and bringing it into combination in the material of which their own cells are composed.

(*c*) Ammonia-making organisms which attack the proteins and other less complex compounds of nitrogen and break them down with formation of ammonia.

(*d*) Nitrifying organisms which oxidise ammonium compounds and give rise to nitrites and nitrates.

(*e*) Denitrifying organisms which reduce nitrates to nitrites and to free nitrogen gas. In this group are generally included a further set of organisms, probably distinct, which set free nitrogen gas from organic compounds of nitrogen.

In addition to these main groups there are other organisms which sometimes play an important part in the soil, for example, the reducing organisms which form sulphides, hydrogen sulphide, and free sulphur from sulphates, and the iron organisms which secrete hydrated ferric oxide from solutions containing ferrous carbonate.

1. The relative predominance of organisms of the bacteria or fungoid type seems to be

determined by the reaction of the soil. In neutral or very slightly alkaline soils, bacteria predominate, in acid soils, micro-fungi are chiefly active and many important groups of bacteria, such as those bringing about nitrogen fixation and nitrification, may be entirely absent.

For the determinations of the number of organisms present in the soil, and indeed for all determinations of bacterial action, special samples must be taken.

A thin brass tube about 1 in. in diameter, sharpened at the lower end like a cork borer, is forced into the soil to a depth of 6 ins., then placed in a sterilised glass tube plugged with cotton wool for removal to the laboratory.

Another method which is more convenient, as yielding samples from various depths, begins by the construction of a special boring tool which can be driven into the ground. The tool consists of two strips of steel, ⅛ in. in thickness, 8 ins. long and 2 ins. wide, each bent down the whole length of the strip so as to form two wings, 1 in. wide, at right angles to one another. The edges are then bevelled off until the two pieces of steel can be put together so as to form a box, 1 sq. in. in section and 8 ins. long, in which position the pieces are retained by steel rings which can be forced over the two ends. The lower end of the tool is sharpened and it is then driven into the soil to the required depth of 6 ins. After removal, the rings can be knocked off, whereupon the box falls apart showing a square core of soil, any portion of which can be taken. In the laboratory the soil, still in a moist condition, is carefully broken down with a spatula and is worked through a sieve with holes 3 mm. in diameter. Two portions of 25 grms. are weighed out, one is dried to determine the water content, the other is shaken up for about 5 minutes with 250 c.c. of sterile physiological salt solution, containing 0·5 p.c. sodium chloride and 0·2 p.c. of magnesium sulphate. From this turbid liquid, 1 c.c. is pipetted off and added to another flask containing 99 c.c. of similar sterile salt solution. After well shaking 1 c.c. from this dilution is again transferred to a further 99 c.c. of sterile salt solution, and after again shaking 1 c.c. of this last dilution is added to a test tube containing 10 c.c. of nutrient gelatine, and the plate poured in the usual way. The plates are incubated for 8 days at a temperature of 20°; each plate represents 0·0001 gram of soil in its moist state. The gelatin medium usually employed contains 1 p.c. of beef extract, 1 p.c. of peptone, and 0·5 p.c. of sodium chloride with 10 to 12 p.c. of gelatin. A gelatin medium has the advantage of showing the liquefying organisms, of which a separate count can be made; humus-making organisms can also be distinguished by the furry appearance of the colonies or even by the formation of a brown ring, but the gelatin has the disadvantage of inhibiting a number of organisms which do not develop in the presence of much organic nitrogen. In place of the gelatin, 1·5 p.c. agar may be used; but though the agar plates permit of the growth of other organisms, they do not distinguish between liquefying and non-liquefying organisms, and many motile organisms work about the surface and may obscure the results or give rise to secondary colonies. Another useful medium is soil-extract agar made up as follows: Equal quantities of water and soil are boiled for half an hour and filtered, the liquid being further filtered through a Chamberland filter to get a clear extract. To the extract, 1 p.c. peptone and 1 p.c. dextrose or 1 p.c. dextrose alone are added, and the jelly is made up with 1½ p.c. agar as usual. This medium, without peptone, will permit of the growth of the nitrogen-fixing organisms, though it will inhibit the putrefactive, ammonia-splitting, and other organisms dependent upon combined nitrogen.

Another method of determining the collective action of the bacteria of the soil has been devised by Russell (J. Agric. Sci. 1905, 1, 261). He determines directly the oxidising power of the soil and finds it correlated with its fertility. The apparatus consists of a bulb of about 100 c.c. capacity with two tubes sealed into its neck, one of which is a long narrow tube dipping into mercury and constituting a gauge, while the other expands into a small flask partly filled at the beginning of the experiment with a solution of potash. 10 grms. of air-dried soil are placed in the flask with 2 c.c. of water, the flask is then sealed up and placed in a water-bath maintained at a constant temperature of about 20°. The apparatus is left for several days, whereupon the oxygen contained in the enclosed air is slowly converted into carbon dioxide which is absorbed by the potash, resulting in the diminution of the pressure of the enclosed air. Finally, the rate of oxidation is determined by the reduction in pressure which has taken place. It is necessary to make comparative trials with soils whose behaviour in the field is known, and while no absolute value can be given to the results, they are valuable as measuring the gross rate of bacterial activity in the soil and as supplying valuable indications of its fertility.

2. *Humus making organisms.* The decay of organic matter in the soil seems to proceed in two distinct fashions; in the presence of air the organic matter is broken down by micro-organisms of all kinds with the eventual production of carbon dioxide, water and ash. On the other hand, if the decay takes place under conditions which exclude oxygen, the process is more limited; carbon dioxide, marsh gas, hydrogen and other compounds are produced and there is left behind a black material containing more carbon but less oxygen and hydrogen than the original vegetable matter. Both aerobic and the anaerobic decay gives rise to brown or black humus compounds, but it is not certain whether the same organisms take part in both processes or which predominate under ordinary soil conditions of partial exclusion of oxygen. The anaerobic processes have been studied in some detail, and Omelianski has isolated two organisms which are capable of attacking carbohydrates like cellulose. In one case, the products are carbon dioxide, hydrogen, various organic acids, and humus; and the other, which is perhaps the more general, carbon dioxide, methane, butyric and other organic acids, are produced. The process may be readily illustrated by filling a flask with a nutrient solution containing 0·1 p.c. KH_2PO_4, 0·1$(NH_4)_3PO_4$, 0·05$MgSO_4$, and a trace of NaCl,

and introducing strips of filter paper with a small quantity of soil, or better still of pond mud. The flask is closed with an exit tube dipping down into water. After some days' incubation at 34°–35°, the filter paper will begin to disintegrate, at the same time gas will be given off consisting of a mixture of carbon dioxide, nitrogen, methane, and sometimes hydrogen. Humus may be either acid (as in peat soils), or neutral when it is formed in the presence of calcium carbonate, as is usual in soils.

Nitrogen fixing organisms. The first demonstration that the soil contains bacteria capable of bringing gaseous nitrogen into combination was due to Hellriegel and Wilfarth in 1886, who showed that the small nodules which may be found upon the roots of clover, beans, and other leguminous plants contain colonies of bacteria living symbiotically with their host plant, deriving from it the carbon compounds which they need, and handing over nitrogen which they have 'fixed' from the atmosphere with which the plant roots are in contact. It was found that clover and other plants possessing such nodules upon their root do become richer in nitrogen and that in practice the soil is markedly enriched by their growth. Such gains in nitrogen only take place when the seedling plant can become infected either by growing in soil which normally contains the organism, or by addition to a sterile soil of either the extract from a nodule of some infected plant or a trace of normal soil. To the organism the name of *Pseudomonas radicicola* has been given, and further investigation has shown that while only one general species can be distinguished it has, to a certain extent, been specialised by association with particular plants. Thus better results are obtained when beans are inoculated with the organism derived from a nodule of a bean plant than with organisms from a lupin plant, and in some cases (lupins and lucerne) this specialisation has proceeded so far that the plant is only very slightly infected by the neutral form of the organism which exists in ordinary soil. In the soil, the organism appears to exist in minute rod-shaped organisms in rapid motion which infect the plant by passing through the cell walls of the root hairs. Inside the plant, the organism first of all develops into much larger rod-shaped organisms, which finally become, in the nodules, characteristically bent or Y-shaped organisms known as bacteroids. It is possible to cultivate *Pseudomonas radicicola* on the non-nitrogenous media described above, as, for example, soil-extract dextrose, agar-agar, but the fixation of nitrogen under these conditions is inconsiderable.

From time to time, soils are found, the commonest example being peats and heaths of an acid reaction, in which *Pseudomonas radicicola* is not present, and when these soils are brought into cultivation, leguminous plants do not at first develop nodules and fix nitrogen. In this case, it may be desirable to proceed to an inoculation of the soil which, however, must first be rendered a suitable medium for the development of the organisms by the removal of its acidity and the addition of lime and phosphates. One method of effecting the inoculation is to strew over the field about $\frac{1}{2}$ ton to the acre of soil taken from a cultivated field on which the leguminous plants have been growing normally. Another method is to prepare an active culture of organisms from a nodule of the crop it is desired to sow, and with this prepare a large bulk of sub-culture by introducing it into ordinary tap water in which $\frac{1}{10}$ p.c. of dextrose and $\frac{1}{100}$ p.c. potassium phosphate have been dissolved. Into the large bulk of crude culture thus obtained after standing two or three days, the seed, tied up in a thin muslin bag, is dipped and allowed to dry somewhat before sowing, when it will be found to carry with it sufficient organisms to ensure inoculation. As a rule, the leguminous crop still grows rather indifferently after its first inoculation, and only really flourishes when grown for a second or third time after the organism has established itself in the soil. Many attempts have been made to improve the growth of leguminous crops in ordinary soil by inoculating them before sowing, but, except in the special cases just mentioned, no success has attended the process. Amongst ordinary farm crops, the only call for inoculation appears to occur with lucerne when attempts are made to grow this plant on soils which have not hitherto carried it, since lucerne does not seem to be readily infected by the neutral form of organism, such as that left by the clover which may have been regularly grown on the same soil previously. Since the discovery of *Pseudomonas radicicola*, other organisms have been discovered living free in the soil which are capable of bringing nitrogen gas into combination. Winogradsky isolated from pond mud and other similar material under anaerobic conditions a widely diffused organism called *Clostridium pastorianum* which breaks down carbohydrates with the formation of humus, butyric acid, &c., accompanied by the fixation of a small amount of nitrogen—two to three mgm. for each gram of carbohydrate destroyed. The most important of the nitrogen fixing organisms, however, is one discovered by Beijerinck, named by him *Azotobacter chroococcum*, which as such or as one of its closely allied forms has been isolated from soils in nearly all parts of the world. Its presence can be readily determined by adding a small portion of soil to 50 c.c. of sterile culture fluid containing per litre 10 grms. of mannite or glucose, 0·2 grm. each of potassium phosphate, magnesium sulphate, and sodium chloride, and 0·1 grm. of calcium sulphate and a trace of ferrous sulphate. The solution is placed in a small Erlenmeyer flask, $\frac{1}{2}$ grm. of calcium carbonate added, the flask is plugged and its contents sterilised. After adding the soil the flask is placed in an incubator at 25° for a week, by which time a considerable fermentation will be found to have taken place accompanied by the evolution of carbon dioxide and the formation of a brown scum upon the surface of the liquid. *Azotobacter* is a powerful oxidising organism, converting the carbohydrate into carbon dioxide and water, together with small quantities of lactic and acetic acid, alcohol and sometimes butyric acid. At the same time about 9 to 10 mg. of nitrogen are fixed for each grm. of carbohydrate oxidised. *Azotobacter* is a large oval organism, 4 to 5 μ in length and 3 μ in width. It differs from most bacteria in containing glycogen, so that it stains a deep brown colour with a solution of iodine. *Azotobacter* is not found on acid soils, the presence of calcium carbonate is essential to its development; to it and kindred organisms must be attributed a large share of the formation and maintenance of the stock of nitrogen contained in soils. Particularly to this agency do we look to explain the formation of the deep black soils of the Russian Steppes, the American North-West, Argentina, &c. It is, however, essential that the organism shall receive a supply of carbohydrate, by the oxidation of which it obtains the energy required to bring gaseous nitrogen into combination. At Rothamsted, it has been shown that the soil of the wheat field, from which the whole crop with the exception of a small quantity of roots and stubble is removed, gains very little nitrogen by bacterial agency, although the *Azotobacter* is present in the soil. An adjoining piece of land, however, on which the débris of grass and other wild vegetation fall back to the soil and is not harvested, there have been accumulations of nitrogen at a rate approaching 100 lbs. per acre per annum over a period of 25 years, and this case is parallel to the formation of the virgin soils above mentioned.

3. *The ammonia-making organisms.* As a group the ammonia-making organisms have not received much study, although recently it has been shown that the fertility of the soil must be largely determined by their activity. The greater number of the organisms found in the soil—the organisms, for example, which grow upon gelatin plates including such well known putrefactive organisms as *Proteus vulgare, Bacillus mycoides, B. mesenterieus vulgatus, B. subtilis, Bact. fluorescens liquefaciens, B. coli,* &c., must belong to this group. Their general function is well known; they are capable of attacking proteins and resolving them successively into a lower form of combination, amino acids, &c., until at last the nitrogen reaches the state of ammonia. In addition the soil contains other organisms not capable of dealing with the proteins, but resolving the simpler nitrogen compounds into ammonia. Of these the best known are the urea splitting organisms, *Micrococcus ureae, Urobacillus pasteurii* and *Planosarcine ureae,* which hydrolise urea with formation of ammonium carbonate and water. These organisms which are exceedingly abundant in stables, cow stalls, &c., are also present in the soil. The dependence of the fertility of the soil upon the numbers of the ammonia-making organisms has been made evident by the work of Russell and Hutchinson (J. Agric. Sci. 1909, 3, 111) on the effects of partially sterilising soil by heat or by exposure to the vapour of antiseptics like chloroform, toluene, &c. These investigators found that a soil which had been heated to a temperature of 100° for 2 hours and then placed under normal conditions favourable to growth gave rise to a much increased crop, the yield being in many cases doubled, while the amount of nitrogen in the plant became three or four times as great as that on the untreated soil. This increased crop was found to follow to a large extent the rate of the formation of ammonia in the soil, the ammonia in this case being taken up as such by the plant, because the nitrifying organisms had been destroyed. It was also found that the soil was not completely sterilised by the processes; the spores of certain groups resist the heat and develop to an unprecedented extent when the soil was once more placed under conditions favourable for growth. For example, a normal soil is found to contain about 8 million bacteria per gram before being subjected to treatment, and this number remained comparatively constant under ordinary conditions of growth. After heating the number of organisms per gram was reduced to as few as 60, but they increased rapidly from day to day when the soil was moistened and placed in the incubator, until in a fortnight's time they amounted to 40 millions or over per gram. The increase in fertility proceeded *pari passu* with the increased rate of production of ammonia, which in its turn depended on the increase in the number of organisms.

It was evident from the experiments that the heating had removed a factor present in ordinary soil which inhibited the development of the bacteria beyond a certain point, and it was found that the untreated soil contained a number of large organisms—protozoa, amoebae, &c., which derive their sustenance from living bacteria. Under normal conditions an equilibrium exists between the numbers of these larger organisms and of the bacteria, and as the heating process kills off the larger organisms entirely while still leaving some of the bacteria, the latter can develop to a hitherto unprecedented extent in the absence of the factor which previously kept them in check. Exposure of the soil to the vapour of chloroform, toluene, &c., for 48 hours, followed by its complete evaporation, has the same effect in destroying the larger organisms while leaving a certain number of the bacteria or their spores ready to develop as soon as conditions favourable to growth are obtained. With these volatile antiseptics, however, destruction of the larger organisms is not so complete nor the gain of fertility so large. It has not yet been found possible to apply these processes of partial sterilisation to increasing the fertility of soils in the open, but considerable success has attended attempts to deal with greenhouse soils, which, owing to their conditions of richness in manure, high temperature and water content, afford a specially favourable medium to the development of the larger organisms.

4. *Nitrification.* The process of nitrification and the factors by which it has been governed have long been worked out in a practical way. For example, in the *Instruction sur la fabrication du nitre: Par les régisseurs Generaux des poudres et saltpetres,* 1777, the formation of nitre beds is carefully described. They were made up of earth containing a certain amount of calcareous matter, mixed with dung and other nitrogenous residues. They were protected from the weather and carefully watered from time to time with diluted urine and other materials containing nitrogen. After two or three years, the contents of the bed were lixiviated, and the solution of calcium nitrate obtained was concentrated and treated with potassium sulphate, whereupon potassium nitrate could be crystallised out of the clarified mother-liquors. It was thus recognised that

soil is capable of converting organic compounds of nitrogen into nitrates in the presence of a base like calcium carbonate, and that warmth and a certain proportion of moisture are factors favourable to the process.

That the process was due to a living agency was first demonstrated by Schloesing and Müntz in 1877. These investigators showed that the action ceased if the soil was heated to the temperature of boiling water or was kept in contact with vapour of chloroform and similar antiseptics, and further that it only took place between the temperatures of 5° and 55°.

Warington, who continued the investigation, further showed that there are two stages of the oxidation process, one being the formation of nitrite followed by its oxidation to nitrate. Cultures were obtained capable of effecting one only of these changes, but owing to the difficulties of growing the organisms on the ordinary gelatin medium, it was not until Winogradsky, in 1890, devised a medium of silica jelly containing no combined nitrogen that the organisms were finally isolated in a pure state. Winogradsky obtained from soils in all parts of the world a single organism which he called *Nitrobacter*, capable of transforming nitrites into nitrates, but he obtained two organisms, *Nitrosomanas europea* in the soils of the old world, and a second *Nitrococcus javanesis* from the soils of Java, America, and Australia, which will transform ammonia into nitrites. The conditions of the activity of these organisms appear to be the absence of excess of organic matter, a neutral or faintly alkaline medium with some base in reserve to combine with the nitric acid produced, and the absence of any excess of alkaline carbonates or chlorides. It has been found possible to accustom the organism by successive cultivations to a toleration of ammoniacal and organic solutions much stronger than would normally inhibit its development. The organism derives the carbon necessary to its growth from carbonates in the culture medium or carbon dioxide in the air with which it is supplied. The nitrifying organisms are confined, as indeed are all bacteria, to the surface layers of the soil, being rarely present in subsoils at greater depth than 2 ft. They may be entirely absent from the soils of heaths of peaty bogs which are acid in their reaction, but are abundant in waters of shallow wells and rivers. Their development is promoted by warmth, by stirring the soil, and by free aeration. It was formerly considered that as the higher plants obtain their combined nitrogen almost entirely in the form of nitrate, the fertility of the soil must be determined by the activity of the nitrification process going on in it, but it is now considered that the nitrification process is only the end term of the oxidation of organic compounds of nitrogen, and that it proceeds as rapidly as ammonia can be supplied by the ammonia-making organisms above described. It is found, for example, that ammonia never accumulates as such in normal soils, whereas nitrates do. Thus the activity of the ammonia-making organisms is the factor determining the rate of production of nitrates, and therefore the fertility of the soil.

5. *Denitrification.* It was observed by Warington that when a soil containing organic matter and sodium nitrate was water-logged so as to deprive it of air, there was a considerable development of nitrogen gas accompanied by a loss of nitrogen to the soil. Gayon and Dupetit isolated two organisms from sewage which would reduce nitrates to nitrogen gas in the presence of organic matter, the action being chiefly carried on when oxygen was absent, but coming to a standstill when plenty of air was supplied so that the organism had no need to attack the nitrates in order to obtain oxygen. This property of reducing nitrates in the absence of free oxygen has since been found to be common to a large number of organisms. To the process the name of denitrification has been given, and it explains the fact observed in many experiments, particularly in pots, that when large quantities of organic manure like dung are used in conjunction with sodium nitrate, smaller returns are obtained than when either of the fertilisers is employed singly. In ordinary field practice, however, losses of this kind are hardly to be feared, because the soil rarely becomes sufficiently rich in active organic matter, nor so sealed from the access of air, as to lead to any attack upon the nitrate. At Rothamsted, for example, it has been found with the mangold crop that of the nitrogen applied as sodium nitrate, 78 p.c. is recovered when no organic or other nitrogenous manure is applied, while 61 p.c. is recovered when the nitrate is added to a plot which also receives dung at the rate of 14 tons per acre per annum, the recovery being reckoned on the excess of crop over that produced by dung alone. The lower recovery, when nitrate is used in connection with dung, is no more than might be normally expected under the law of diminishing returns. In certain circumstances, however, as in rice growing on water-logged soils containing much organic matter, it is inadvisable to apply sodium nitrate because of the denitrification that takes place. The term 'denitrification' is also more loosely applied to the loss of gaseous nitrogen which takes place whenever soils are brought into very high condition by excess of organic manures. There exist in the soils various groups of bacteria destroying organic matter with evolution of nitrogen gas, and the activity of the organisms increases with the amount of organic matter with which the soil is supplied. Thus a very highly manured soil tends to reach a condition of equilibrium in which the supply of nitrogen is balanced, in part, by the output of crop, but also by the accelerated activity of the organisms setting free nitrogen gas. For example, on the wheat field at Rothamsted, to which dung is applied at the rate of 14 tons per acre per annum, it has been found that during the 50 years, 1844–93, of the 200 lbs. of nitrogen annually applied, only about 26 p.c. was recovered in the crop and 25 p.c. was accumulated in the soil. Thus nearly 50 p.c. was wasted, and though some of it would have been removed by drainage water as nitrates, the greater part has been dissipated as nitrogen gas formed by bacterial action in the very rich soil. The condition of water logging which leads to denitrification may also be accompanied by the reduction of sulphates and the formation of black ferrous sulphide in ordinary soils. For the bacteria of sulphate reduction and other

sulphur organisms, also for iron organisms, *v.* Lafar, *infra.*

The great extent of the literature existing on soil organisms precludes the setting out of references, but further details, together with a full bibliography, may be found in Lafar, Technische Mycologie, 2nd Auf., Jena, 1904. A. D. H.

SOJA BEAN OIL *v.* Soya Bean Oil.

SOLANINE *v.* Vegeto-alkaloids.

SOLDERS. Solders consist of fusible alloys, which are used for joining metals together and are of various kinds, depending on the nature of the metals to be joined. They are distinguished by specific names, as hard-, soft-, white-, spelter-, silver-, gold-, aluminium-, copper-, tin-, plumbers'-, pewterers'-, and button-solder, &c. For whatever purposes they may be intended they should always be rather more fusible than the metal or metals to be united; and, to give the maximum strength, they should have about the same hardness and malleability as these metals. Solders may be divided into two classes, *hard* and *soft solders.*

Hard solders are commonly called *spelter* (a name which is also in technical use for cast zinc). Hard soldering is usually termed *brazing,* since the solders most commonly employed are similar to brass in composition. Brazing is used where greater strength is required than can be given by soft solder, or when an article has to stand a temperature that would cause soft solder to melt. Hard solders contain such metals as copper, silver, &c., and require a red heat to fuse them. The heat necessary is derived from either a forge fire, a benzoline or paraffin brazing lamp, or a brazing hearth, which is an arrangement of gas blowpipes (*v.* J. Soc. Chem. Ind. 1902, 21, 259). A brazed joint is commonly considered to be stronger than the adjacent metal, and is generally cheaper, easier, simpler, and quicker to make than a welded joint.

Soft solders are composed of lead and tin in varying proportions; sometimes bismuth is added. The following table (Tomlinson) of melting-points of a series of lead-tin alloys shows that soft solders melt below 300°; numbers 4 to 8 represent common solders :—

Tin-lead Solders.

No.	Tin	Lead	Melting-point	No.	Tin	Lead	Melting point
1	1	25	292°	7	1½	1	168°
2	1	10	283°	8	2	1	171°
3	1	5	266°	9	3	1	180°
4	1	3	250°	10	4	1	185°
5	1	2	227°	11	5	1	192°
6	1	1	188°	12	6	1	194°

The addition of bismuth lowers the melting-point; by varying the proportions of the constituents such alloys may be made, within certain limits, to melt at any desired temperature, even below 100°, thus admitting of various applications for electrical and other purposes. Examples are shown in the following table :—

Bismuth Solders.

Parts of tin	Parts of lead	Parts of bismuth	Melting-point	Parts of tin	Parts of lead	Parts of bismuth	Melting point
3	5	3	94·4°	1	1	1	123·3°
1	1	2	96·1°	2	2	1	143·5°
1	2	2	112·8°	3	3	1	154·4°

Soft solders are usually weaker in tensile strength than the joined metals.

Although soft solders are sometimes employed in conjunction with a mouth blowpipe, they are usually applied by means of a suitably shaped copper bit, miscalled a soldering iron.

In preparing solders, care must be taken to avoid two faults, want of uniformity and loss of a constituent that is either volatile or readily oxidised. Thus where copper, silver, &c., are to be mixed with tin, zinc, &c., it is necessary to melt the least fusible metal first; the zinc or tin is finally added, and after stirring, the mass is quickly cast. Efficient stirring, preferably with a piece of green wood, is necessary to secure uniformity of composition. Soft solders should be melted under tallow; they are cast in sticks, or run out into strips. Hard solders should be melted under powdered charcoal or borax. They may be granulated, or cast into small ingots and reduced to powder by filing. Gold and silver solders are generally rolled out into thin sheets and cut into narrow strips or else drawn into thin wire.

In the practical application of solders it is necessary that the metal surfaces to be united should be heated to a temperature above that at which the solder melts, and that the surfaces should be bright and clean, both mechanically and chemically. They may be cleaned mechanically by scraping or filing, and chemically by washing with a suitable acid or alkali. Since most metals tarnish when heated, owing to surface oxidation, it is necessary to protect the metal surfaces from air during the period of heating, or the solder will not wet the metals and adhere to them. Hence the use of *fluxes* in soldering. The flux used in hard soldering is *borax.* For soldering small articles, it may be prepared for use by rubbing a lump with water on a clean slate to a creamy consistency, and is then applied to the surfaces with a brush. When heated, the water is first expelled; at a red heat the anhydrous borax melts, and, flowing over the surfaces, it not only prevents access of air but also dissolves any surface films of oxides, producing double metaborates which remain dissolved in the excess of borax. It has been proposed to carry out brazing in an atmosphere of hydrogen or carbon monoxide (J. Soc. Chem. Ind. 1911, 30, 695).

Soft solders melt at temperatures below the fusing point of borax and other fluxes are therefore necessary. *Zinc chloride* solution is commonly used with most sheet metals, brass, copper, gun-metal, and bright iron. *Hydrochloric acid* is used with zinc and galvanised ware; *ammonium chloride* with copper and iron; *resin* with soft alloys and tinware; *Venice turpentine* or *Gallipoli oil* with pewter or Britannia metal; *Russian tallow* with heavy lead and *palm-oil candle* with light lead work. Lactic acid 1 pint, glycerol 1 pint, water 8 pints makes a good flux, as also does a solution of phosphoric acid in alcohol.

Resin possesses an advantage over acid fluxes like hydrochloric acid or zinc chloride as it does not induce subsequent corrosion. All excess of an acid flux should be thoroughly washed away. When it is necessary to use soft solder for repairing jewellery, resin cannot be used as it spreads all over the surfaces and is difficult to remove; zinc chloride should be used. The common prejudice against using zinc chloride when soldering electrical joints is stated by Lippmann to be groundless (Zeitsch. angew. Chem. 1909, 22, 2042). For a comparison between several fluxes, *v.* Samter (*ibid.* 1909, 22, 729).

Soft solders can be obtained in the form of narrow bore-tubes, with the central portion filled up with resin or other material, so as to obviate the necessity for using a separate flux. They may also be obtained, mixed with flux, in the form of a paste, *e.g.* (1) granulated soft solder is mixed with beeswax and impregnated with zinc chloride (J. Soc. Chem. Ind. 1906, 25, 269); (2) powdered solder is mixed with borax, ammonium chloride or other flux that leaves no acid residue and incorporated with glycerol or other inert and not too volatile substance (*ibid.* 1905, 24, 32); (3) powdered tin or solder is mixed with zinc chloride and celluloid paste and applied with a brush (*ibid.* 1903, 22, 1052).

For practical details of the art of soldering and descriptions of the requisite apparatus, consult books on metal working, Rowell's Hard Soldering, and Hobart's Brazing and Soldering.

Hard solders. *Gold solders.* Articles the fineness of which vary from 14 to 22 carats, may be soldered with alloys of lower grade prepared by fusing 2 grs. of silver and 1 gr. of copper with 1 pennyweight of gold of the same fineness as the article. These alloys are used in *dental* work. By replacing the 3 grs. of silver and copper by an equal weight of spring brass (2 of Cu, 1 of Zn), solders of good colour are obtained, suitable for use with *ornaments* and *jewellery.*

Coin gold is usually soldered with an alloy of pure gold 3 parts, spring brass 1 part.

Gold of a fineness of 12 carats or less may be soldered with 10 or 12 carat gold to which one-twelfth its weight of zinc has been added. A gold solder should not contain less than one-third its weight of gold. Lower grades of gold are best soldered with silver solder.

A good solder for *general use* contains gold 18, silver 4, copper 5, zinc 2 parts; another can be readily prepared by fusing 1 pennyweight of 18 carat gold with 5 grs. of spring brass. Among other jewellers' gold solders, the following may be mentioned; (1) best solder, gold 12½, silver 4½, copper 3 parts; (2) medium solder, gold 10, silver 6, copper 4 parts; (3) common solder, gold 8½, silver 6½, copper 5 parts; *v.* Gee, The Goldsmith's Handbook.

Antimony, arsenic, tin and lead should not be used in solders for gold.

Silver solders. These are employed a good deal in the arts; owing to the careful, sparing way in which they are used, most work requires but little finishing after soldering. The use of silver solders is not therefore unreasonably expensive; the results are extremely satisfactory. Besides being employed by jewellers and silversmiths, silver solders are also used for joining brass, copper, and even iron and steel.

Hard solders for *jewellers* and for *general use* contain: (1) silver 18, copper 4, zinc 1 part; (2) silver 15, copper 4, zinc 1 part. A good solder may be prepared by melting coin silver and adding one-third its weight of spring brass. An easy melting solder is prepared by fusing 2 parts of fine silver and adding 1 of spring brass, or by employing silver 4, copper 1, zinc 1 part, while an alloy of silver 16, zinc 1 part forms a very hard, white solder. A very common solder contains silver 1, brass 1, arsenic 1 part.

Many other silver solders are in use. A selection is given in the accompanying table, with remarks upon their uses. *See* also Gee, The Silversmith's Handbook.

SILVER SOLDERS.

Remarks on use	Parts of silver	Parts of spring brass	Parts of copper	Parts of zinc
Jewellers', hardest .	4	—	1	—

Brass, small articles .	2	—	5	3
Jewellers', instrument makers', very tough and fluid . .	11	—	13	—

Coin silver, rolled out thin, is an excellent solder for iron, copper, and very difficultly fusible brass.

Brass, bronze or copper to which 4 to 10 p.c. of silver has been added, forms a solder for thin sheets of mild steel (Diegel, Chem. Zeit. 1909, 33, 427).

A very full discussion of hard solders for *brass* is given by Schwirkus (Dingl. poly. J. 293, 64, 89), who recommends copper-zinc-silver alloys containing 40–50 p.c. of copper and 4–12 p.c. silver. For general use and repairs, an alloy of copper 43, zinc 48, silver 9 parts is best; for first soldering, copper 48, zinc 48, silver 4 parts should be used.

Copper-zinc-tin solders. Ordinary brazing processes are carried out with *spelter solder,* a mixture of equal parts of copper and zinc. It may be used on *brass, copper, iron* or *steel.* For pale brass, the proportion of zinc in the solder is increased, while for ironwork that has to be hammered afterwards the proportion of copper should be increased. The composition of a number of brazing solders is given in the following table.

Remarks on use	Parts of copper	Parts of zinc	Parts of tin
Soft spelter for brass . .	1	1	—
,, ,, ,, . .	4	3	—
Hard ,, gunmetal, iron-work .	2	1	—

,, ,, ,, . .	7	3	2
Soft ,, ,, and brass	4	3	1
Hard ,, brass (white or button solder) . . .	6·5	1	7·5

Ferrofix brazing process. This process for brazing broken iron parts, especially *cast iron,* was invented by Pich; the brass that cements the two pieces together is made to alloy with the iron surfaces as deep as $\frac{1}{16}$ inch. The *flux* used is a mixture of equal parts of sodium carbonat and boric acid, with a little sodium chloride. The *brazing liquid* is prepared by boiling cuprous oxide with concentrated borax solution and allowing the mass to cool down to a sort of paste. The method of procedure is to set the casting to be brazed on firebrick, in perfect alignment; mix fluxing powder with the brazing liquid and apply to the surfaces with a brush; heat, and apply more flux until it runs through the joint. Then apply ordinary spelter with a little flux until it flows through thoroughly. Remove the source of heat and continue adding spelter to the joint until the heat of the casting is insufficient to melt it (U.S. pats. 688030, 647632).

The spelter must not melt below 650°; hence hard brass must be used. The cuprous oxide of the brazing liquid transfers its oxygen to the carbon contained in the surface layers of the iron, which become decarbonised, while finely divided copper remains diffused through the joint. The hard solder quickly alloys with the copper and the new alloy immediately combines with the red-hot decarbonised soldering surfaces of the cast iron.

Solders for platinum. Fine gold, laminated and cut into shreds, is employed for soldering platinum. Pure silver may be used also and the following alloys have been proposed: (1) platinum 12, gold 7, silver 1 part; (2) platinum 1, gold 2, silver 1 part. Platinum joints are usually welded.

Solder for small steel springs. 18 carat gold may be used for repairing small, freshly broken springs; the spring must then be hardened and tempered.

Solder for German silver. An alloy of German silver 5, zinc 4 parts may be used; *v.* also *Silver solders* (p. 89).

Solders for aluminium bronze. (1) Tin 900, copper 100, bismuth 2 to 3 parts; silver chloride is used for flux; (2) gold 89, silver 4·5, copper 6·5 parts; (3) gold 54·5, silver 27, copper 18·5 parts; (4) the zinc-aluminium alloys given for aluminium (*v. infra*).

Soft solders. These contain tin, lead, and sometimes bismuth; for their melting-points, *v.* p. 88. The following table gives the composition of a number of solders, with remarks on their use.

SOFT SOLDERS.

Remarks on use	Parts of tin	Parts of lead	Parts of bismuth	Parts of zinc
Ordinary soft, plumbers', tinmen's . . .	1	1	—	—

Soft solders should be kept carefully free from zinc (*v.* J. Soc. Chem. Ind. 1909, 28, 1139). According to Sperry (Eng. and Min. J. 1909, 87, 1140) the addition of *cadmium* to soft solder makes it stronger and more fusible; an alloy of tin 2, lead 1, cadmium 1 part melts at 144·5° and can be used on lead, pewter, Britannia metal, &c.

Chemical solder. Tinfoil, cut to the size of the joint to be made, is painted over with a solution of sal-ammoniac, then placed between the two portions to be soldered together, and heated upon hot iron, or over a spirit lamp, until the solder melts, the pieces being held together by the hand during the operation. On cooling, a firm joint is the result. This method is very useful for the soldering of small articles together without a soldering iron—*e.g.* pieces of brass or copper wire, the ends of which should first be filed flat.

Solder for aluminium. No really good solder for aluminium is known, although considerably over fifty alloys have been proposed. The difficulty, which was known to Deville, arises from two causes, (1) the ease with which a film of oxide forms on the surface and the difficulty of properly removing it, and (2) the highly electropositive nature of aluminium, which causes electrolytic action to be set up, particularly if the soldered joint be wetted, and inevitably leads to disintegration at the joint. Ordinary soft solder will not do, but either pure tin or zinc may be used as solder. The zinc joint is very brittle, however, and the tin joint disintegrates since it slowly absorbs oxygen from the air. Aluminium-zinc alloys containing respectively 8, 12, 15, and 20 p.c. of aluminium, may be used (Tissier Bros.), the flux consisting of copaiba balsam 3, Venice turpentine 1 part, and a few drops of lemon juice. For heavy work, aluminium 12, zinc 80, copper 8 parts may be used; for light work, aluminium 6, zinc 90, copper 4 parts (Dagger, J. Soc. Chem. Ind. 1891, 10, 436). Mourey's solder, for blowpipe work, contains tin 6, zinc 3, aluminium 2, copper 1, silver 1 part. Frishmuth recommends tin 95, bismuth 5 parts, or tin 97, bismuth 3 parts as good soft solders.

Richard's solder (J. Soc. Chem. Ind. 1896, 15, 200; *cf. ibid.* 1899, 18, 281) is largely used; it contains aluminium 1, zinc 11, tin 29, 10 p.c. phosphor-tin 1 part. No flux is required, the solder being self-fluxing owing to the phosphorus it contains. For numerous other solders *v.* J. Soc. Chem. Ind. from 1892 onwards. It appears preferable to weld or rivet aluminium joints, rather than to solder them.

Cold soldering. This process may be adopted when the article to be soldered cannot be heated. The *flux* consists of sodium amalgam (1 part of sodium to 50 or 60 of mercury). The *solder* is a copper amalgam prepared as follows: copper is precipitated from a solution of its sulphate by means of zinc, and the spongy metal is washed, drained and shaken with twice its weight of mercury and a little dilute sulphuric acid. The pasty amalgam is quickly formed into small pellets; in a few hours they set to intensely hard lumps. The process consists in heating a pellet until mercury oozes from its surface in small beads, wiping these off and rubbing the pellet into a soft paste in a mortar.

The surfaces to be united are amalgamated with the flux, the pasty, prepared pellet then applied and the surfaces pressed tightly together. A perfectly hard joint is obtained in about three hours.

Autogenous soldering. In this process, soldering takes place by the fusion of the two edges of metal themselves without the interposition of a metallic alloy as a go-between; the metal acts as its own solder. Joints thus made are less liable to rupture when submitted to varying temperatures, &c., than when the common soldering process is employed; moreover, corrosion of the joint owing to electrolytic action does not occur. The process is adopted for the manufacture of sulphuric acid chambers and concentration pans, and the soldering is effected by directing a jet of burning hydrogen or coal-gas upon the edges to be joined together. Brass may be similarly soldered. For copper, iron, steel, platinum, and aluminium, the oxy-hydrogen or oxy-acetylene flame is necessary. Care must be taken to allow no excess of oxygen in the flame; with platinum, however, excess of hydrogen must be avoided, as it is absorbed by the molten metal.

SOLENITE *v.* EXPLOSIVES.

SOLIDE JAUNE *v.* AZO-COLOURING MATTERS.

SOLUBILITY. The term 'solubility' denotes the extent to which different substances, in whatever state of aggregation, are miscible with each other. That constituent of the resulting solution which is present in large excess is commonly known as the 'solvent,' the other constituent being the 'solute.' This, however, is merely a convenient distinction, not an essential one, and in cases where it cannot be easily drawn, the term 'miscibility' may be used as synonymous with 'solubility.'

It is proposed to give in this article an outline (1) of the methods available for the determination of solubility or miscibility, (2) of the general results obtained and their significance. For this purpose it is convenient to arrange the material according to the state of aggregation of the substances involved.

Solubility of gases. Two gases are miscible with each other in all proportions, that is, no definite value can be assigned for the solubility of *one gas in another*. The question of the solubility of *gases in solids* has been discussed elsewhere; such cases of absorption present peculiar features, inasmuch as the absorbed gas is not uniformly distributed throughout the mass of the solid, but is concentrated in the superficial layers, *v.* COLLOIDS.

The solubility of *gases in liquids* is a subject to which much attention has been devoted. The extent to which a given gas will dissolve in a given liquid is a function of the temperature and pressure. At any given temperature, the weight of the gas dissolved by a definite volume of the liquid is directly proportional to the pressure. This law was first formulated by Henry (Phil. Trans. 1803, 93, 29, 274), and its general validity has been confirmed by subsequent investigators (for example, Bunsen, Annalen, 1855, 93, 1; Khanikof and Louguinine, Ann. Chim. Phys. 1867, 11, 412; Woukuloff, Compt. rend. 1889, 108, 674; 109, 61). Strict conformity to the law, however, is exhibited only by those gases which dissolve in the liquid to a comparatively small extent. If the gas is highly soluble—for instance, ammonia or hydrogen chloride in water,—then the weight dissolved is no longer proportional to the pressure. An important extension of Henry's law was made by Dalton (Mem. Lit. Phil. Soc. Manchester, 1805, 1, 273), who showed that when a mixture of two indifferent gases is absorbed by a liquid each dissolves proportionally to its partial pressure.

The extent to which a gas is absorbed by a liquid is expressed by the 'absorption coefficient,' or, simply, by the 'solubility.' The absorption coefficient is defined as that volume of the gas (reduced to normal temperature and pressure) which is absorbed by unit volume of the liquid under normal pressure. Thus, if experiment shows that at $t°$ C. and p mm. pressure v cub. cm. of the gas are absorbed by V cub. cm. of the liquid, then the absorption coefficient $\beta=\frac{v}{V(1+\alpha t)}$. The solubility λ of a gas in a liquid, on the other hand, is defined simply as the volume of the gas absorbed by unit volume of the liquid; so that $\lambda=\frac{v}{V}$. In the following table are recorded the absorption coefficients for various common gases in water at different temperatures:—

Temp.	Oxygen.	Hydrogen.	Nitrogen.	Carbon dioxide.
0°	0·0492	0·0215	0·0237	1·713
5°	0·0434	0·0204	0·0211	1·424
10°	0·0385	0·0195	0·0191	1·194
15°	0·0346	0·0188	0·0173	1·019
20°	0·0314	0·0182	0·0159	0·878
25°	0·0286	0·0175	0·0147	0·759

The actual determination of the solubility of a gas in a liquid may be carried out in various ways. The method most commonly employed is to bring together known volumes of the gas and the gas-free liquid, to agitate them until saturation has been attained, and then to determine the diminished volume of the gas. Many forms of apparatus, based on this principle, have been suggested from time to time (Bunsen, Annalen, 1855, 93, 1; Mackenzie, Ann. Physik, 1877, 1, 438; Müller, *ibid.* 1889, 37, 24; Timoféeff, Zeitsch. physikal. Chem. 1890, 6, 141; Winkler, Ber. 1891, 24, 89; Setchenow, Ann. Chim. Phys. 1892, 25, 226; Steiner, Ann. Physik, 1894, 52, 275; Gordon, Zeitsch. physikal. Chem. 1895, 18, 1; Roth, *ibid.* 1897, 24, 114; Estreicher, *ibid.* 1899, 31, 176; Braun, *ibid.* 1900, 33, 721; Just, *ibid.* 1901, 37, 342; Skirrow, *ibid.* 1902, 41, 139; Knopp, *ibid.* 1904, 48, 97; Geffcken, *ibid.* 1904, 49, 257; Christoff, *ibid.* 1906, 55, 622; Usher, Chem. Soc. Trans. 1910, 97, 66; Drucker and Moles, Zeitsch. physikal. Chem. 1910, 75, 405). An alternative method is to saturate the liquid and then measure the volume of gas which is expelled on exhausting and boiling out (Hüfner, Ann. Physik, 1877, 1, 632; Dittmar, 'Challenger' Report, Physics and Chemistry, 1, 161; Pettersson and Sondén, Ber. 1889, 22, 1439; Bohr and Bock, Ann. Physik, 1891, 44, 318). Instead of expelling and measuring the gas present in the saturated liquid, it may be determined chemically if a suitable method is available (Schönfeld, Annalen, 1855, 95, 1; Carius, *ibid.* 1856, 99, 129; Roscoe and Dittmar, Chem. Soc. Trans

1860, 12, 128; Sims, *ibid.* 1862, 14, 1; Watts, Annalen Suppl. 1865, 3, 227; Winkler, Ber. 1889, 22, 1764; Bohr, Ann. Physik, 1900, 1, 244; Fox, Zeitsch. physikal. Chem. 1902, 41, 458; Clowes and Biggs, J. Soc. Chem. Ind. 1904, 23, 358). In certain cases an aspiration method of finding the partial pressure of a gas in its solutions may be utilised in the determination of solubility coefficients (Gaus, Zeitsch. anorg. Chem. 1900, 25, 236; Abegg and Riesenfeld, Zeitsch. physikal. Chem. 1902, 40, 84; McLauchlan, *ibid.* 1903, 44, 600; Jones, Chem. Soc. Trans. 1911, 99, 392).

As a general rule, the solubility of a gas in a liquid diminishes as the temperature rises, and a connection has been traced between this diminution and the viscosity of the liquid. It appears that the diminution in the absorption coefficient for any temperature interval is approximately proportional to the corresponding diminution in the viscosity coefficient of the solvent (Winkler, Zeitsch. physikal. Chem. 1892, 9, 171; Thorpe and Rodger, Chem. Soc. Trans. 1894, 65, 782). Cases, however, are known in which the solubility of a gas increases as the temperature rises. Thus, the existence of a minimum solubility has been established for hydrogen in water (Bohr and Bock, Ann. Physik, 1891, 44, 318) and for the rare gases in water (Estreicher, Zeitsch. physikal. Chem. 1899, 31, 176; von Antropoff, Proc. Roy. Soc. A, 1910, 83, 474). Further, Just (Zeitsch. physikal. Chem. 1901, 37, 342) has found that the solubility of nitrogen, hydrogen, and carbon monoxide in a number of organic solvents is greater at 25° than at 20°.

The factors which determine the solubility of a gas in a pure liquid are not clearly understood, but it is at least highly probable that, *ceteris paribus*, the greater the compressibility of the solvent and the smaller the volume change associated with the absorption of the gas, the greater is the solubility (*see* Ritzel, Zeitsch. physikal. Chem. 1907, 60, 319). In this connection, it should be pointed out that the relative volume change in a liquid resulting from absorption of a gas is proportional to the concentration of the gas (Angström, Ann. Physik, 1882, 15, 297; 1888, 33, 223; Mackenzie and Nichols, *ibid.* 1878, 3, 134; Nichols and Wheeler, Phil. Mag. 1881, 11, 113; Ritzel, *l.c.*). Further, the study of the solubility of gases in mixed organic solvents has revealed the existence of points of maximum solubility, such points corresponding with the occurrence of minimum surface tension (Skirrow, Zeitsch. physikal. Chem. 1902, 41, 139; compare Christoff, *ibid.* 1906, 55, 622).

Much attention has been devoted to the influence of salts and other dissolved substances on the absorption of gases by water. Provided there is no chemical action between the gas and the other dissolved substance it is generally the case that the gas is less soluble in the solution than in pure water at the same temperature (*see*, for example, Steiner, Ann. Physik, 1894, 52, 275; Gordon, Zeitsch. physikal. Chem. 1895, 18, 1; Roth, *ibid.* 1897, 24, 114; Braun, *ibid.* 1900, 33, 721; Knopp, *ibid.* 1904, 48, 97; Geffcken, *ibid.* 1904, 49, 257; Usher, Chem. Soc. Trans. 1910, 97, 66). An important result deducible from these and other investigations is that when a number of salts are arranged according to their power of lowering the solubility of one gas in water, the order is very nearly the same as when they are arranged with reference to their influence on the solubility of another gas. It appears, therefore, that the diminished solvent power of a salt solution as compared with pure water is mainly determined, not by the specific nature of the dissolved gas, but by some factor involved in the relationship of the water and the salt. What this factor is, has not yet been determined with certainty. It has been suggested that the influence exerted by salts is a function of the internal pressure or the compressibility of the solution (Euler, Zeitsch. physikal. Chem. 1899, 31, 368; Geffcken, *ibid.* 1904, 49, 257; Ritzel, *ibid.* 1907, 60, 319). On the other hand, interaction between the molecules or ions of the dissolved substances has been assumed to account for the influence of salts in lowering solubility (Levin, Zeitsch. physikal. Chem. 1906, 55, 503; Rothmund, *ibid.* 1909, 69, 523). Again, it has been suggested that the lower solvent power of a salt solution as compared with water is connected with the hydration of the salt (Rothmund, Zeitsch. physikal. Chem. 1900, 33, 413; Baur, Ahrens' Sammlung, 1903, 8, 466; Lowry, Trans. Faraday Soc. 1905, 1, 197; Philip, Chem. Soc. Trans, 1907, 91, 711; Hudson, Zeitsch. Elektrochem. 1908, 14, 821).

Solubility of liquids in liquids. As regards their mutual solubility, a pair of liquids is commonly assigned to one of three classes. They may be miscible in all proportions, they may be only partially miscible, or they may be practically immiscible. Such a classification, however, has only a general value, for the difference between the second and third classes is merely one of degree, and the line of division between the first and second classes is displaced by altering the temperature.

In finding the solubility of one liquid in another when the solubility is very small, as, for instance, in the case of chloroform or carbon disulphide in water, two methods may be adopted. One consists in bringing together a large known volume of the first liquid with a small known volume of the second, shaking until saturation has been reached, and then finding the volume of the second liquid remaining undissolved (Schuncke, Zeitsch. physikal. Chem. 1894, 14, 331; Bödtker, *ibid.* 1897, 22, 511; Herz, Ber. 1898, 31, 2669; Rex, Zeitsch. physikal. Chem. 1906, 55, 355). Another method is to shake quantities of the two liquids together until they are mutually saturated, and then remove portions of each layer for analysis (Chancel and Parmentier, Compt. rend. 1884, 99, 892; 1885, 100, 773; Walker, Zeitsch. physikal. Chem. 1890, 5, 196; Klobbie, *ibid.* 1897, 24, 616; Euler, *ibid.* 1899, 31, 364; Osaka, Mem. Coll. Sci. Eng. Kyoto, 1909–1910, 2, 21). Determinations are naturally made at various temperatures.

In the case of liquids the mutual solubility of which is greater than in the afore-mentioned cases, the method commonly employed is a synthetic one. That is, weighed quantities of the two liquids are put in a tube, which is then sealed and suspended in a bath of water or other suitable liquid. The temperature of the bath is altered until the contents of the tube become uniform and determinations of this point are then repeatedly alternated with determinations of the temperature at which, as indicated by the appearance of turbidity, the uniform contents of the tube begin to separate into two layers (Guthrie, Phil. Mag. 1884, 18, 22, 495; Alexéeff, Ann. Physik, 1886, 28, 305; Rothmund, Zeitsch. physikal. Chem. 1898, 26, 433; Bingham, Amer. Chem. J. 1907, 37, 549; 38, 91; Flaschner and MacEwen, Chem. Soc. Trans. 1908, 93, 1000). Experience shows that these two points, the one observed with rising, the other with falling temperature, are generally very close together, and the mean of the observed temperatures may be taken as the point at which the liquid is saturated.

For each temperature there are generally found two saturated mixtures of different composition, corresponding to the two layers obtained when the pure liquids are shaken up together. As a rule, the mutual solubility of two liquids increases as the temperature rises, and the compositions of the conjugate layers approximate more and more to each other. In such a case (Fig. 1), the two solubility curves, *i.e.* the curve representing the solubility of B in A and that representing the solubility of A in B, join at a point above which the liquids are completely miscible. As suggested by Masson (Zeitsch. physikal. Chem. 1891, 7, 500), who emphasises the parallelism between the case just described and the gradual approximation in density of a liquid and its saturated vapour, the temperature above which two partially miscible liquids become miscible in all proportions is called the 'critical solution temperature.' The existence of this temperature limit has been recorded for such cases as phenol and water, aniline and water, benzoic acid and water, carbon disulphide and methyl alcohol, methylethylketone and water. In these and other instances, it is further found that the middle points of the horizontal chords cut off between the two branches of the solubility curve lie on a straight line—another analogy with the density-temperature curve for a pure liquid and its saturated vapour (*see* Rothmund, *l.c.*). It is noteworthy that bismuth + zinc and lead + zinc furnish examples of limited miscibility in the fused state: the solubility curve for each pair is of the foregoing type (Spring and Romanoff, Zeitsch. anorg. Chem. 1897, 13, 29).

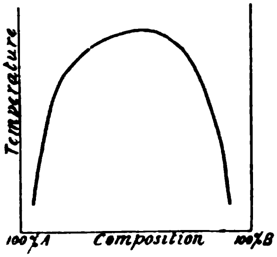

FIG. 1.

In a few cases—for instance, triethylamine and water, β-collidine and water, 1-methyl piperidine and water—the change of miscibility with temperature is the opposite of that described above. The mutual solubility increases as the temperature falls and there is a limit, known as the 'lower critical solution temperature,' below which the liquids are miscible in all proportions, and above which separation into two layers takes place increasingly as the temperature rises. The relation between solubility and temperature in such a case is represented in Fig. 2.

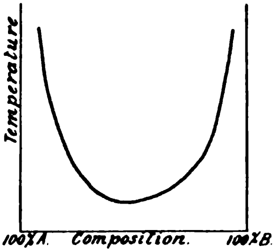

FIG. 2.

In two cases, nicotine and water (Hudson, Zeitsch. physikal. Chem. 1904, 47, 113), and 2-methyl piperidine and water (Flaschner and MacEwen, Chem. Soc. Trans. 1908, 93, 1000), both upper and lower critical solution temperatures are known, and the complete solubility curve is a closed ring. According to Rothmund (*l.c.*), this is the normal type of solubility curve for a pair of partially miscible liquids. There need not, however, be an upper critical solution temperature in every such case (Kuenen and Robson, Zeitsch. physikal. Chem. 1899, 28, 342), and the occurrence of a lower critical solution temperature has been held to be abnormal (Dolgolenko, *ibid.* 1908, 62, 499).

The mutual solubility of two liquids may be materially modified by the addition of a third substance. In this way two liquids which are miscible in all proportions may be made to undergo at least partial separation: for example, a homogeneous mixture of propyl alcohol and water, which are miscible in all proportions at ordinary temperatures, separates into two layers on the addition of salt. In the case of two liquids which are only partially miscible, the area of non-miscibility may be notably extended or reduced by the introduction of a third substance, and a measure of this influence is found in the effect of the third substance on the critical solution temperature. According to Timmermans (Zeitsch. physikal. Chem. 1907, 58, 129), who has made an exhaustive study of this phenomenon, the upper critical solution temperature is lowered when the solubilities of the third substance in the two liquids are of the same order of magnitude. If the third substance is much more soluble in the one liquid than in the other the critical solution temperature is raised, *i.e.* the area of non-miscibility is extended. It is noteworthy that when different salts are arranged according to their ability to cause the system water + propyl alcohol to separate into two phases, or according to their power to raise the critical solution temperature of water + phenol, the order is approximately the same as when they are arranged according to the magnitude of their influence on the solubility of gases in water. These effects have an obvious bearing on the well-known practice of 'salting out' organic compounds from their aqueous solutions.

Solubility of solids in liquids. The equilibrium between a solid and a liquid is established more slowly than that between two liquids, and this fact explains the precautions that must be taken if the solubility of a solid in a liquid is to be determined with rapidity and yet with accuracy. The solvent and the finely divided solid are put in a suitable glass vessel and shaken together at constant temperature, either intermittently by hand, or regularly by some mechanical arrangement. This is continued until the solution is saturated, when samples are extracted and analysed. The time necessary for the attainment of saturation varies from one case to another, and should be ascertained by preliminary experiments in which samples of the solution are taken out at intervals until the quantity of substance in solution is found constant. A guarantee that the value so found for the solubility is the correct one at the temperature of observation may be obtained by approaching the saturation point from the other side. A saturated solution is prepared at a higher temperature (on the supposition that the solubility increases with rising temperature), and is then put in a bath at the desired temperature, when the excess of solid in solution gradually separates out, the attainment of equilibrium being preferably facilitated by shaking or stirring. The analysis of the saturated solution obtained in this way ought to give the same result as the previous method (*see* Andreae, J. pr. Chem. 1884, 29, 456).

In the extraction of samples of the saturated solution an ordinary pipette may be used, with an auxiliary tube containing a plug of glass wool or cotton wool to keep back the solid. If the temperature at which the solution has been saturated is higher than the temperature of the room, the pipette may have to be warmed slightly to avoid crystallisation of the solid. It is, however, preferable in such cases to carry out the operation of filtration into a weighed vessel inside the constant temperature bath.

Many forms of apparatus for carrying out these various operations have been described (*see*, for instance, V. Meyer, Ber. 1875, 8, 998; Andreae, *l.c.*; Carnelley and Thomson, Chem. Soc. Trans. 1888, 53, 782; Meyerhoffer, Zeitsch. physikal. Chem. 1890, 5, 99; Reicher and van Deventer, *ibid.* 1890, 5, 560; Nicol, Phil. Mag. 1891, 31, 374; Noyes, Zeitsch. physikal. Chem. 1892, 9, 606; Arrhenius, *ibid.* 1893, 11, 392; Goldschmidt, *ibid.* 1895, 17, 152; Pawlewski, Ber. 1899, 32, 1040; Lumsden, Chem. Soc. Trans. 1902, 81, 350). For very high temperatures, such as the boiling point of the solvent and beyond it, the solubility apparatus must be specially modified (*see* V. Meyer, Ber. 1875, 8, 1000; Tilden and Shenstone, Phil. Trans. 1884, 175, 23; Goeckel, Chem. Zentr. 1897, ii. 401; Thiele and Calberla, Zeitsch. angew. Chem. 1906, 19, 1263; Schroeder, Zeitsch. anal. Chem. 1909, 48, 349; Tyrer, Chem. Soc. Trans. 1910, 97, 621). Attempts have been made to determine solubility by finding the temperature at which a minute quantity of the solid in contact with its solution neither increases nor diminishes in amount (Andreae, *l.c.*; Alexéeff, Ann. Physik, 1886, 28, 305; Schroeder, Zeitsch. physikal. Chem. 1893, 11, 453).

In the case of very sparingly soluble solids, such as the silver halides in water, the ordinary method of determining solubility is impracticable, because the amount of solid in the saturated solution cannot be estimated with any accuracy. For the silver halides in water, it is true, Whitby (Zeitsch. anorg. Chem. 1910, 67, 107) suggests heating the saturated solution with sucrose and sodium hydroxide under standard conditions and estimating colorimetrically the quantity of colloidal silver produced. But various physical methods are available for determining the solubility in water of sparingly soluble salts generally. Thus the electrical conductivity of the saturated solution may be compared with that of pure water, and the solubility of the salt deduced therefrom (Holleman, Zeitsch. physikal. Chem. 1893, 12, 125; Kohlrausch and others, *ibid.* 1893, 12, 234; 1904, 50, 355; Sitzungsber. K. Akad. Wiss. Berlin, 1901, 1018; Böttger, Zeitsch. physikal. Chem. 1903, 46, 521; 1906, 56, 83; Weigel, *ibid.* 1907, 58, 293). A knowledge also of the potential difference between a suitable electrode and the saturated solution of the sparingly soluble salt in question permits a calculation of the solubility (Goodwin, Zeitsch. physikal. Chem. 1894, 13, 641; Morgan, *ibid.* 1895, 17, 533; Thiel, Zeitsch. anorg. Chem. 1900, 24, 49; Immerwahr, Zeitsch. Elektrochem. 1901, 7, 477). Another method has been suggested by Biltz (Zeitsch. physikal. Chem. 1907, 58, 288), who shows that in the case of two salts giving a sparingly soluble compound by double decomposition, the ultramicroscope indicates when the solutions have been so far diluted that no precipitate forms. From such an observation the solubility of the precipitate may be calculated.

In the majority of cases, the solubility of a given solid in a given liquid increases as the temperature rises, and as a rule the solubility-temperature curve is convex to the temperature axis. No general law, however, is known which connects solubility and temperature. A decrease of solubility with rising temperature over the whole or part of the temperature range, has been observed in a number of cases, *e.g.* calcium sulphate, calcium hydroxide, sodium sulphate, ferrous sulphate (Tilden and Shenstone, Phil. Trans. 1884, 175, 23; Étard, Compt. rend. 1888, 106, 206, 740; Lieben and others, Monatsh. 1894, 15, 404; Lumsden, Chem. Soc. Trans. 1902, 81, 350). In some of these and other instances, points of maximum and minimum solubility occur on the solubility-temperature curve, *e.g.* for the calcium and barium salts of the fatty acids in water. Maxima are observed also in numerous cases where the dissolved solid forms a compound with the solvent: this occurs most commonly for the combination salt + water (*see*, for example, Roozeboom, Zeitsch. physikal. Chem. 1893, 10, 477). Discontinuities occur on the solubility-temperature curve at points where the solid in contact with the solution undergoes a change. Such breaks may be associated with the disappearance of one hydrate of a salt and the appearance of another (*see* de Coppet, Ann. Chim. Phys. 1883, 30, 429; Roozeboom, Zeitsch. physikal. Chem. 1890, 5, 198; 1893, 10, 477; Donnan and Burt, Chem.

Soc. Trans. 1903, 83, 335), or with the transition of one crystalline form of a substance into another (Rabe, Zeitsch. physikal. Chem. 1901, 38, 175; Müller and Kaufmann, *ibid.* 1903, 42, 497; Steele and Johnson, Chem. Soc. Trans. 1904, 85, 113).

Although there is no general law enabling us to predict the relation between solubility and temperature for a given solvent and solute, there is a close connection, deducible thermodynamically, between the heat of solution and the variation of solubility with temperature (Le Chatelier, Compt. rend. 1885, 100, 441; van 't Hoff, Kongl. Svenska Vet. Akad. Handl. 1886, 21, 17). According to this, the solubility of a solid in a liquid must increase with rising temperature when the process of dissolution is accompanied by the absorption of heat, and decrease with rising temperature when there is evolution of heat. The validity of this relationship has been confirmed by experiment (*see* Reicher and van Deventer, Zeitsch. physikal. Chem. 1890, 5, 559; van Deventer and van de Stadt, *ibid.* 1892, 9, 43; von Stackelberg, *ibid.* 1898, 26, 533).

As in the case of gases and liquids, the solubility of a solid in a liquid may be profoundly modified by the presence of a third substance. This may be due to definite chemical action; iodine, for instance, is more soluble in potassium iodide solutions than in pure water, and silver chloride, almost insoluble in pure water, dissolves readily in potassium cyanide solution. In other cases the solubility change appears to be connected with a displacement of equilibrium, as when the solubility of a salt is diminished by adding another electrolyte with a common radicle, or when it is increased by adding another electrolyte with both radicles different. The influence of salts on the solubility of non-electrolytes is more difficult to explain, the general, although not the universal, rule being that a non-electrolyte is less soluble in a salt solution than in pure water at the same temperature. The solubility of a non-electrolyte in water is sometimes raised, sometimes lowered, by the addition of another non-electrolyte. (For a detailed discussion of this whole question, *see* Rothmund's Löslichkeit und Löslichkeitsbeeinflussung, vol. vii. of Bredig's Handbuch der angewandten Physikalische Chemie; also Eyre, Brit. Assoc. Reports, 1910, 425.)

As regards the factors which determine the solubility of a given solid in a given solvent, little is known. From the mass of data available a number of regularities have been deduced, but these are of limited scope. Thus, for instance, it is known that, with water as solvent, the solubility of the monohydric alcohols diminishes as the preponderance of the alkyl radicle increases and that an increase in the number of hydroxyl groups introduced into a molecule leads to an increased solubility. For isomeric substances, certain rules have been deduced, such as that the more fusible isomer is also the more soluble in a given solvent, and that the ratio of the solubilities of two isomers in different solvents is approximately the same. *See* Lumsden, Chem. Soc. Trans. 1902, 81, 363; Rothmund, *l.c.* and Eyre, *l.c.*) J. C. P.

SOLUTION. The history of chemistry has been marked by constant speculation on the nature of the system formed when a substance dissolves in a liquid. The theories held at one time or another in regard both to the process of dissolution and to the constitution of solutions may be roughly classed as chemical or physical, according to the nature of the forces supposed to be at work. In either case, however, the experimental basis is furnished by the physical properties of solutions, and the utility and fitness of any theory of solution must be judged by the extent to which it is capable of interpreting these properties.

It is impossible within the limits of this article to deal exhaustively with the physical properties of solutions, but it is proposed to discuss the experimental results which have been achieved in connection with some of the more salient characteristics, and then to sketch the modern theories, based on these properties, which bear on the question of the nature of solution.

Density. It has been found that when aqueous solutions of different salts of the same molecular concentration (for example, 1 mol. salt to 100 mols. water) are compared, the density of the solution increases with the molecular weight of the dissolved salt. This rule, however, is not strictly valid unless the metals in the salts belong to the same group (*see* Kremers, Pogg. Ann. 1854, 92, 497; 1855, 94, 87, 255; Mendeléeff, Ber. 1884, 17 (Ref.), 155; Gerlach, Zeitsch. anal. Chem. 1888, 27, 271; 1889, 28, 290, 466; Charpy, Compt. rend. 1892, 114, 539). More definitely quantitative in character is the observation made by Valson, that if solutions of two salts AB and AB′ are compared, each solution containing 1 gram-equivalent in 1 litre of water, the difference in density is practically the same whatever the acid radicle A may be. Similarly the difference in density of comparable solutions of two salts AB and A′B with a common positive radicle is independent of B. There may therefore be assigned to each radicle, positive or negative, a certain figure or 'modulus,' such that the density of a normal solution of any salt can be calculated approximately by simply adding together the two values for the radicles contained in the salt (Valson, Compt. rend. 1871, 73, 441). This additive character of the density of dilute aqueous salt solutions has been confirmed by subsequent observers (*see* Ostwald, J. pr. Chem. 1878, 18, 353; Nicol, Phil. Mag. 1883, 16, 121; 1884, 17, 150; Bender, Ann. Physik, 1883, 20, 560). Bender was able to extend Valson's law of moduli on the strength of the observation that if Δ represents the difference between the densities of two salt solutions, each containing m equivalents of salt per litre of solution, then Δ/m is a constant for the two salts at a given temperature.

Investigation has shown that the density of a salt solution increases less rapidly than the concentration and that accordingly the value of the expression $\frac{s-1}{m}$, where s is the specific gravity and m is the concentration in gram-equivalents per litre, decreases as the concentration of the solution increases. If $\frac{s-1}{m}$ is plotted against m, the decrease is often found to be exceptionally marked in very dilute solutions, although the curves obtained by plotting $\frac{s-1}{m}$ against $m^{\frac{1}{3}}$ are practically straight lines (Kohlrausch and Hallwachs, Ann. Physik, 1893, 50, 118). More recently it has been found that within certain concentration limits the quantity $\frac{s-1}{m}$ is a linear function of the degree of dissociation as defined by Arrhenius (*see* Magie, Physical Review, 1907, 25, 171; Heydweiller, Ann. Physik, 1909, 30, 873; 1910, 31, 1063).

Much attention has been devoted to the character of the density-concentration curve in the case of aqueous solutions of sulphuric acid and ethyl alcohol. When the first or second differential of the sp.gr.—$\frac{ds}{dp}$ or $\frac{d^2s}{dp^2}$—is plotted against the percentage composition p, a series of straight lines is obtained in place of the continuous curve which results when s is plotted against p. It is maintained by some investigators that the discontinuities thus exhibited correspond with the formation of definite compounds between water and the dissolved substance (*see* Mendeléeff, Ber. 1886, 19, 379; Zeitsch. physikal. Chem. 1887, 1, 273; Chem. Soc. Trans. 1887, 51, 778; Pickering, *ibid.* 1890, 57, 64; compare Crompton, *ibid.* 1888, 53, 116; Arrhenius, Phil. Mag. 1889, 28, 30; Pickering and others, Chem. Soc. Proc. 1891, 105).

Closely related to the subject of density is the question how far the process of dissolution is accompanied by change of volume. A study of mixtures of organic liquids from this point of view has shown that the differences between the densities directly determined and the values calculated on the assumption that no change of volume occurs on mixing are considerably greater where associated liquids are involved than where both liquids are 'normal.' In the majority of cases where the mixed liquids belong to the latter class the observed density is less than the calculated value (Linebarger, Amer. Chem. J. 1896, 18, 429).

The investigation of solutions of such substances as paraffin, naphthalene, anthracene, dinitrobenzene and benzil in non-associated organic solvents has shown that the volume occupied by the solute in solution is approximately a constant, independent of the concentration and, with certain limitations, of the solvent. This volume, further, is approximately equal to the volume which the pure solute would occupy in the liquid state at the same temperature (Beilby, Chem. Soc. Trans. 1883, 43, 138; Nicol, *ibid.* 1896, 69, 142; Forch, Ann. Physik, 1905, 17, 1012; Lumsden, Chem. Soc. Trans. 1907, 91, 24; Dawson, *ibid.* 1910, 97, 1041, 1896; Tyrer, *ibid.* 2620).

The changes of volume which accompany the dissolution of a substance in water are much more notable. For some anhydrous salts and other substances, such as sodium hydroxide in dilute solution, the volume of the solution is actually less than the volume occupied by the pure solvent (*see* Macgregor, Chem. News, 1887, 55, 3). Attempts to find the volume occupied by a solute in aqueous solution are generally based on the assumption that the volume of the solvent in the solution is the same as if it were in the pure state. On this basis the molecular solution volume v_m, that is, the volume occupied by 1 gram-molecule of the dissolved substance, is given by the formula $v_m = \frac{m+w}{d} - \frac{w}{\delta}$, where m is the molecular weight of the solute in grams, w is the weight of water in which the gram-molecule is dissolved, d and δ are the densities of solution and pure water respectively (*see* Nicol, Phil. Mag. 1883, 16, 121; 1884, 18, 179; Kohlrausch and Hallwachs, Ann. Physik, 1893, 50, 118; 1894, 53, 14; Kohlrausch, *ibid.* 1895, 56, 185; Traube, Ueber den Raum der Atome, Ahrens' Sammlung, 1899, 4, 255). The value of the molecular solution volume for a non-electrolyte in aqueous solution does not vary much, as a rule, with the concentration (*see* also Wanklyn, Chem. News, 1892, 65, 122). For an electrolyte, on the other hand, the molecular solution volume diminishes as the concentration of the solute diminishes and, in many cases at least, approaches a constant value in very dilute solution. From these values, Traube has deduced figures which represent the atomic solution volumes and he finds that for a non-electrolyte in aqueous solution the molecular solution volume is equal to the sum of the atomic volumes, *plus* an increment of 12·4 c.c., which is termed the 'molecular co-volume.' He further concludes that the contraction accompanying the dissolution of a gram-molecule of any non-electrolyte in water (a *dilute* solution being formed) is 13·5 c.c. at 15°, and that the contraction for each gram-ion of a binary electrolyte is the same as that for the gram-molecule of a non-electrolyte.

Osmosis and related properties. If a layer of concentrated sugar solution is put at the bottom of a tall jar and the jar is then carefully filled up with water, diffusion sets in, with the result that the concentration of the sugar ultimately becomes uniform throughout the jar. The existence of the force which thus brings about the intermixture of the sugar and the water could be rendered evident by interposing between solution and solvent some surface which would differentiate between sugar and water, preventing the passage of the former, but freely permeable to the latter. If a membrane with these properties were interposed between the water and the strong sugar solution the system would seek to reach equilibrium in the only way left open to it, viz. by water entering the solution through the membrane; that is, a one-sided diffusion, or 'osmosis,' would occur. The resulting increase in the bulk of the solution would lead either to the bursting of the membrane or, if the membrane were rigid and strong enough, to the production of a hydrostatic pressure opposing the further passage of water into the solution. The pressure developed in the solution in the latter case might be taken as a measure either of the driving force under the influence of which the sugar molecules diffuse; or, simply, of the attraction between solvent and solution.

These conditions are capable of experimental realisation. Membranes are known which may be described as 'semi-permeable,' since they are freely permeable to water, but impermeable to certain dissolved substances. A membrane of copper ferrocyanide, for instance, produced at the common surface of solutions of copper sulphate and potassium ferrocyanide, is permeable to water, but impermeable to dextrose or sucrose, and has been much used in the quantitative study of osmosis. When the copper ferrocyanide is deposited in the walls of a porous porcelain pot, sufficient strength and rigidity are imparted to the membrane to enable it to withstand high pressures. The porous pot, connected with a closed mercury manometer, is filled with a solution of dextrose or sucrose, and is then immersed in pure water. The force with which water seeks to enter the solution is then determined by measuring the pressure developed within the cell—the 'osmotic pressure,' as it is called.

The first direct determinations of this force (Pfeffer, Osmotische Untersuchungen, 1877) showed that the osmotic pressure of sucrose solutions at a constant temperature is approximately proportional to the concentration, and that the osmotic pressure of a given sucrose solution varies nearly as the absolute temperature (*see* van 't Hoff, Phil. Mag. 1888, 26, 81; Ladenburg, Ber. 1889, 22, 1225; Adie, Chem. Soc. Trans. 1891, 59, 344; König and Hasenbäumer, Zeitsch. angew. Chem. 1909, 22, 1009, 1070). The validity of these relationships has recently been subjected to a searching investigation by Morse, Frazer and others (Amer. Chem. J. 1905, 34, 1; 1906, 36, 1, 39; 1907, 37, 324, 425, 558; 38, 175; 1908, 39, 667; 40, 1, 194; 1909, 41, 1, 257; 1911, 45, 91, 237, 383, 517, 554). Working with dextrose and sucrose solutions containing from 0·1 to 1·0 gram-molecule per 1000 grms. of water, these investigators find that the osmotic pressure is proportional to the concentration, provided that this latter is referred, not to unit volume of the solution, but to unit volume of the solvent. For the temperature range 0°–25°, they find that the osmotic pressure of a given solution is proportional to the absolute temperature.

Direct determinations of the osmotic pressure of strong solutions have been made by Lord Berkeley and co-workers (Phil. Trans. A, 1906, 206, 481; 1909, 209, 177, 319; *see* also Proc. Roy. Soc. A, 1909, 82, 271). They have investigated sucrose solutions containing up to 750 grms. sucrose per litre and measured osmotic pressures up to 133 atmospheres. It is found that the osmotic pressure increases more rapidly than the concentration, even when the latter is referred to unit volume of the solvent. (For a summary of this work on osmotic pressure, *see* Lowry, Science Progress, 1913, 7, 544.)

For the purpose of finding 'isotonic' solutions—that is, solutions of equal osmotic pressure—a study of the water exchange taking place across a semipermeable membrane of animal or vegetable origin has been found useful (*see*, for instance, Tammann, Ann. Physik, 1888, 34, 299; de Vries, Zeitsch. physikal. Chem. 1888, 2, 415; Hamburger, *ibid.* 1890, 6, 319; Hedin, *ibid.* 1895, 17, 164). One chief result of these investigations has been to show that, for equal molecular concentrations, the osmotic activity of a binary salt (*e.g.* sodium chloride) is much greater than that of a non-electrolyte such as sucrose, and that ternary salts (*e.g.* calcium chloride) are still more active.

The vapour pressure p' of a solution of a non-volatile solute is lower than the vapour pressure p of the pure solvent at the same temperature, and the relation between these and the concentration is expressed by the formula $\frac{p-p'}{p}=\frac{n}{n+N}$, where n and N are the numbers of solute and solvent molecules respectively in the solution (*see* Raoult, Zeitsch. physikal. Chem. 1888, 2, 353). There is also a quantitative relationship between the osmotic pressure of a solution and its vapour pressure (van 't Hoff, *ibid.* 1887, 1, 481; Gouy and Chaperon, Ann. Chim. Phys. 1888, 13, 124; Arrhenius, Zeitsch. physikal. Chem. 1889, 3, 115; Berkeley and Hartley, Proc. Roy. Soc. A, 1906, 77, 156; Spens, *ibid.* 234; Porter, *ibid.* 1907, 79, 519; 1908, 80, 457). In order to deduce osmotic pressure from vapour pressure by this relationship it is necessary to know only the *ratio* of the vapour pressures of solvent and solution at the same temperature, not their absolute values. The value of the ratio can be found by Ostwald and Walker's method (Zeitsch. physikal. Chem. 1888, 2, 602), and Berkeley and Hartley, using a modified form of apparatus, have found that the values of the osmotic pressure deduced from the relative vapour pressures of solvent and solution are in good agreement with the values obtained by direct measurement (Proc. Roy. Soc. A, 1906, 77, 156; Phil. Trans. A, 1909, 209, 177).

The boiling point of a solution of a non-volatile solute is higher than that of the pure solvent, the extent of the rise being proportional to the molecular concentration of the solute (Raoult, Compt. rend. 1878, 87, 167; Beckmann, Zeitsch. physikal. Chem. 1889, 4, 532; 1890, 6, 437; 1891, 8, 223; 1894, 15, 656; compare, for other practical methods of finding the rise of boiling point for a solution: Sakurai, Chem. Soc. Trans. 1892, 61, 989; Landsberger, Ber. 1898, 31, 458; Walker and Lumsden, Chem. Soc. Trans. 1898, 73, 502; Turner, *ibid.* 1910, 97, 1184). For each solvent there is a characteristic figure or constant, known as the 'molecular elevation of the boiling point,' which is defined as the rise of boiling point for a solution containing 1 gram-molecule of solute in 100 grms. of solvent. This constant can be evaluated either empirically, from the rise of boiling point observed with normal solutes of known molecular weight, or from van 't Hoff's formula $k=0{\cdot}02T^2/l$, where T is the boiling point of the solvent on the absolute scale, and l is its latent heat of vaporisation.

The osmotic pressure P of a moderately dilute solution can be calculated from its boiling point T by the formula $P=\frac{1000Sl}{24{\cdot}25}\cdot\frac{T-T_0}{T_0}$ atmospheres, where S is the sp.gr. of the solvent at its boiling point T_0, and l is the latent heat of vaporisation for 1 grm. of solvent. For aqueous solutions this formula reduces to $P=56{\cdot}8\ (T-T_0)$ atmospheres.

The freezing point of a solution is lower than that of the pure solvent by an extent which is proportional to the molecular concentration of the dissolved substance (for details of this, *see* CRYOSCOPY). The osmotic pressure P of a solution is quantitatively related to its freezing point T by the formula $P=\frac{1000Sw}{24{\cdot}25}\cdot\frac{T_0-T}{T_0}$ atmospheres, where S is the sp.gr. of the solvent at its freezing point T_0, and w is the latent heat of fusion for 1 grm. solvent. For aqueous solutions this formula becomes $P=12{\cdot}03\ (T_0-T)$ atmospheres.

The quantitative relationships already referred to between osmotic pressure, lowering of vapour pressure, rise of boiling point, and depression of freezing point, on the one hand, and molecular concentration on the other, are, generally speaking, valid only for solutions of non-electrolytes. For electrolytic solutions, notably those of salts in water, the osmotic value, determined directly or indirectly, is abnormally high. The observed depression of freezing point, for instance, for a dilute solution of sodium chloride in water is nearly twice as great as the depression calculated from the accepted freezing point constant for water, on the assumption that the molecular condition of the dissolved salt is represented by NaCl. If $i=\frac{\text{observed depression}}{\text{theoretical depression}}$, it is found that for dilute solutions of binary salts such as sodium chloride or potassium nitrate, the values of i run up to 2, while for dilute solutions of ternary salts such as calcium chloride or sodium sulphate, the values run up to 3 (*see* Arrhenius, Zeitsch. physikal. Chem. 1887, 1, 635; 1888, 2, 495; Bedford, Proc. Roy. Soc. A. 1910, 83, 454). It is noteworthy that for solutions of sodium mellitate a value of i almost equal to 6 has been recorded (Taylor, Zeitsch. physikal. Chem. 1898, 27, 361).

Electrical conductivity. The significance of this property in relation to the constitution of solutions is generally admitted. The accurate determination of the electrical conductivity of aqueous salt solutions dates from the investigations of Kohlrausch (Ann. Physik, 1879, 6, 1, 145; 1885, 26, 161; *see* especially Kohlrausch and Holborn, Leitvermögen der Elektrolyte, 1898, where there is a full list of references to all the fundamental work on the subject). These, supported by the work of later investigators, have shown that whilst for a given salt the conductivity referred to standard dimensions of the conducting column diminishes as the dilution increases, on the other hand the conductivity referred to a fixed quantity of the dissolved salt *increases* with the dilution. The 'specific resistance' of an electrolytic solution is now defined as the resistance in ohms between two opposite faces of a centimetre cube containing the solution. The 'specific conductivity,' represented by the symbol κ, is the reciprocal of the specific resistance, and diminishes as the dilution increases. A measure of the conductivity referred to a fixed quantity of the dissolved electrolyte is given by the product $\kappa\times\phi$, where ϕ is the volume of solution (in cub. cm.) containing 1 gram-equivalent of the solute. The product $\kappa\times\phi$ is represented by the symbol Λ (or λ) and is termed the 'equivalent conductivity.' The equivalent conductivity of a salt (acids and bases included) increases as the concentration diminishes, and approaches a maximum limit at very high dilutions. In many cases at least, an extrapolation may be made and the limiting value Λ_∞ of the equivalent conductivity at infinite dilution thus obtained (*see* Kohlrausch, Ann. Physik, 1885, 26, 161; Bredig, Zeitsch. physikal. Chem. 1894, 13, 191). The variation of specific and equivalent conductivity with dilution for non-aqueous solutions appears to be generally of the same character as for aqueous solutions (*see* Walden, *ibid.* 1906, 54, 133; 1911, 78, 257; Turner, Amer. Chem. J. 1908, 40, 571; Dutoit and Duperthuis, J. Chim. phys. 1908, 6, 703; Philip and Courtman, Chem. Soc. Trans. 1910, 97, 1261).

The values of Λ_∞ for aqueous solutions, more particularly those of binary electrolytes, were shown by Kohlrausch to be additive in character; that is, Λ_∞ may be represented as the sum of two other values, attributable to the positive and negative ions respectively. The equation $\Lambda_\infty=u+v$, where u is the contribution of the cation and v is that of the anion, is the algebraic expression of Kohlrausch's Law of the Independent Migration of the Ions, for it is found that the contribution which any ion makes to the equivalent conductivity at infinite dilution is independent of the other ion with which it is associated (*see* Kohlrausch, *l.c.*; Loeb and Nernst, Zeitsch. physikal. Chem. 1888, 2, 948). The actual values of u and v are obtained by a combination of the figures for Λ_∞ and Hittorf's transport numbers (Pogg. Ann. 1853, 89, 177; 1856, 98, 1; 1858, 103, 1; 1859, 106, 338, 513; reprinted in Ostwald's Klassiker der exakten Wissenschaften: *see* also Loeb and Nernst, *l.c.*; Drucker, Zeitsch. Elektrochem. 1907, 13, 81; Kohlrausch, *ibid.* 333; McBain, Proc. Wash. Acad. Sci. 1907, 9, 1; Washburn, Technology Quart. 1908, 21, 164; Denison, Trans. Faraday Soc. 1909, 5, 165). The relation between the conductivity and the viscosity of salt solutions has also an important bearing on their constitution (*see* Kohlrausch, Sitzungsber. K. Akad. Berlin, 1902, 572; Bousfield and Lowry, Proc. Roy. Soc. 1902, 71, 42; Walden, Zeitsch. physikal. Chem. 1906, 55, 207; 1911, 78, 257).

Theories of solution. The remarkable way in which physical and chemical conceptions of the relation between solute and solvent have long struggled for pre-eminence has been sketched in detail by Walden (Ahrens' Sammlung, vol. 15: 'Die Lösungstheorien in ihrer geschichtlichen Aufeinanderfolge'). The last three decades have witnessed a renewed activity in the investigation of solutions, resulting in the accumulation of a vast amount of material, some part of which has been indicated in the preceding paragraphs. Some scientists have interpreted these facts in terms of a chemical interaction of solute and solvent: by others physical considerations have been put in the foreground, to the exclusion of any chemical factor.

The 'hydrate' theory is based on the view that the formation of an aqueous solution is essentially a process of association, and that the solution contains compounds of solute and solvent, the complexity of which increases with dilution. The supporters of this theory originally found evidence for their views in the character of the density-concentration curves (*see* Mendeléeff, Zeitsch. physikal. Chem. 1887, 1, 273; Chem. Soc. Trans. 1887, 51, 778; Pickering, *ibid.* 1890, 57, 64; Watts' Dictionary, 1894, 'Solution,' second article). The method, however, adopted for deducing the composition of the definite hydrates supposed to be present in the solutions has been subjected to serious criticism, and in its original form the theory is hardly tenable. If modified in harmony with the conceptions of reversibility and mass action a hydrate theory of solution has many facts in its favour (*see* Lowry, Science Progress, 1908, 3, 124). The case in support of the view which regards the solvent as exercising an associative function has been stated also by Armstrong (Proc. Roy. Soc. A, 1906, 78, 264; *ibid.* 1908, 81, 80; Chem. News, 1911, 103, 97).

More generally accepted at the present time and more commonly employed as a working hypothesis in the investigation of solutions are the theories associated with the names of van 't Hoff and Arrhenius. By a thermodynamical argument, based on the validity of Henry's Law, van 't Hoff reached the conclusion that the osmotic pressure of a dilute solution must be proportional (1) to the concentration of the solute and (2) to the absolute temperature (Zeitsch. physikal. Chem. 1887, 1, 481; Phil. Mag. 1888, 26, 81; compare Rayleigh, Nature, 1897, 55, 253; Kelvin, *ibid.* 272; Larmor, *ibid.* 545). He pointed to Pfeffer's measurements (see above) as an experimental verification of these conclusions, and therefore felt justified in extending Boyle's Law and Gay-Lussac's Law to dilute solutions. Further, van 't Hoff extended Avogadro's hypothesis to solutions and assumed that at a given temperature equal volumes of two dilute solutions which have equal osmotic pressures contain the same number of dissolved molecules. Evidence in favour of this extension of Avogadro's hypothesis was found in the known influence of different substances on the vapour pressure and freezing point of a solvent. In analogy then with the gas equation $pv = RT$, the behaviour of substances in dilute solution may be represented by an equation $PV = R'T$, where P is the osmotic pressure and V is the volume of solution containing 1 gram-molecule of solute. The known values of P, V, and T, for dilute sucrose solutions showed that $R' = R$, and hence van 't Hoff concluded that the osmotic pressure of a dilute sugar solution is equal to the pressure which the sugar would exert if it were in the gaseous state at the same temperature and occupied the same volume as the solution. While this statement is valid for dilute solutions it is not strictly accurate for higher concentrations. Under these conditions the observed osmotic pressure for sucrose solutions is greater than the corresponding gas pressure, even when the concentration is referred to unit volume of solvent instead of unit volume of solution (*see* Morse and others, Amer. Chem. J. 1911, 45, 554; Berkeley and Hartley, Phil. Trans. A, 1906, 206, 481; Berkeley, Proc. Roy. Soc. A, 1907, 79, 125; Callendar, *ibid.* 1908, 80, 466).

It should be noted that the quantitative relationships involved in van 't Hoff's theory are independent of the exact way in which the osmotic pressure originates. Indeed, diverse views are held as to the origin and mechanism of osmotic pressure (*see*, for instance, Bredig, Zeitsch. physikal. Chem. 1889, 4, 444; L. Meyer, *ibid.* 1890, 5, 23; van 't Hoff, *ibid.* 1890, 5, 174; Ber. 1894, 27, 6; Whetham, Nature, 1896, 54, 571; Poynting, *ibid.* 55, 33; Armstrong, *ibid.* 55, 78; Barmwater, Zeitsch. physikal. Chem. 1899, 28, 115; Lowry, Kahlenberg and others, Trans. Faraday Soc. 1907, 3, 14; Traube, Ber. 1909, 42, 86).

In his original paper, van 't Hoff drew attention to the fact (see above) that there are certain substances which in aqueous solution give abnormally high osmotic pressures and the behaviour of which cannot be represented by the formula $PV = RT$. These exceptional cases are very numerous, but can be brought into line with normal substances by assuming that the abnormal substances are dissociated. Arrhenius had pointed out that it is precisely those substances (viz. salts, acids and bases) which give abnormally high osmotic values in aqueous solution that make water a conductor of the electric current, and he proposed a common explanation for the two phenomena by suggesting that when a salt is dissolved in water it dissociates to a greater or less extent into positively and negatively charged particles or ions. Such a dissociation would mean an increased number of units in solution and so would account for the abnormally high osmotic values observed with salt solutions. The presence of the ions would confer on the water the power of conducting the electric current, the passage of the current through a conductor of this kind being supposed to consist in the streaming of positive ions in the one direction and of negative ions in the other, under the influence of the applied E.M.F.

In relation to conduction, Arrhenius classified the molecules in a salt solution as active or inactive, according as their ions were independent in their movements or were closely linked together. Only the active molecules were able to take part in the conduction of the current, but it was supposed, in view of the variation of equivalent conductivity with concentration, that at extreme (infinite) dilution all the molecules of the dissolved salt became active. On this basis, a measure of the extent of dissociation in any salt solution is obtained by comparing the value Λ of the equivalent conductivity for that solution with the value Λ_∞ of the equivalent conductivity at infinite dilution. If α is the 'degree of dissociation' (or 'coefficient of ionisation') then $\alpha = \frac{\Lambda}{\Lambda_\infty}$. On the other hand, if i is a measure of the osmotic abnormality (see above), it follows that $\alpha = \frac{i-1}{n-1}$, where n is the number of ions into which a molecule of solute dissociates. Arrhenius was able to show that the values of α deduced for a given salt by the two independent methods were in fair, although not perfect, agreement (Arrhenius, Zeitsch. physikal. Chem. 1887, 1, 631; 1888, 2, 495; Watts' Dictionary, 1894, 'Solution,' first article; Whetham. Proc. Roy. Soc. 1900, 66, 192; Noyes, Technology Quart. 1904, 17, 293; Drucker, 'Die Anomalie der starken Electrolyte,' Ahrens' Sammlung, 1905; Bedford, Proc. Roy. Soc. A, 1910, 83, 454).

The electrolytic dissociation theory of Arrhenius has proved very serviceable in the quantitative study of numerous phenomena exhibited by aqueous solutions of acids, bases and salts; as, for instance, in the interpretation of diffusion (Nernst, Zeitsch. physikal. Chem. 1888, 2, 613; 1889, 4, 129; Arrhenius, *ibid.* 1892, 10, 51), of the relative strength of acids and bases (Ostwald, *ibid.* 1888, 2, 36, 270; van 't Hoff and Reicher, *ibid.* 779; Arrhenius, *ibid.* 1889, 4, 226; Walker, *ibid.* 319; Shields, Phil. Mag. 1893, 35, 365), of the influence of salts on the activity of the corresponding acids (Arrhenius, Zeitsch. physikal. Chem. 1888, 2, 284; 1890, 5, 1), of reciprocal solubility influences (Nernst, *ibid.* 1889, 4, 372; Noyes and others, *ibid.* 1890, 6, 241; 1892, 9, 603; 1898, 27, 267, 442), of the distribution of an electrolyte between two immiscible solvents (Nernst, 1891, 8, 110), and of the thermo-chemistry of salt solutions (Arrhenius, Zeitsch. physikal. Chem. 1889, 4, 96; 'Theories of Chemistry,' 1907, chap. xiii.).

The fact that water is such a good dissociating or ionising solvent is probably connected with its high dielectric constant (Thomson, Phil. Mag. 1893, 36, 320; Nernst, Zeitsch. physikal. Chem. 1894, 13, 531; Walden, *ibid.* 1906, 54, 129; compare Crompton, Chem. Soc. Trans. 1897, 71, 925; Dutoit and Friderich, Bull. Soc. chim. 1898, 19, 321; Dutoit and Aston, Compt. rend. 1898, 125, 240; Brühl, Zeitsch. physikal. Chem. 1898, 27, 319). This, however, does not adequately explain the cause of ionisation, or indicate the source whence the energy necessary for ionisation is derived. It has been growingly felt that in the earlier presentation and applications of the theory of electrolytic dissociation the part played by the solvent was too much neglected, and at the present time the view is commonly held that, in many cases at least, the ions of a salt solution are hydrated. Not only so; it is urged by some that it is the hydration of the ions which is the source of energy in ionisation (*see* Lowry, Science Progress, 1908, 3, 202). The evidence bearing on the existence of hydrated ions and the methods available for determining the extent of hydration have been summarised by Washburn (Technology Quart. 1908, 21, 360).

J. C. P.

SOMATOSE. An albumose preparation from meat.

SOMBRERITE. A mixed calcium and aluminium phosphate occurring on Sombrero and other islands of the Antilles (*v.* FERTILISERS; also PHOSPHORUS).

SOMNOFORM *v.* SYNTHETIC DRUGS.

SOPHORA JAPONICA (Linn.). This is a large and beautiful tree, not unlike an acacia, belonging to the *Leguminosæ*, which grows abundantly throughout China.

The undeveloped flower buds constitute an important yellow dyestuff employed by the Chinese for colouring the silken vestments of the mandarins. For this purpose the buds are collected and dried rapidly, either in the sun or by artificial means, usually with the addition of a little chalk. The method of dyeing consists in simply boiling for 1–1½ hours in a decoction of the flower buds, silk which has been previously mordanted by steeping overnight in a decoction of alum. Less frequently it is employed in the dyeing of cotton and wool. Its price is about 30*s.* a cwt.

This dyestuff has been studied by many chemists, especially by Schunck (Chem. Soc. Trans. 1888, 53, 262; 1895, 67, 30), who has proved that the glucoside which it contains formerly called sophorin (Förster, Ber. 1882, 15, 214) is in reality identical with rutin, the quercetin glucoside first isolated from rue (*Ruta graveolens* [Linn.]) by Weiss (Chem. Zentr. 1842, 903). (Compare also Stein, J. pr. Chem. [i.] 58, 399; 85, 351; 88, 280; Schunck, Manchester Memoirs, 1858, 2 ser. 15, 122.)

When applied to wool the *Sophora Japonica* buds give colours somewhat like those obtained with quercitron bark, viz. a dull orange with chromium, a yellow of moderate brilliancy with aluminium, a bright yellow with tin and a dark olive with iron. In dyeing power it seems to be equal if not slightly superior to quercitron bark, and is to be regarded as an excellent dyestuff, quite equal to those of similar character in general use (Hummel and Perkin, J. Soc. Chem. Ind. 1895, 458).

A. G. P.

SORANJES, or **SURANJI**, *v.* AAL.

SORBITE. One of the constituents of steel. It is intermediate in properties between cementite and pearlite (*q.v.*), and may be regarded as pearlite in which the lamellæ or granules are so fine that no microscope can resolve them (Osmond, Revue de Métallurgie, 1904).

It is an important constituent of structural steels, *v.* METALLOGRAPHY.

SORBITOL *v.* CARBOHYDRATES.

SORBOSE *v.* CARBOHYDRATES.

SOUDAN BROWN *v.* AZO- COLOURING MATTERS.

SOY. A well-known sauce made from soy beans (*Soja hispida* (Moench.); nat. ord. *Leguminosæ*), chiefly in Japan, and to a less extent in China, India, and the Moluccas. It is known to the Japanese as 'Sho-ju,' and to the Dutch, by whom it appears to have been introduced into Europe, as 'shoya.'

To prepare the sauce, the beans are ground up with an equal quantity of wheat or barley, and boiled with water until soft, when the mixture is left in a warm place for about 24 hours to ferment. It is then covered with a thick layer of salt, water poured over it, and the mass stirred daily for about a couple of months. The liquor is then poured off, squeezed out of the sediment and stored in wooden vessels, in which it clears on standing.

A Chinese sauce, known as 'kit-jap' (hence 'ketchup'), is sometimes sold as 'soy,' and often the article described under this name is nothing more than diluted molasses flavoured to imitate soy.

J. C.

SOYA (*Soja*) **BEAN OIL** (*Soy-Bean oil, Bean oil, Chinese Bean oil*). This oil is obtained from the seeds of *Glycine Soja*, Sieb. et Zucc., *Dolichos Soja*, Linn., *Soja hispida*, Moench, *Soja japonica* Savi, *Glycine hispida*, Maxim (' Sachuca bean '), a plant indigenous to China, Manchuria, Korea, Japan, Formosa, and Indo-China, where the oil and the expressed cake are largely used as foodstuffs. The seeds contain 18 p.c. of oil and about 30–40 p.c. of proteins.

The cultivation of the soya bean has been for centuries the main agricultural industry of Manchuria, and the industries based on the production of soya bean oil and soya bean cake have formed the most important manufacture of Manchuria, and to a large extent of Japan.

Up to the last Russian-Japanese war, the soya bean and soya bean oil were practically unknown in Europe. Since then, however, enormous quantities have been imported into Europe and the oil has in an extremely short time acquired the position of one of the foremost oleaginous seeds, rivalling in extent and importance the cotton-seed oil industry of Europe. Owing to their high proportion of proteins, they have rapidly acquired great commercial importance; especially so as it is stated that the soya cake is instrumental in producing cow-milk richer in butter fat than is obtained when feeding with linseed and cotton-seed cake. In this country, however, the cake has not yet been employed for feeding milk cows to the same extent that it has on the Continent (Denmark, Holland).

In Manchuria, three varieties of Soja are known, commercially, namely, yellow, green and black, but the commercial seeds represent at least seven varieties. The almost phenomenal importance which the soya bean industry has acquired in the course of two years has led to the attempt to cultivate the soya bean for commercial purposes in other countries, and at present experiments are being made to produce soya beans in Australia, South Africa, United States of America, Italy, Spain, South America, and even in this country.

In Manchuria, the beans are soaked in water over night, then crushed and boiled with a little water so as to burst the oil cells. The oil is then expressed in the most primitive fashion; but owing to the long time the cakes are allowed to remain in the press the yield of oil amounts to 13 p.c., whereas experiments made with modern machinery are stated to have yielded no more than 10 p.c. The expressed meal is made into bean-cakes which constitute one of the staple foods of the country, and form the most important article of export. Before the Russian-Japanese war, the chief export of beans from Manchuria was directed to Japan, where the bean is used on the most extensive scale for the preparation of the condiment 'Shoyu' and 'Misu' (Soja sauce).

For the characteristics of soya bean oil *see* OILS, FIXED, AND FATS.

The oil must be classed with the drying oils, inasmuch as it (or at least some varieties of the soya bean oil) yields up to 5 p.c. of hexabromide in the bromide test. The drying powers are, however, weak as compared with linseed oil.

J. L.

SOZAL *v.* SYNTHETIC DRUGS.

SOZOIODAL *v.* SYNTHETIC DRUGS.

SPANISH GRASS *v.* ESPARTO and PAPER.

SPANISH OCHRE. *Burnt Roman Ochre* *v.* PIGMENTS.

SPAR (Ger. *Spath*, *Spat*). A general term applied to a variety of minerals without metallic lustre which occur as crystals or which cleave into fragments with bright surfaces. Such sparry minerals are well known to miners as the gangue of metallic ores. Several kinds of spar are distinguished by popular names, and the term also enters into certain mineralogical names. For example: Derbyshire-spar (fluorspar); calc-spar, Iceland-spar, doubly-refracting spar, dog-tooth-spar, and nail-head-spar (calcite); heavy spar (barytes); satin-spar (gypsum and calcite); tabular spar (wollastonite); adamantine spar (corundum); felspar, feldspar; &c. In special trades, however, the term 'spar' is often used for one particular kind of spar.

L. J. S.

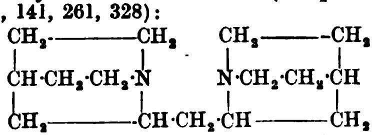
SPARTEINE $C_{15}H_{26}N_2$ (Mills, Chem. Soc. Trans. 15, 1) is the alkaloid of the common broom, *Cytisus Scoparius* (Link), in which it was discovered by Stenhouse (Chem. Soc. Trans. 4, 218). It is produced in greatest quantity during the early part of the life of the plant (Chevalier, Compt. rend. 1910, 150, 1068), and is prepared from broom-tops by adding caustic soda to the aqueous extract and then distilling with steam, or by evaporating the extract to dryness and dissolving out the alkaloid with dilute hydrochloric acid (Stenhouse). 1000 grms. of the plant yield 3 grms. pure product (Houdé, J. Pharm. Chim. [v.] 13, 39). For other methods of extraction *see* Houdé, *l.c.*; Kerchmann, Arch. Pharm. [iii.] 9, 209.

Sparteine is a thick, heavy liquid, colourless when freshly prepared, becoming brown on exposure to light and air. It boils at 180°–181° at 20 mm. (Bernheimer, Gazz. chim. ital. 13, 451); 287° (Houdé); 311°–311·5° at 723 mm. (Bamberger, Annalen, 235, 368); 326° (Wackernagel and Wolffenstein, Ber. 1904, 37, 3238); 188° (corr.) at 18·5 mm. and 325° (corr.) in a current of dry hydrogen at 754 mm. (Moureu and Valeur, Compt. rend. 1903, 137, 194). It has sp.gr. 1·034 at 0°, 1·0196 at 20° (Moureu and Valeur, *loc. cit.*), 1·0199 at 20° (Semmler, Ber. 1904, 37, 2428); the specific rotation $[\alpha]_D$ is $-16{\cdot}42°$ (M. and V.), $-14{\cdot}6°$ at 26° (Bernheimer, *l.c.*); and the refractive index n_D is 1·5293 at 19° (M. & V.), 1·5291 at 20° (Semmler).

It is soluble in water to the extent of 0·304 parts in 100 (Moureu and Valeur, *loc. cit.*), and is readily soluble in alcohol, ether, and chloroform; insoluble in benzene and petroleum (Houdé, *loc. cit.*).

Sparteine has a strong alkaline reaction and behaves as a diacid base towards phenol phthalein, &c., but as a monacid base to litmus. It has a very bitter taste and is a powerful narcotic poison. Administered in small doses (as the sulphate in aqueous solution) it strengthens the action of the heart and immediately regulates any disorder of the cardiac rhythm (Sée, Compt. rend. 101, 1046; *see* also Maurel, Compt. rend. Soc. Biol. 1903, 55, 1427, and Arch. Experim. Pathol. Pharm. 1892, 141).

Sparteine is a ditertiary base and is completely saturated; it does not contain methyl groups attached to nitrogen (Herzig and Meyer, Monatsh. 1895, 16, 599). On these and other grounds, the following formula has been proposed by Moureu and Valeur (Compt. rend. 1905, 141, 261, 328):



When oxidised with a strong solution of potassium permanganate or with silver oxide and water in sealed tubes it undergoes profound decomposition, among the products being pyridine, *a*-picoline and allied compounds (Peratoner, Gazz. chim. ital. 22, 566; Bernheimer, *ibid.* 13, 451; *cp.* Bamberger, Annalen, 235, 368). Hydrogen peroxide, however, converts it into *oxy-* and *dioxy- sparteine* (Ahrens, Ber. 24, 1095; 25, 3607; 26, 3035; 30, 195). The alkaloid *retamine*, obtained from the shoots and bark of *Genista* [*Retama*] *sphaerocarpa* (Lam.), is a hydroxy sparteine, $C_{15}H_{26}N_2O$, crystallising in long needles, m.p. 162° with decomposition (Battandier and Malosse, Compt. rend. 1897, 125, 360, 450; *see* also Willstätter and Marx, Ber. 1904, 37, 2351).

Tests for sparteine. Sodium picrate gives a yellow colour which on addition of sulphuric acid, ammonium persulphate and potassium thiocyanate turns orange-red. If the dry residue obtained by evaporating solutions of ferric chloride and potassium thiocyanate together be touched with a solution containing sparteine an intense bluish-violet colouration is obtained (Reichard, Pharm. Zeit. 48, 385).

Sparteine sulphate $C_{15}H_{26}N_2{\cdot}H_2SO_4,5H_2O$, prepared by dissolving the alkaloid in 10 p.c. sulphuric acid and allowing the solution to crystallise in a warm place, forms colourless rhombohedral crystals, soluble in 1·1 parts of water and in 2·4 parts of alcohol at 25°, insoluble in ether and chloroform. In aqueous solution at 15°–20° it has $[a]_D$ $-22{\cdot}12°$ (Moureu and Valeur, J. Pharm. Chim. 1903, [vi.] 18, 545).

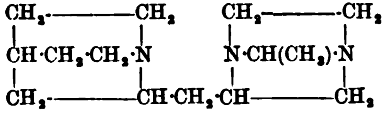
Sparteine hydrochloride and **hydriodide** are white crystalline solids, soluble in water; the latter has m.p. 226°–228°. The *platinichloride* $C_{15}H_{26}N_2{\cdot}H_2PtCl_6,2H_2O$ is yellow and decomposes at 244°–257°.

Sparteine picrate $C_{15}H_{26}N_2{\cdot}2C_6H_3O_7N_3$ has m.p. 208° (Moureu and Valeur, Compt. rend. 1903, 137, 194), 199°–200° (Wackernagel and Wolffenstein, *l.c.*).

Sparteine ferrichloride $C_{15}H_{26}N_2{\cdot}2HCl{\cdot}FeCl_3$ sinters at 190° (Scholtz, Arch. Pharm. 1909, 247, 534).

Sparteine ferrocyanide is a white crystalline solid, easily soluble in water (Beckurts, Arch. Pharm. 228, 347).

***iso*-Sparteine**



has been isolated by Moureu and Valeur (Compt. rend. 1907, 145, 1184, 1343).

Numerous derivatives of sparteine and *iso*-sparteine have been prepared: for an account of these the original papers must be consulted—

Dihydrosparteine (Ahrens, Ber. 20, 2218; 21, 825).

Oxysparteine (Ahrens, Ber. 24, 1095; 25, 3607; 26, 3035; 30, 195).

Hydroxysparteine $C_{15}H_{24}ON_2$ (Ahrens, *ibid.* 1905, 38, 3268).

Dehydrosparteine (Ahrens, *ibid.* 26, 3035).

Spartyrine $C_{15}H_{24}N_2$ (Willstätter and Marx, Ber. 1905, 38, 1772).

Ethylspartylammonium iodide $C_{15}H_{27}EtN_2I_2$ (de Coninck, Compt. rend. 104, 513).

Methyl-derivatives of *sparteine* and *iso-sparteine* (Moureu and Valeur, Compt. rend. 1905, 140, 1645; 141, 49, 117; 261, 328; 1907, 145, 815, 929, 1184; 146, 79; Moureu and Valeur, Bull. Soc. chim. 1908, [iv.] 3, 674; Compt. rend. 1908, 147, 127, 864, 1318; Valeur, Bull. Soc. chim. 1909, [iv.], 5, 31 *et seq.*).

SPATHIC IRON-ORE *v.* CHALYBITE.

SPEARMINT-OIL *v.* OILS, ESSENTIAL.

SPECIFIC GRAVITY. This term, taken strictly, means the ratio of the true weight of a given volume of a substance to the true weight of an equal volume of water at the same temperature *t*°C.; the ratio is frequently indicated by the symbol d^t_t. The correction for displaced air, however, is not always made, so that the value quoted for d^t_t often means the ratio of the *apparent* weights of equal volumes of substance and water at the same temperature. The higher the specific gravity of the substance, the greater is the difference in value between the two ratios, as just defined. In the case, for example, of a liquid with a specific gravity of 1·9, the difference would amount to 1 unit in the third place of decimals.

Again, 'specific gravity' is frequently taken to mean the ratio of the true weight of a given volume of a substance at temperature *t*° to the true weight of an equal volume of water at 4°: the ratio is frequently indicated by the symbol d^t_4. In view of the relation between weight and volume of water in the C.G.S. system it is evident that the specific gravity of a substance, as thus defined, has the same numerical value as its absolute density, which is the mass in grams of a cubic centimetre. It should be pointed out that the values of d^t_4 recorded in the literature often refer to the ratio of the *apparent* weights of equal volumes of the substance and water at *t*° and 4° respectively. The indefiniteness that prevails in the use of the term 'specific gravity' makes it desirable to indicate along with each recorded value (1) whether water at *t*° or water at 4° is taken as the standard of reference; (2) whether a correction has been made for displaced air.

The term 'specific gravity' is used mainly in connection with the densities of liquids and solids relatively to water. Gases are usually compared with air or hydrogen as a standard, and the 'relative density' of a gas means the ratio of the weight of a given volume of the gas at given temperature and pressure to the weight of an equal volume of air (or hydrogen) under the same conditions. Owing to the uniform influence of temperature on the volumes of different gases this ratio is independent of temperature; whilst, on the other hand, the relative density or specific gravity of a liquid, $d^t_{t'}$, is a variable figure.

In all determinations of specific gravity or density, the essential operation is to find the weight of a known volume of the substance at known temperature and, in the case of a gas, known pressure. In the following sections, an account is given of the chief methods used in such determinations.

DENSITY OF GASES AND VAPOURS.

The standard method for the accurate determination of the density of gases is the one employed originally by Regnault and perfected by later workers, notably von Jolly (Trans. Munich Acad. 1880, 13, ii. 49), Rayleigh (Proc.

Roy. Soc. 1893, 53, 134), Leduc (Compt. rend. 1891, 113, 186), and Morley (Smithsonian Contributions to Knowledge, 1895; Zeitsch. physikal. Chem. 1896, 20, 68, 242). The principle of the method may be suitably explained by reference to the apparatus used by Lord Rayleigh (*l.c.*). The glass globe S, which can be surrounded with ice in the inverted bell-jar T, contains about 1800 c.c. and is connected with the rest of the apparatus by a short piece of thick-walled indiarubber tubing U. The tube V communicates with the gas-generating apparatus and connection is made through the tap W with a Töpler pump X, and further, through the tube D, with the vacuum chamber of a special manometer. The side tube E leads to the pressure chamber of the same manometer.

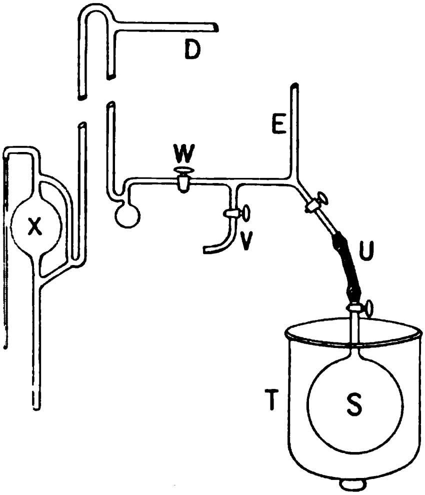


FIG. 1.

The volume of the globe is ascertained by finding the weight of boiled-out distilled water which it contains up to the top of the passage in the stopcock. After it has been dried it is attached to the rest of the apparatus as shown in Fig. 1. The globe is then alternately evacuated and filled with the gas under examination, its weight being determined between each operation. During the filling of the globe it is surrounded with ice, and before the stopcock is closed the pressure is read off on the manometer. The temperature and pressure of the gas filling the globe are thus accurately known. In order to eliminate the effects of changes in the temperature and pressure of the atmosphere, and therefore in the buoyancy of the displaced air, in the interval between the weighing of the vacuous globe and the weighing of the filled globe, a counterpoise must be employed. This should be a closed glass globe of the same external volume as the one already referred to. The 'dummy' globe, further, should be subjected to the same treatment, in regard to washing and wiping, as the working globe, so that the two glass surfaces, when the weighing is made, shall, as far as possible, be in the same condition. In the most accurate work it is necessary to make a correction, indicated by Lord Rayleigh, for the contraction which the globe undergoes when it is evacuated. In the case of a globe of 1800 c.c. capacity, this contraction amounts to about 0·43 c.c., and the air displaced by the vacuous globe is less by this amount than the air displaced by the full globe. The weight of 0·43 c.c. of air at the temperature and pressure of the balance case must therefore be added to the observed weight of the gas filling the globe.

The foregoing method, when applied with all due precautions, gives results of high accuracy. Successive determinations by Lord Rayleigh of the weight of oxygen filling his working globe under constant conditions gave figures the extreme variation of which was about 1 part in 9000, and this although the oxygen was obtained from different sources. Where the available supply of gas is small, and the use of large globes is therefore out of the question, the attainable accuracy is not so high. Travers has estimated that in the case of helium, for instance, with a globe of 30 c.c. capacity, it should be possible to determine the density to within 1 p.c. of the true value. A description of the apparatus used in finding the densities of the rare gases has been published by Ramsay and Travers (Phil. Trans. A, 1901, 197, 54).

The accurate determination of the densities of gases has assumed great importance in connection with certain atomic weight problems. When allowance is made for the extent to which the different gases deviate from strict adherence to Boyle's Law, that is, when the compressibility is taken into account, it is possible to deduce from the relative density of a gas found for a pressure of 760 mm. the value which it would have at an infinitely low pressure. It is then assumed that the molecular weights of different gases would be strictly proportional to such limiting densities (*see* D. Berthelot, Compt. rend. 1898, 126, 954, 1030, 1415, 1501; Rayleigh, Phil. Trans. A, 1905, 204, 351). The molecular weights so calculated were in harmony with the accepted atomic weights except in one case, viz. that of nitrogen. Here the application of the physical method of limiting densities has led to a revision of the atomic weight for this element (*see* Gray, Chem. Soc. Trans. 1905, 87, 1601; 1906, 89, 1173; Guye and others, Compt. rend. 1905, 140, 1386; 141, 826; J. Chim. phys. 1905, 3, 537; Ber. 1906, 39, 1470).

Schloesing's method for finding the relative density of a gas depends on certain well-known hydrostatic principles and can be used when only 5–10 c.c. of gas are available (*see* Compt. rend. 1898, 126, 220, 476, 896). Two long capillary tubes, arranged vertically and communicating at the bottom through a 3-way tap, with each other or with a mercury reservoir, are charged with air, carbon dioxide and a gas X of unknown density. The carbon dioxide (supposed to be the heaviest of the three gases) occupies the lower part of the tubes, while the upper parts are occupied by air and X respectively. When equilibrium has been established between the two tubes, the positions of the two surfaces air—CO_2 and CO_2—X will obviously depend on the relative densities of air and X. These positions can be determined by allowing mercury to rise into each tube separately and drive over the contents into an absorption vessel filled with caustic potash. The unabsorbed air or X is then brought back into its tube, and the position of the mercury at atmospheric pressure is read off. In this way, without weighing and without reading the barometer, the density of X can be deduced from the densities of air and carbon dioxide.

Another method for the determination of the densities of gases was devised by Bunsen, and depends on the rate of effusion through a minute hole in a thin plate of platinum. The densities of two gases are proportional to the squares of the times of effusion, so the experiment consists in determining the time occupied by the passage of a certain volume of air through the aperture, and then determining the time required for the effusion of the same volume of the gas. The density in relation to air is obtained by dividing the square of the number of seconds recorded in the second case by the square of the number found in the first.

Bunsen's apparatus, described in his Gasometry (1857, 121–127), has since been improved by Schilling, and in this form is employed for controlling the density of coal gas. The results given by this apparatus are reliable to about 1 part in 500. The Simmance-Abady specific gravity bell is used for a similar purpose and is based on the same principle. Effusion apparatus has been employed also in the study of the rare gases (Donnan, Phil. Mag. 1900, 49, 423; compare Emich, Monatsh. 1903, 24, 747; 1905, 26, 505).

The control of the density of coal gas, already referred to, is frequently effected with the help of a so-called gas balance. The characteristic part of such an apparatus is a hollow brass sphere which takes the place of one side of the beam, and which can be filled *in situ* with the gas under examination. On the other side, the beam carries a rider and ends in a pointer which moves in front of a vertical scale (*see* Lux, Zeitsch. anal. Chem. 1887, 26, 38; 1890, 29, 13; J. Soc. Chem. Ind. 1890, 9, 415).

When it is desired to ascertain the density in the state of vapour of a substance which is liquid under the ordinary conditions of temperature and pressure, special methods must be adopted.

In Dumas' method of determining vapour densities, the weight of a known volume of the vapour is determined. A light glass flask, of a capacity of from 100 to 350 c.c. (according to the density of the vapour to be determined), has its neck drawn out to a fine point and bent nearly at right angles (see Fig. 2). The flask has to be filled with dry air, which is done by connecting the point with a calcium chloride tube and attaching the latter to an air-pump. The flask is several times exhausted, and filled with air which has passed through the drying tube. The flask full of air is now weighed, the temperature and the barometer being simultaneously read. The end of the tube is next dipped into the liquid, or the fused substance, if the body of which the vapour density is to be determined is solid at the ordinary temperature, and by alternate heating and cooling some of the liquid is introduced into the flask. The flask is lowered into a bath of boiling water or of hot oil; the liquid boils, and its vapour expels the air. The introduction of the flask into the bath must be done with caution, for a dangerous pressure might be produced in the flask if the evaporation were too rapid. When the temperature of the bath is well above the boiling point of the liquid and vapour ceases to escape from the orifice, the point is sealed by a blowpipe flame, the temperature of the bath and the height of the barometer being observed at the same time. The flask is removed from the bath, cleaned, and weighed. The next process is to determine the capacity of the flask. For this purpose the point of the flask is broken under mercury, and the mercury is forced in by atmospheric pressure. If the mercury completely fills the flask it shows that no air was mixed with the vapour of the substance. The mercury is now poured out into a graduated vessel, and the quantity measured. This gives the volume of the vapour that the flask contained. If a bubble of air is observed above the mercury in the flask, its volume must be determined either by refilling the flask completely after measuring the mercury, or more conveniently by running mercury in from a burette until the flask is quite full of mercury with the condensed liquid above it; the volume of mercury thus introduced is equal to the volume of the residual air. The capacity of the flask is now determined by measuring the mercury as before described. The data are sufficient for the calculation of the vapour density; the weight of the flask is the weight first obtained *minus* the weight of the volume of air at the temperature and pressure at the time of weighing calculated from the volume of the flask found in the last operation. The weight of the vapour is the weight obtained in the second weighing *minus* the weight of the flask. The volume of the vapour at 0° and 760 mm. pressure is calculated from the volume of the flask and the temperature and pressure at the time of sealing, and the weight of an equal volume of air or of hydrogen is calculated from the known weights of a litre of these gases. A correction may be made for the increase of the capacity of the globe at the temperature at which it is sealed, but in most cases this correction is unnecessary. When Dumas' method is used the substance must be pure, for if it is a mixture the portions with the lower boiling point pass off first, and the density ultimately arrived at is vitiated by the presence of the substances of higher boiling point.

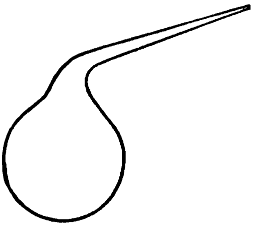

FIG. 2.

The original Dumas' method has been variously modified. Habermann suggested that the vaporisation in the bulb should be carried out under reduced pressure (Annalen, 1877, 187, 341). Less material is then required, and the bulb need not be heated beyond the ordinary boiling point of the substance. Minor modifications have been proposed by Pettersson and Ekstrand (Ber. 1880, 13, 1191), Pawlewski (*ibid.* 1883, 16, 1293), Schall (*ibid.* 1885, 18, 2068), Friedel and Crafts (Compt. rend. 1888, 106, 1764), Winkler (Chem. Zeit. 1899, 23, 627). For use at very high temperatures, the bulbs may be made of porcelain instead of glass (Deville and Troost, Ann. Chim. Phys. 1860, 58, 257).

Instead of determining the weight of a known volume of the gasified substance it is possible to start with a known weight of the liquid, the vapour density of which is to be ascertained, and then to find the volume occupied by this in the gaseous state at known temperature and pressure. This is the principle underlying Gay-Lussac's method, in which a small sealed bulb with a known quantity of the liquid under investigation was introduced into a graduated tube filled with mercury and standing in a bath of this metal. This tube was surrounded by a cylinder containing a suitable liquid, and by heating the mercurial trough the temperature was brought to such a point that the substance in the inner tube was completely gasified. Gay-Lussac's method was notably improved by Hofmann (Ber. 1868, 1, 198). The graduated tube was lengthened up to a metre, so that the substance vaporised into a vacuous space and the vapour produced was under a very small pressure. This fact made it possible to ascertain the vapour density of a substance at temperatures well below its boiling point. The tube, further, was jacketed with the vapour of a boiling liquid, such as aniline or water, and the use of small stoppered bottles was suggested instead of sealed bulbs.

Hofmann's method has been applied in various modified forms (*see* Brühl, Ber. 1876, 9, 1368; 1879, 12, 197; Thorpe, Chem. Soc. Trans. 1880, 37, 147; Capstick, Phil. Trans. A, 1894, 185, 1; Ramsay and Steele, Phil. Mag. 1903, 6, 492; Blackman, Ber. 1908, 41, 768, 4141) and is capable of giving results of high accuracy. The apparatus devised by Thorpe is shown in Figs. 3–5.

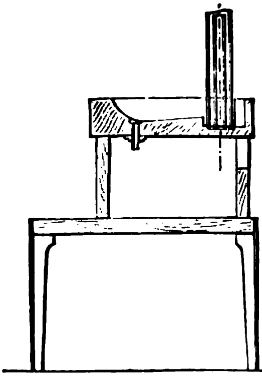

FIG. 3.—SECTION OF MERCURY TROUGH.

Instead of the barometer tube being graduated through its whole length, only one mark is etched on it near the closed end. The capacity of the closed end to the mark is first determined, and the rest of the tube is calibrated by pouring in known quantities of mercury as in calibrating a eudiometer, the levels of the mercury in the tube being read off on a graduated scale placed by its side. The mercury trough is provided with a shallow well in which the barometer tube and the surrounding cylinder stand, and there is an opening at the bottom of the other portion of the trough by means of which the mercury may be drawn through a caoutchouc tube into a tubulated bottle. Through the bottom of the trough and into the well pass two nickel-plated copper tubes, one of which passes to the bottom and the other to the top of a copper boiler placed below the level of the trough, and containing the liquid the vapour of which is to heat the barometer. When an experiment is to be made the two copper tubes are connected by a short india-rubber tube (to prevent the access of mercury), and the bottle of mercury raised so as to fill the trough. The calibrated tube is next filled with mercury and inverted in the trough, and the weighed substance introduced. The tube is placed in the well, the mercury run out from the trough, and the india-rubber tube removed from the copper tubes. A wide cylinder is now placed round the barometer tube so as to inclose the tubes connected with the boiler between the cylinder and the barometer, and to the top of the wide tube a cap is fitted connected to a vertical metal condenser, which also acts as the support of the glass tubes. The liquid in the boiler is now raised to ebullition, and the vapour which condenses in the cylinder returns to the boiler by the tube which passes to the bottom, and which is a little shorter than the other tube. Any vapour which passes through the cylinder is condensed by the vertical condenser and falls into a funnel attached to the return tube to the boiler. The mercury expelled from the barometer flows over the edge of the well, and runs into the bottle. In this form of apparatus the whole of the mercury in the barometer tube is uniformly heated, which renders it possible to make an accurate correction for the pressure. When the vapour ceases to expand, the lower end of the steel scale is brought in contact with the mercury in the well, and the level of the mercury in the tube is measured by moving downwards by rack and pinion a piece of brass which partly surrounds the wide tube. This gives the height of the column in the barometer, and, by reference to the calibration table, the volume of the vapour in the tube.

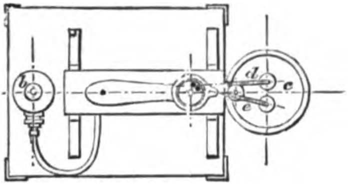

FIG. 4.—PLAN OF MERCURY TROUGH.

A more convenient, if less accurate, process for the determination of vapour densities was devised by V. Meyer (Ber. 1878, 11, 1867, 2253), and depends on the measurement of the volume of air expelled from a closed vessel by the volatilisation of a known weight of the substance. The apparatus (see Fig. 6) consists of a cylindrical bulb, B, of about 100 c.c. capacity, attached to the end of a long tube. Near the upper end of the latter a side-tube, D, is attached which dips downwards into a water trough, and over the end of this delivery tube a graduated cylinder, H, full of water may be placed, the top of the vertical tube being closed by a cork. At the bottom of the cylindrical bulb a quantity of asbestos is placed to prevent the fracture of the glass by the introduction of the vessel containing the substance under investigation. The bulb and part of the long tube are heated in the vapour of a liquid boiling at least 20° higher than the boiling point of the substance itself, or in a bath of molten lead. When the temperature of the tube becomes constant (indicated by the cessation of escape of air through the water in the trough) the graduated tube is placed over the end of the delivery tube, the cork withdrawn from the long tube, and a small vessel, containing a weighed quantity of the substance, is allowed to fall into the apparatus and the cork immediately replaced. Instead of falling directly to the bottom of the bulb B, the small vessel may be allowed to rest on a movable rod (see Fig. 6), until the cork has been replaced. The said vessel may be a small stoppered bottle or sealed bulb: in the latter case the capillary end of the bulb must be broken off before it is introduced into the apparatus. The volatile body is rapidly transformed into vapour, and air is expelled and collected in the graduated cylinder. The evaporation takes place so rapidly that none of the vapour has time to diffuse into the cooler parts of the apparatus, and the air expelled, when reduced to the normal temperature and pressure, is equal to the corrected volume of the vapour produced from the weighed quantity of the substance. From the data thus obtained the vapour density is calculated.

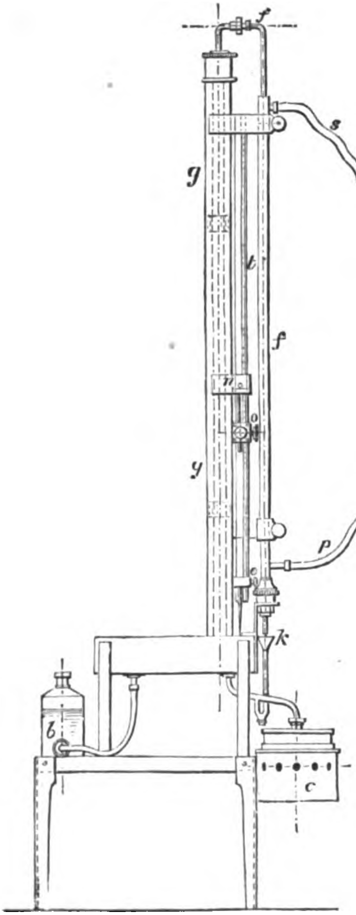

FIG. 5.

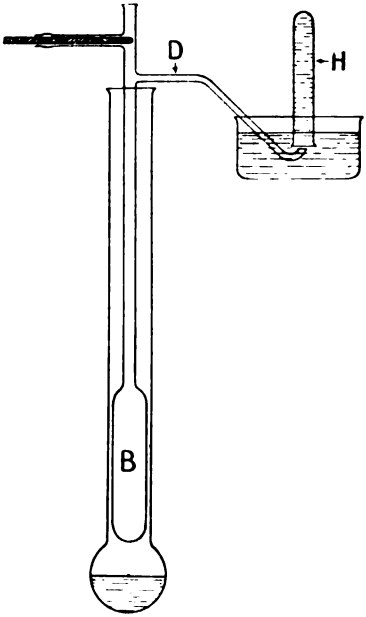

FIG. 6.

The air displaced from the apparatus may be collected and measured in a gas burette, instead of in a graduated tube over water, while the reduction to N.T.P. may be facilitated by using a Lunge gas volumeter (Lunge and Neuberg, Ber. 1891, 24, 729). This latter apparatus has the further advantage that it permits the determination of vapour density by V. Meyer's method under reduced pressure (*see* also Meunier, Compt. rend. 1884, 98, 1268; La Coste, Ber. 1885, 18, 2122; Schall, *ibid.* 1887, 20, 1827, 2127; Richards, Chem. News, 1889, 59, 39; Bodländer, Ber. 1894, 27, 2267). Various devices have been suggested which permit the introduction of the substance into the heated space without opening the apparatus (L. Meyer, Ber. 1880, 13, 991; La Coste, *l.c.*; Bott and Macnair, Ber. 1887, 20, 916; Biltz and V. Meyer, Zeitsch. physikal. Chem. 1888, 2, 189; Eykman, Ber. 1889, 22, 2754; Patterson, Chem. News, 1908, 97, 73).

In determining vapour density at atmospheric pressure by V. Meyer's method, the temperature of the bath should ordinarily be somewhat higher than the boiling point of the substance under examination; but Demuth and Meyer have shown (Ber. 1890, 23, 311) that if the apparatus is filled with hydrogen and provision is made for rapid diffusion and dilution of the vapour, the density may be satisfactorily determined at temperatures below the boiling point. If it is desired to find vapour densities at very high temperatures the apparatus must be made of some refractory material, such as platinum, porcelain or iridium (*see* V. and C. Meyer, Ber. 1879, 12, 1112; V. Meyer, *ibid.* 1880, 13, 394; Crafts, Compt. rend. 1880, 90, 183; Nilson and Pettersson, J. pr. Chem. 1886, 33, 1; Zeitsch. physikal. Chem. 1889, 4, 211; Biltz and Meyer, *ibid.* 1889, 4, 249; Biltz, *ibid.* 1896, 19, 385; Meyer and Recklinghausen, Ber. 1897, 30, 1926). For vapour density determinations in the neighbourhood of 2000°, Nernst uses a small iridium vessel, coated with magnesia and asbestos, in which 0·1–1·0 mg. of the substance under investigation is vaporised. The substance is weighed on a special micro-balance and the increase of volume due to vaporisation is measured by the displacement of a thread of mercury in a calibrated capillary tube (*see* Zeitsch. Elektrochem. 1903, 9, 622: also Löwenstein, Zeitsch. physikal. Chem. 1906, 54, 707; von Wartenberg, Zeitsch. anorg. Chem. 1907, 56, 320).

It is one of the advantages of V. Meyer's displacement method that the temperature at which vaporisation takes place need not be known. In certain cases, however, notably those in which the vapour density varies with temperature, it is desirable to know the temperature of vaporisation. This can readily be ascertained either by using the vapour density bulb itself as an air thermometer (Nilson and Pettersson, J. pr. Chem. 1886, 33, 1; Biltz and Meyer, Zeitsch. physikal. Chem. 1889, 4, 249), or by sweeping out and measuring the volume of some readily absorbed gas, such as carbon dioxide or hydrogen chloride, which fills the bulb at the temperature of observation (*see* Crafts and Meier, Compt. rend. 1880, 90, 606; Meyer and Züblin, Ber. 1880, 13, 2021; Mensching and Meyer, Zeitsch. physikal. Chem. 1887, 1, 145). In both these methods the uncertainty arising from the unequal temperature of the stem of the vapour density bulb is eliminated by the use of a 'compensator,' a blind tube of the same dimensions as the stem. The compensator is exposed to the same conditions as the stem, and the gas it gives up or contains is deducted from the corresponding volume for the stem + bulb.

As has been already pointed out, the vapour density of a substance may be deduced from the increase in volume due to the vaporisation of a known weight at constant pressure. It is equally possible to deduce the vapour density from the increase of pressure due to the vaporisation of a known weight at constant volume. Such a method of finding vapour density is based on the principle that equimolecular quantities of different substances, vaporised in a given space and at a given temperature, produce the same increase of pressure. Many forms of apparatus, based on this principle, some of them adapted for working under reduced pressure, have been proposed (Pfaundler, Ber. 1879, 12, 165; Dyson, Chem. News, 1886, 55, 88; Bott and Macnair, Ber. 1887, 20, 916; Schall, Ber. 1887, 20, 1435, 1759; 1888, 21, 100; 1889, 22, 140; 1890, 23, 919, 1701; Malfatti and Schoop, Zeitsch. physikal. Chem. 1887, 1, 159; Eykman, Ber. 1889, 22, 2754; Richards, Chem. News, 1889, 59, 87; Bleier and Kohn, Monatsh. 1899, 20, 505; Erdmann, Zeitsch. anorg. Chem. 1902, 32, 425; Lumsden, Chem. Soc. Trans. 1903, 83, 342; Haupt, Zeitsch. physikal. Chem. 1904, 48, 713; Blackman, Chem. News, 1909, 100, 13, 174). Fig. 7 shows the apparatus used by Bleier and Kohn. The vaporisation bulb A is connected with a manometer, B, and, through the stopcock *h*, with a pump. By adjusting the height of the reservoir R, the mercury in the right-hand limb of the manometer is brought to the same level *a* before and after vaporisation; the change of pressure due to vaporisation is read off on the left-hand limb. The fine adjustment of the mercury at *a* is effected by the screw clip *m*.

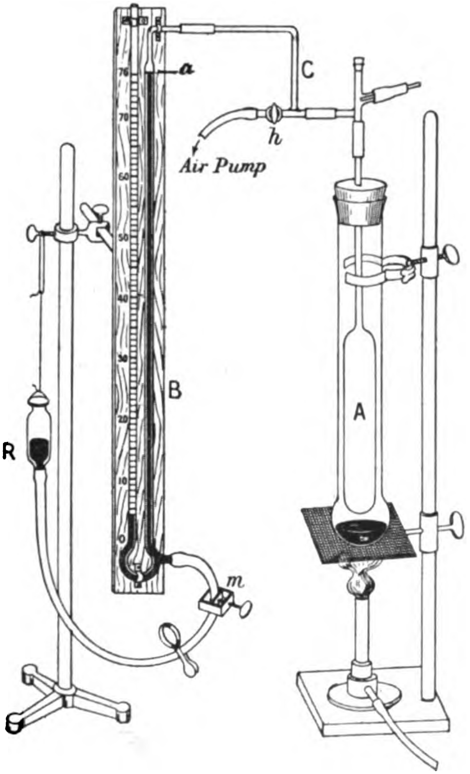

Fig. 7.

Density of Liquids.

One common way of finding the density of a liquid is to determine the mass of the liquid which exactly fills a vessel of known volume. The vessels usually employed for this purpose are known as specific gravity bottles and pyknometers. The simplest form of specific gravity bottle is a thin glass flask with a flat bottom and an accurately-fitting stopper, through which a fine hole is drilled (see Fig. 8). The dry, clean flask is carefully weighed and then filled with the liquid, the temperature being noted. The stopper is then placed in the neck, the excess of liquid escapes through the perforation in the stopper and is wiped off from the glass, and the flask is again weighed. The flask is now emptied, cleaned, filled with distilled water, and again weighed. If the temperature of the water is the same as that of the liquid at the moment of putting in the stopper, then the weight of the liquid (w) divided by the weight of the water (w') gives the relative density of the liquid to that of water at the particular temperature $t°$. If the absolute density is required, a correction must be made (1) for the quantity of air displaced by the liquids and the weights, (2) for the deviation of the density of the water from unity. If D is the absolute density of the liquid at $t°$, then $D=\frac{w}{w'}\Delta+\sigma\left(1-\frac{w}{w'}\right)$, where Δ is the density of water at $t°$, and σ is the density of the air at the time of the observations. In most cases it is sufficient to take $\sigma=0{\cdot}0012$, and a table may therefore be constructed giving the values of the correction term $\sigma\left(1-\frac{w}{w'}\right)$ for various values of the uncorrected density $\frac{w}{w}$. (For a discussion of these corrections *see* Wright, J. Soc. Chem. Ind. 1892, 11, 297; Wade and Merriman, Chem. Soc. Trans. 1909, 95, 2174.)

FIG. 8.

The specific gravity bottle just described is not free from objection, for evaporation takes place at the top of the perforated stopper, and further, if the temperature of the balance case is higher than the temperature at which the bottle was filled, there is an overflow. The first difficulty may be avoided by having a cap ground to fit the neck of the bottle (Louis, J. Soc. Chem. Ind. 1894, 13, 322). The second difficulty may be met by grinding into the neck of the flask a tube which is contracted in its middle to a capillary bore, and is provided at the top with a small reservoir closed by a stopper (Fig. 9). To use this modification, the flask is filled and the tube inserted. This forces a small quantity of the liquid through the capillary tube into the reservoir above. The flask is now placed in a bath of known temperature, or even in water at 4°, and left there until its temperature is constant. If the liquid contracts so as to empty the reservoir above the capillary tube, a small additional quantity is introduced. When no change of volume is perceptible, a thin piece of filter paper or a fine glass tube is introduced into the reservoir so as to reduce the level of the liquid to a mark, *a*, which is made on the outside of the capillary tube. The stopper may then be introduced into the reservoir, the flask removed from the bath and its outside dried, and it may now be left until it has reached the temperature of the balance case where it is to be weighed.

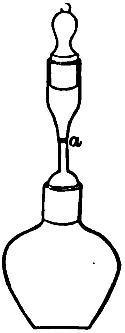

FIG. 9.

Various modifications of this form of specific gravity bottle have been suggested (*see* Squibb, J. Amer. Chem. Soc. 1897, 19, 111; Leimbach, J. pr. Chem. 1902, 66, 475; Bošnjaković, Zeitsch. anal. Chem. 1904, 43, 230). It has been proposed, too, that the capillary tube should be provided not with a single mark, but with regular graduations, the values of which are determined once for all (Tribe, Chem. News, 1873, 28, 211; Squibb, J. Amer. Chem. Soc. 1897, 19, 111; *see* also Louis, J. Soc. Chem. Ind. 1894, 13, 322).

The Sprengel pyknometer (Chem. Soc. Trans. 1873, 26, 577) is a U-shaped tube terminating in two capillary tubes bent in opposite directions (Fig. 10). The liquid is aspirated into the tube, which is then sunk in a beaker of water, the capillary tubes resting on the edge of the beaker. When the temperature of the contained liquid is constant, as shown by the cessation of movement of the liquid in the capillary tube, some of the liquid is removed from one capillary, which terminates in a fine point, *a*, by means of a piece of filter paper, until the liquid in the other capillary reaches a mark, *b*, near the bend. Should the amount of liquid in the pyknometer be insufficient a little is conveniently added by touching the point *a* with a drop held on the end of a glass rod. Sprengel's pyknometer was modified by Ostwald (J. pr. Chem. 1877, 16, 396), who made the limb of the U-tube next *b* of narrow-bore tubing throughout. In the case of volatile or hygroscopic liquids, it is advisable to close the ends of the capillaries, after the adjustment has been made, with glass caps.

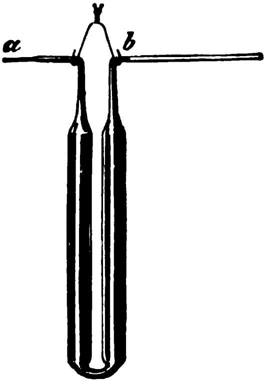

FIG. 10.

Immediate contact of the liquid with the air is avoided, and determination of the density at temperatures below that of the laboratory is made possible by Perkin's modification of the Sprengel pyknometer (Chem. Soc. Trans. 1884, 45, 443; 1896, 69, 1043). In this the narrow tubes are bent at obtuse angles instead of right angles, and a small bulb is blown on the tube adjoining the shorter limb (see Fig. 11). A mark, *a*, is made just below the small bulb, the other limb terminating in a fine opening at *b*. After the liquid has been introduced into the tube, the latter is immersed in a beaker of water until the temperature of the liquid is constant. The tube is then tilted, and a piece of filter paper is placed in contact with the point *b* until the liquid in the other limb falls to the mark *a*; the filter paper is withdrawn, and the tube restored to the vertical position. The liquid recedes from the end *b* of the tube and rises in the other limb, and if the temperature becomes higher before weighing, the small bulb offers sufficient space to contain the liquid and thus prevent overflowing.

Various other modifications of the pyknometer have been suggested (Minozzi, Gazz. chim. ital. 1899, 29, i. 406; Leimbach, J. pr. Chem. 1902, 66, 475; Fischer, Chem. Zeit. 1904, 28, 359; Stanford, Phil. Mag. 1905, 10, 269; Bousfield, Chem. Soc. Trans. 1908, 93, 679; Hartley and Barrett, *ibid.* 1911, 99, 1072).

In chemical technology the densities of liquids are most usually determined by means of the hydrometer. This instrument is based on the fact that when a solid floats in a liquid, the weight of the liquid displaced is equal to the weight of the floating body. The general form of the hydrometer is a spherical or cylindrical glass bulb, with a narrow stem, and the bulb is weighted at the bottom so that the instrument floats vertically in the liquid (Fig. 12).

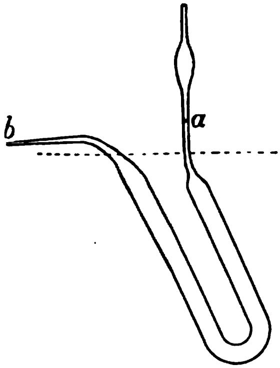

FIG. 11.

FIG. 12.

When the hydrometer is placed in a liquid, it sinks until it has displaced a quantity of liquid equal to the weight of the instrument; it then floats in a position of equilibrium. If placed in a liquid of higher density it will not sink so deep, for the volume of this latter liquid possessing the same weight as the hydrometer will be smaller than in the first case. Again, when placed in a liquid of lower density, it will sink deeper, for a larger volume has to be displaced before the weight of the hydrometer is supported. The density of the liquid is found by readings of the graduations marked on the stem. The stem may be divided to give densities directly, but then the divisions are not of equal length, the differences of length being proportional to the differences of the reciprocals of the densities. Hydrometers, however, are frequently graduated with divisions of equal length, tables being employed to convert the readings into densities if desired. In any case it should be borne in mind that a hydrometer is a comparatively rough apparatus, and too much reliance should not be placed on the readings of any particular instrument, until its scale has been checked at one or two points.

In technical work, hydrometers indicating the specific gravity directly are often used for liquids lighter than water, but almost never in the case of liquids heavier than water. Twaddell's hydrometer, commonly used in this country, is graduated on the same principle as those giving the specific gravity directly, but the readings on the scale are in degrees, each one of which corresponds to a difference of 0·005 in the specific gravity. The zero of the scale is at the point to which the hydrometer sinks in water, so that a reading of 9°Tw., for example, corresponds to a gravity $1{\cdot}000+0{\cdot}005\times9=1{\cdot}045$, and one of 53°Tw. corresponds to the gravity 1·265. To cover the range of specific gravity 1·00–1·85, a set of six instruments is generally supplied. An instrument based on the same principle as Twaddell's hydrometer is the densimeter described by Fleischer (Dingl. poly. J. 1876, 222, 159).

The chief hydrometer with a scale graduated in divisions of equal length is Baumé's, commonly used on the Continent and in the United States. The scale was fixed according to Baumé's original directions in the following manner. For liquids denser than water, 15 parts of pure sodic chloride are dissolved in 85 parts of water at a temperature of 10° Réaumur (12·5°C. or 54·5°F.). The zero of the instrument is the point to which the hydrometer sinks in distilled water, and the point to which it sinks in the 15 p.c. solution of salt is marked 15. The distance between the zero and this point is divided into 15 equal parts, and the whole stem graduated with similar divisions. For liquids lighter than water the zero of the hydrometer is fixed by a 10 p.c. solution of sodic chloride, distilled water giving the division 10. This instrument is, of course, graduated in the opposite direction, the zero being at the bottom of the scale.

Much confusion and irregularity, however, arose in connection with the interpretation of the Baumé degree (*see* Gerlach, Dingl. poly. J. 1870, 198, 315; Chandler, Acad. Nat. Sciences, Philadelphia, 1881). Recently the practice has been to mark the hydrometer 66°B. at the point to which it sinks in 'English sulphuric acid' (93–95 p.c. H_2SO_4) at 17·5°C., and to divide the interval between this and 0° into 66 equal parts. Obviously, this definition of the Baumé degree is not satisfactory, and accordingly attempts have been made to construct a 'rational' Baumé hydrometer. If one of these instruments sinks to 0° in water and to $n°$ in a liquid of specific gravity d, it is easy to show that $\frac{nd}{d-1}=C$, a constant. If now for $d=1{\cdot}842$, n is taken as 66° at 15°C., then C=144·3 and hence $d=\frac{144{\cdot}3}{144{\cdot}3-n}$ (*see* Fuchs, Zeitsch. anal. Chem. 1899, 38, 333). The Baumé hydrometer with a scale based on this formula is commonly used in Germany, but elsewhere other formulæ are employed for the evaluation of the degree. Thus, in Holland, the formula $d=\frac{144}{144-n}$ is taken as the basis of the Baumé scale, in the United States the formula $d=\frac{145}{145-n}$ (*see* Emery, J. Amer. Chem. Soc. 1899, 21, 119). If Gerlach's determination (*l.c.*) of the specific gravity of a 10 p.c. salt solution at 15°C. is taken as a basis, the resulting formula is $d=\frac{146{\cdot}3}{146{\cdot}3-n}$.

In the following table are recorded the specific gravities corresponding to readings of the Baumé instrument, deduced (1) from the formula $d=\frac{144{\cdot}3}{144{\cdot}3-n}$, (2) from the formula $d=\frac{145}{145-n}$.

Degrees n	$d=\frac{144{\cdot}3}{144{\cdot}3-n}$ at 15°C.	$d=\frac{145}{145-n}$ at 60°F.	Degrees n	$d=\frac{144{\cdot}3}{144{\cdot}3-n}$ at 15°C.	$d=\frac{145}{145-n}$ at 60°F.
1	1·007	1·007	34	1·308	1·306
2	1·014	1·014	35	1·320	1·318
3	1·022	1·021	36	1·332	1·330
4	1·029	1·028	37	1·345	1·343

23	1·190	1·189	56	1·634	1·629
24	1·200	1·198	57	1·652	1·648
25	1·210	1·208	58	1·671	1·667
26	1·220	1·219	59	1·691	1·686
27	1·231	1·229	60	1·711	1·706
28	1·241	1·239	61	1·732	1·726
29	1·252	1·250	62	1·753	1·747
30	1·263	1·261	63	1·774	1·768
31	1·274	1·272	64	1·796	1·790
32	1·285	1·283	65	1·819	1·813
33	1·297	1·295	66	1·842	1·835

The Baumé hydrometer for liquids lighter than water is graduated in two ways, the relation between degrees and gravity being given by the formula $d=\frac{146}{136+n}$, or the American formula $d=\frac{140}{130+n}$ (*see* Emery, J. Amer. Chem. Soc. 1899, 21, 119). The following table gives the values of the specific gravity corresponding to the readings of this instrument.

Degrees Baumé	$d=\frac{140}{130+n}$ at 60°F.	$d=\frac{146}{136+n}$ at 12·5°C.	Degrees Baumé	$d=\frac{140}{130+n}$ at 60°F.	$d=\frac{146}{136+n}$ at 12·5°C
10	1·000	1·000	36	0·843	0·849
12	0·986	0·987	38	0·833	0·839
14	0·972	0·973	40	0·824	0·830
16	0·959	0·961	42	0·814	0·820
18	0·946	0·948	44	0·805	0·811
20	0·933	0·936	46	0·796	0·802
22	0·921	0·924	48	0·787	0·794
24	0·909	0·913	50	0·778	0·785
26	0·897	0·901	52	0·769	0·777
28	0·886	0·890	54	0·761	0·768
30	0·875	0·880	56	0·753	0·760
32	0·864	0·869	58	0·745	0·753
34	0·854	0·859	60	0·737	0·745

Other hydrometers designed for liquids lighter than water are occasionally used. In Cartier's hydrometer 21° corresponds with 21°B., but above and below this point 15 degrees Cartier=16 degrees Baumé. In Beck's hydrometer the zero corresponds with $d=1{\cdot}000$ and 30° with $d=0{\cdot}850$: the thirtieth of this interval is 1° and equal divisions are continued in both directions as far as desired.

In addition to the general hydrometers just referred to there are also a number of instruments used for certain special purposes, such as Sikes' hydrometer and Tralles' alcoholometer for ascertaining the strength of spirits (*see* ALCOHOLOMETRY), and various saccharometers for finding the specific gravity of saccharine solutions (*see* SUGAR).

All the foregoing hydrometers are instruments of variable immersion.

Nicholson's hydrometer, on the other hand, is a constant immersion instrument, and consists of a cylindrical metallic bulb connected at the bottom by a wire to a cup, and also an inverted cup pierced with holes. The top of the float is connected by a wire to a pan, on which weights may be placed. This wire has a single mark on it, which is brought to the surface of the liquid by weights placed on the upper scale pan. The instrument is so adjusted that when floating in distilled water at 62°F., 1000 grs. placed on the scale pan will bring the mark on the stem to the surface of the water. When placed in a denser liquid, more weights have to be added to the 1000 grs. in order to bring the mark to the level of the liquid, and as the same volume of liquid is displaced as in the case of the water, the weights at once give the density of the liquid referred to that of water at 62°. The cups below the float are used in the determination of the densities of solids, and will be referred to subsequently.

Another somewhat similar hydrometer consists of a cylindrical glass weight suspended from the arm of a balance, and is so counterpoised that the balance is in equilibrium when the plunger is sunk in distilled water. This is the principle of the Mohr-Westphal balance (Fig. 13). When placed in liquids of other densities the weights have to be altered to bring the balance to equilibrium, and the weights, which are generally used in the form of riders, are so arranged that the density of the liquid is read off directly. A thermometer may be placed within the glass plunger with its bulb projecting below, so that the temperature of the liquid can be determined simultaneously.

Another method of determining the densities of liquids depends on the fact that if columns of two liquids of different densities are made to support one another, the lengths of the columns will be inversely as the densities. An inverted glass U tube with the limbs graduated upwards from 0 near the open ends is employed; at the bend of the tube there is attached a tubulure closed by a stopcock, or by a piece of caoutchouc tube with screw-clip. One of the open ends of the tube is placed in water, and the other into the liquid of which the density is sought, and suction is applied. The liquids rise in the tubes, and after adjusting the outside levels to the zero marks, the lengths of the columns are read off. In order to avoid capillarity effects the tubes should be not less than 6 mm. internal diameter. Various forms of apparatus based on this principle have been described (Hare, Silliman's J. 1826, 11, 133; Alexander, Ann. Chim. Phys. 1847, 70, 137; Tate, Phil. Mag. 1859, 17, 254; Schiff, Annalen, 1862, 121, 82; Weber, Beiblätter, 1879, 3, 770; Girardet, Bull. Soc. chim. 1901, 25, 936; *see* also Watson's Practical Physics, 29; compare Lefebvre, Chem. Zentr. 1897, ii. 402).

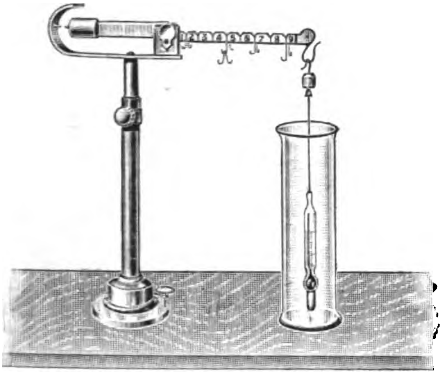

FIG. 13.

For some purposes the density of a liquid has to be determined at its own boiling point. This may be done by suspending a specific gravity flask filled with the liquid in another vessel containing some of the same liquid, which is raised to the boiling point. This heats the contents of the flask, and when the liquid ceases to expand the stopper is placed in the bottle, which is then removed from the vessel, allowed to cool, and weighed (C. Schall, Ber. 1884, 17, 2201). Instead of a specific gravity bottle one may conveniently use a pyknometer of the shape shown in Fig. 14 (Neubeck, Zeitsch. physikal. Chem. 1887, 1, 652). Another instrument employed in finding densities at high temperatures is the dilatometer, which is a kind of thermometer with a graduated tube, the capacity of the tube and bulb being accurately known. The density of the liquid is first determined by the ordinary specific gravity bottle, and then some of the liquid is introduced into the dilatometer, the temperature of which is gradually raised, and the increase of volume measured. When the coefficient of expansion has been thus determined, the density at any temperature may be calculated. For a complete account of the methods of using dilatometers, and all the precautions necessary in their manipulation, *see* Thorpe (Chem. Soc. Trans. 1880, 37, 155; 1893, 63, 262).

FIG. 14.

For the determination of critical densities and of the densities of liquids in contact with saturated vapour at temperatures up to the critical temperature special methods are employed (*see* Ramsay and Young, Phil. Trans. A, 1886, 177, 123; 1887, 178, 57, 313; 1889, 180, 137; Young, Chem. Soc. Trans. 1889, 55, 486; 1891, 59, 37, 125, 911; Proc. Phys. Soc. 1895, 13, 617; Phil. Mag. 1900, 50, 291; Amagat, Compt. rend. 1892, 114, 1093; Young and Thomas, Chem. Soc. Trans. 1893, 63, 1199; Centnerszwer, Zeitsch. physikal. Chem. 1904, 49, 199).

DENSITY OF SOLIDS.

In determining the density of a solid it is necessary to find its mass, and also the mass of an equal volume of water, or, what comes to the same thing, to find the volume of the solid, from which the mass of the water can be calculated. In some few cases this may be done by measurement, as, for example, the measurement of a cubic foot of a body, like stone, which may be cut into a regular shape. It more generally happens, however, that the solid is irregular in shape, or is even in the form of powder: other methods must then be adopted.

One of the simplest methods is to place some water or other liquid of known density in a graduated tube and measure it, and then introduce a weighed quantity of the solid, and observe the rise of level of the liquid in the tube. Or the tube may be weighed before and after the introduction of the solid, the increase of weight giving the quantity of the solid introduced. (Schiff, Annalen, 1858, 107, 59; Osann, Ann. Phys. Chem. 1859, 106, 334; Dobbie and Hutcheson, Phil. Mag. 1884, 17, 459; Erdmenger and Mann, Chem. Zeit. 1893, Suppl. 289; Stanger and Blount, J. Soc. Chem. Ind. 1894, 13, 456; McKenna, J. Amer. Chem. Soc. 1899, 21, 50; Jacobsen, Bull. Soc. chim. Belg. 1904, 18, 198; von Wrochem, Chem. Zentr. 1905, i. 1577). Gentilé (J. Pharm. 1867, [iv.] 5, 401) uses a small bottle with a bulb at the top of 1 c.c. capacity. The bulb is connected to the bottle by a narrow tube with a mark on it, and there is another mark on a similar tube above the bulb. The bottle is filled with liquid to the lower mark and weighed; the solid is introduced until the liquid reaches the upper mark, and the whole is again weighed. This increase of weight is that of 1 c.c. of the solid.

A similar process that may be employed when the solid is in small fragments or in powder is to fill a specific gravity bottle with water, and counterpoise it on a balance. Some of the solid is then placed on the pan of the balance and weighed; the solid is now placed in the specific gravity bottle, and the level of the water adjusted. On again weighing, the quantity will be found to be less than the previous amount, the difference being due to the quantity of water expelled by the introduction of the solid, this water, of course, occupying the same volume as the solid. The relative density of the solid to water at the same temperature is at once found by dividing the weight of the solid by the weight of the quantity of water expelled. Some precautions are necessary in this method. Many solids, especially in the form of powder, entangle a quantity of air, which replaces some of the water in the bottle, or may even cause some of the solid to float in the liquid. This may often be removed by placing the specific gravity bottle containing the water and the solid in an air-pump receiver and exhausting the air; the diminution of pressure causes the entangled air to expand and form large bubbles, which readily escape from the surface of the water.

In the case of solids that are soluble in water this method is obviously inapplicable, and it is necessary to use another liquid of known density which does not act on the solid. Petroleum or alcohol may be used, care being taken to determine the density of the particular sample of liquid used. For a description of the precautions necessary in this method, *see* Tutton, Chem. Soc. Trans. 1894, 65, 650; 1897, 71, 865; Earl of Berkeley, *ibid.* 1907, 91, 56.

When the body of which the density is to be determined is of such a shape that it can be suspended by a piece of fine platinum wire, the piece is first weighed and then attached by means of the fine platinum wire to the hook at the bottom of a small scale pan. A vessel of water is placed under the scale pan, and the solid immersed in it. When a solid is thus immersed in water it displaces its own volume of water, and there is at the same time an apparent loss of weight; this is due to the surrounding water producing a pressure on the solid which is exactly equal to the pressure on the volume of water which the solid has displaced, and which previously kept the water in the vessel in equilibrium. The apparent loss of weight is therefore the weight of the quantity of water displaced by the solid, that is to say of an equal volume of water, so that we obtain the necessary data for determining the relative density of the solid at the temperature of the water at the time of the observation, the mass of the solid divided by the loss of weight in water being the density.

If the body is less dense than water it is obvious that its density cannot be determined precisely in this manner, for the solid will float. To cause it to sink, it is attached to a piece of metal of known weight and density. On weighing the two bodies together in water part of the apparent loss of weight is due to the displacement of the water by the metal and part to the displacement by the light body. The loss caused by the sinker can be calculated from its known weight and density, and this deducted from the total apparent loss of weight gives the weight of the water displaced by the body of which the density is to be determined.

In practice it is, however, better to determine the amount of water displaced by the sinker than to calculate it. The substance may first be weighed, and then the sinker attached by thin platinum wire to the scale-pan and weighed; then a vessel of water placed under the scale-pan, and the sinker immersed in it. The apparent loss will give the quantity of water displaced by the sinker. The substance is now also attached to the wire and weighed, together with the sinker, in water, and the difference between the weight and the sum of the weights of the wire, sinker, and substance is the weight of the water displaced by the sinker and substance. As the weight of water displaced by the sinker has been determined, the difference between these two weights is the amount of water displaced by the substance alone, and the weight of the substance divided by this number gives the density.

The weight of water displaced by the light body may be obtained by the employment of three weighings, whereas the method just described requires four. It depends on the following facts: when a body floats on a liquid it displaces a weight of the liquid equal to its own weight; if the body is now totally immersed there is an upward pressure due to the additional quantity of the liquid displaced; this flotation pressure, determined by weights added to the weight of the body, gives the weight of the liquid displaced by the whole solid. In determining the density of such a body it is therefore necessary to know its weight, the apparent weight of the sinker when immersed, and the apparent loss of weight when the light body is attached to the sinker and weighed under water. The difference between the two last weighings, added to the weight of the body in air, gives the quantity of water displaced by the solid. Thus if P is the weight of the light body, P' the weight of the sinker in water, and P'' the weight of sinker and the light body in water, the density $D=\dfrac{P}{P'-P''+P}$.

Nicholson's hydrometer (as previously mentioned) may be used for the determination of the densities of solids. Weights are placed in the upper scale-pan until the instrument sinks to the mark. The weights are removed, and the substance is placed on the pan, and weights added until the mark is again at the level of the liquid; the difference between the weights is the weight of the solid in air. The solid is then placed on the lower scale-pan if of a higher density than water, or underneath the inverted cup if of a lower density, and weights are placed on the upper scale-pan to restore equilibrium. From the numbers thus obtained the amount of water displaced by the solid can be calculated, and from this, together with the weight of the body in air, the density is determined.

There are some solids which must not be wetted by any liquid, in consequence of a possible change of composition, and in these cases the usual methods of determining densities are of course not available. Others which are porous retain air so persistently that errors may arise by the presence of quantities of air which cannot be removed. In such cases an instrument similar to Say's stereometer (Ann. Chim. Phys. 1797, 23, 1) may be employed. This apparatus is now known as the volumenometer.

The air inclosed in a glass bulb and adjoining tubes is shut off at atmospheric pressure; the space at the disposal of the air is then increased or decreased by a known amount, and the new pressure is read off on a manometer connected with the apparatus. These operations are repeated when the air space contains a known weight of the solid under examination and from the data obtained the density of the solid is calculated. Many forms of apparatus based on this principle have been described (Miller, Phil. Mag. 1834, 5, 203; Kopp, Annalen, 1840, 35, 17; Regnault, Ann. Chim. Phys. 1845, 14, 207; Grassi, J. Pharm. Chim. 1847, 11, 184; Baumhauer, Arch. Néerl. 1868, 385; Rüdorff, Ann. Physik, 1879, 6, 288; Paalzow, *ibid.* 1881, 13, 332; Bremer, Rec. trav. chim. 1898, 17, 263, 405; Mameli and Sanna, Gazz. chim. ital. 1902, 32, ii. 211; Zehnder, Ann. Physik, 1903, 10, 40). A description of one of the more recent modifications (Bremer's) will make clear the manipulation of the volumenometer. The wide-mouthed flask F (Fig. 15), immersed in a small water-bath, is connected through the three-way stopcock R with the tubes *ab* and *cd*, which contain mercury. On *ab* there are two marks or movable rings at *p* and *q*, the volume *v* of the tube between these being accurately known. With the stopcock R turned so as to connect both F and *ab* with the air, the tube *cd* is adjusted until the top of the mercury meniscus is at *p*. The stopcock R is then turned so as to leave F and *ab* in connection but shut off from the air. The tube *cd* is now lowered until the top of the mercury meniscus in *ab* is at *q*, and the difference *h* in level between the mercury in the two tubes is determined with a cathetometer. A similar operation is carried out when the flask F contains a weighed quantity of the solid under examination, the difference in level now found being *h'*. From these data the volume *x* of the solid can be calculated by the formula $x = vH\frac{h'-h}{hh'}$, where H is the barometric height.

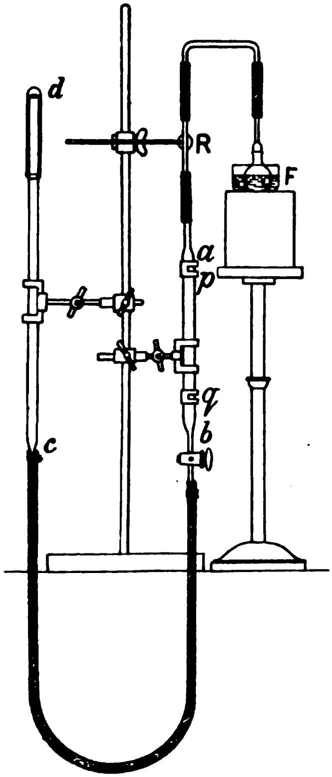

FIG. 15.

The volumenometer obviously cannot be employed for the determination of the densities of solids which give off any gas or vapour under reduced pressure, such as efflorescent salts, for the increase of volume would be due not only to the expansion of the air in the apparatus, but also to the production of aqueous vapour. It answers very well for porous bodies like cotton wool, the entangled air from which at once expands on the pressure being diminished.

Occasionally it is necessary to determine the densities of small fragments of crystals or minerals, and for this purpose liquids in which the solids will just float may be used. The densities of the liquids may be afterwards determined, or a number of solutions of known densities may be kept in readiness. It is obvious that the method is valid only when the solid is not acted on or dissolved by the liquid. For the application of this method *see* Schaffgotsch, Pogg. Ann. 1862, 116, 279; Sonstadt, Chem. News, 1874, 29, 127; Church, Mineral. Mag. 1877, 1, 237; Goldschmidt, Jahrb. Mineral. Beilageband, 1881, 179; Klein, Compt. rend. 1881, 93, 318; Rohrbach, Ann. Physik, 1883, 20, 169; Brauns, Jahrb. Mineral. 1886, ii. 72; Retgers, Zeitsch. physikal. Chem. 1889, 3, 289; 4, 189; 1893, 11, 328; Jahrb. Mineral. 1896, i. 212; ii. 183. Among the heavy liquids used by these authors are a solution of the double iodide of potassium and mercury, which can be obtained of the density 3·196; a solution of cadmium borotungstate (density of saturated solution 3·281); a solution of mercuric and barium iodides, which can be obtained of the density 3·588, but is unstable on mixing with water; and methylene iodide (density 3·33). In the first cases, water is added if a liquid of lower density is required, while benzene is similarly used with methylene iodide. Liquids the density of which is varied in the way described are used not only for determining the density of minerals, but also for separating the constituents of mixed minerals. Fused solids have been employed for a similar purpose (*see*, for example, Thoulet, Compt. rend. 1878, 86, 454; Klein, *l.c.*; Bréon, Compt. rend. 1880, 90, 626).

The floating method of determining the specific gravity of solids has been utilised also in the examination of fats (Hager, Zeitsch. anal. Chem. 1880, 19, 239). In this case the liquid medium is a suitable mixture of water and ethyl alcohol.

It has been suggested (Andreae, Zeitsch. physikal. Chem. 1911, 76, 491) that the foregoing method may be advantageously varied by putting the crystals under examination along with a mixture of methylene iodide and benzene of about the same specific gravity in a dilatometer. This is placed in a bath the temperature of which is slowly altered until the crystals float. From the weight and volume of the dilatometer the density of the liquid can be accurately determined. J. C. P.

SPECTRUM ANALYSIS. I. **Introduction.** When Fraunhofer investigated the solar spectrum he designated the most strongly-marked lines in the visible region by the letters of the alphabet, starting from A at the red end with a wave-length of 7600 ten-millionths of a mm. to K at the violet end with a wave-length of 3930 ten-millionths of a mm. When the extension of the solar spectrum into the ultra-violet region was discovered by photographic methods this lettering of the principal lines was continued into this region as far as the wave-length 2950 ten-millionths of a mm., the letters L to U being used. Owing to the absorption exerted by the great thickness of air through which the light has to pass, the solar spectrum does not extend much beyond the limit of about the wave-length 3000 ten-millionths of a mm.

Recent investigation has shown that oxygen has an absorption band for light of very short wave-length, and that even with an extremely thin layer of oxygen at atmospheric pressure this absorption extends up to at least as far as 1800 ten-millionths of a mm.

It is evident that this absorption sets a lower limit beyond which it is impossible to investigate the ultra-violet spectrum unless a vacuum spectrograph is employed.

Owing to their great convenience as landmarks in the spectrum the Fraunhofer lettering of the principal lines is still used very largely, and in Fig. 1 is shown a diagram in which these principal lines are set out according to their wave-lengths. The elements to which these lines are due are marked at the bottom of the diagram. It may be remarked that A and B are, in reality, absorption lines due to the atmosphere. As regards the extension of the spectrum into the invisible region beyond the red, usually called the infra-red, a considerable portion has been investigated by photographic methods using specially prepared plates. The radiation in this part of the spectrum partakes of the nature of heat, and therefore may readily be investigated by instruments sensitive to heat rays, such as thermopiles, radiometers, radiomicrometers, or bolometers. With these instruments investigations have been pushed to an extraordinary distance, and in one case radiations have been detected in the emission spectrum of a quartz mercury vapour lamp with a wave-length of 3,160,000 ten-millionths of a mm.

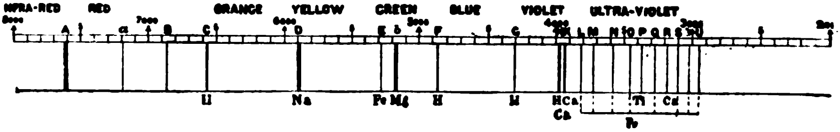

FIG. 1.

Owing to the fact that within the last year or two a new spectroscopic standard has been set up based upon measurements of the wave-length with interference apparatus it will perhaps be advisable to define the various units now used in spectroscopy. The original unit of wave-length used by Ångström himself in his measurements was the ten-millionth of a mm., which is often called the tenth-metre since the unit is 10^{-10} metre. About the year 1890 a new standard of wave-lengths was introduced by Rowland who, basing his measurements upon the well-known coincidence method with gratings, determined the wave-lengths of a very great number of the Fraunhofer lines. From that time until quite recently all spectroscopic measurements were referred to these solar standards of Rowland.

Not long after Rowland published his map, Michelson, by means of interference methods, determined the wave-length of the red cadmium line with exceedingly great accuracy with reference to the standard metre in Paris. Fabry and Perot then, by somewhat similar interference methods, determined the wave-length of a number of iron lines and solar lines in terms of Michelson's value, and showed that there is a periodic error in Rowland's scale.

As the result of Fabry and Perot's work the International Union for Solar Research have decided to adopt as secondary standards of all spectroscopic measurements the means of the values obtained by three independent observers of the wave-lengths of various lines in the spectrum of the iron arc. As all these observations are determined in relation to Michelson's value of the red cadmium line, the International Union have decided that the primary standard for spectroscopic measurements shall be the wave-length of the red line of cadmium $\lambda=6438{\cdot}4722$ Ångströms, and that the Ångström shall be so defined. This unit only differs from the original Ångström unit by less than one part in 10 million. It has also been agreed that all wave-lengths expressed in terms of this standard shall be denoted by the symbol I.A. Since the difference between the new unit and the old Ångström unit is so small it may still be spoken of as the tenth metre, and therefore it may be said that the wave-length of the red cadmium line is $\lambda=6438{\cdot}4722$ Ångströms or 10^{-10} metres, or $643{\cdot}84722\mu\mu$ or $0{\cdot}64384722\mu$. The units μ and $\mu\mu$ are more especially used in cases of the long wave-lengths which, of course, cannot at present be measured with such great accuracy.

It has been further agreed that tertiary standards shall be determined by interpolation between the secondary standards, and this has been done by Kayser for the iron-arc spectrum. These wave-lengths may therefore be used in all cases where great accuracy is required.

II. **The spectroscope.** The limits of absorption exerted by various materials are given below, and from these it may be seen that in spectroscopes, designed for the examination of the visible spectrum, the optical parts may be made of glass, whilst for the examination of the ultra-violet and infra-red rays some other material transparent to one or other of these regions must be substituted.

(*a*) *Direct vision spectroscope.* The simplest form of visual spectroscope is the direct vision instrument in which the dispersion of a very wide-angled dense flint-glass prism is partially corrected by crown-glass prisms. Since in this way it is possible entirely to correct the deviation of the mean rays of the spectrum and only partially correct that of the extreme rays a spectrum will be produced.

The usual arrangement of such an instrument is shown in Fig. 2, where the centre prism p' is made of dense flint glass, and the two outer prisms p, p, of crown glass. In Fig. 3 is shown the complete instrument, which is provided with a slit and eye-piece. This direct-vision spectroscope is very useful for the qualitative investigation of flame spectra or absorption spectra in the visible region, but although in some cases arrangements are made whereby readings of the position of lines or absorption bands can be made upon some form of scale, yet it is clear that such measurements can only be very rough.

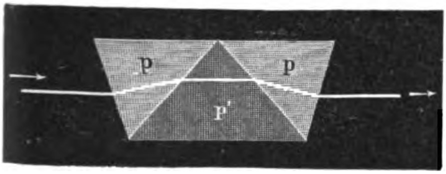

FIG. 2.

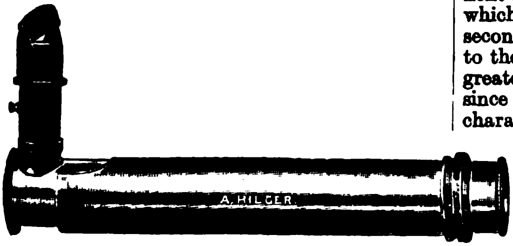

FIG. 3.

(*b*) *Spectrometer.* For more accurate visual work some form of spectrometer must be used, the term spectrometer being applied to a spectroscope in which some device is at hand for the more accurate reading of the deviation of the lines or their actual wave-lengths. In the first case by means of a graduated arc the angular deviation of the lines may be read off, and from these the wave-lengths of the various lines may be obtained, either by the method of graphical interpolation, or by means of a simple interpolation formula as described below. It has been found possible, however, by the use of a constant deviation prism to construct a simple form of spectrometer by means of which the wave-lengths of the lines in the visual region can be read off directly. This instrument is shown in Fig. 4, and is of the fixed arm type, that is the collimator and telescope are rigidly fixed, and the spectrum is made to pass across the field of view of the telescope by rotating the prism. The rotation of the prism is carried out by means of a micrometer screw carrying a drum head, which is so divided that the wave-length of any line under observation may be directly read off. In the best form of the instrument the accuracy of the reading is about 1 Ångström.

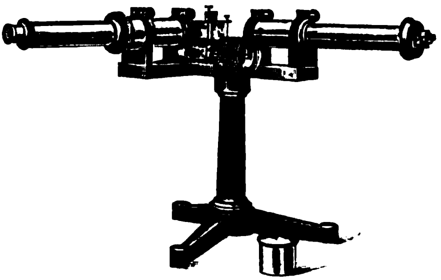

FIG. 4.

(*c*) *The spectrograph.* In accurate work upon the measurement of the wave-lengths of spectrum lines it is necessary to have recourse to photographic methods for two reasons, firstly, a permanent record of the spectrum is thereby obtained which may be measured at leisure; and in the second place, the photographic plate is sensitive to the ultra-violet region, which indeed is of far greater importance than the visible region, since the former generally contains the most characteristic lines of the elements. It is, of course, possible to fit a photographic attachment to either of the spectroscopes mentioned above, yet it is far preferable that the optical parts of the instruments be made of quartz. It would seem from the limits of absorption of the various substances referred to below, that fluorite would even be better than quartz; but unfortunately it is almost impossible at the present time to obtain this material in sufficiently large masses from which to cut prisms and lenses.

The construction of a spectrograph with glass optical parts is simplified by the fact that it is possible to use achromatic lenses which give a flat field upon a photographic plate. It has also been found possible to make achromatic lenses with quartz-calcite or quartz-fluorite combinations. To the first of these there is the objection that calcite exerts an absorption beginning at $\lambda = 2200$A, and to the second there is the objection, already mentioned above, arising from the scarcity of fluorite. It will generally be found, therefore, with a spectrograph the lenses and prisms of which are made of quartz, that the foci of the various spectrum lines lie upon a curve, so that photographic films must be used. Recently, however, there have been introduced spectrographs with quartz prisms and lenses so cut in relation to the optic axes that the whole spectrum from $\lambda = 8000$A to $\lambda = 2000$A may be photographed on a flat plate in good focus.

An essential point is that the photographic plate must be set at an acute angle (27°) with the axis of the telescope lens. An illustration of one of these instruments is shown in Fig. 5.

It is convenient in any spectrograph to have a wooden screen placed in front of the photographic plate, and in this screen to cut a narrow horizontal slot to allow the passage of the spectrum to the photographic plate. The dark slide carrying the plate may then be so mounted as to be capable of movement up and down by means of a rack-work adjustment so that several photographs may be taken upon the same plate.

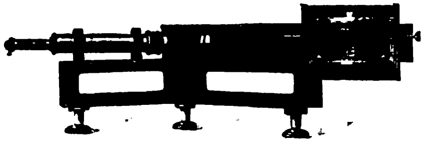

FIG. 5.

Since the determination of wave-lengths in general practice is always carried out by interpolation between lines of known wave-length photographed upon the same plate, it is necessary that the two spectra, the unknown one and the standard, be photographed in juxtaposition. This is most conveniently carried out by the use of draw-slides fitted over the slit, so that any portion of the slit may be exposed at will. The two spectra to be compared are successively photographed through two adjacent portions of the slit, when, of course, it will be found that they are in juxtaposition on the photograph.

It must not be forgotten that, unless precautions are taken, errors may readily be introduced owing to the spherical aberration of the spectrograph lenses. Unless the same portions of the lenses are used in comparing two spectra, it will generally be found that these are not in correct relation to one another upon the photographic plate. If a condensing lens is used to focus an image of the source of light upon the slit, then it is easy enough to obtain photographs of the two spectra in correct relation to one another. The condensing lens is fixed in such a position that its axis passes through the centre of the slit and the centre of the collimating lens, and also at such a distance from the slit that an image of the source may be focussed upon the slit. When the spectra of two sources have to be accurately compared, one of these is placed in such a position that its image is thrown upon a portion of the slit of the spectrograph. A photograph is then taken of the spectrum and, without closing the dark slide carrying the plate, the first source is removed and the second so placed that its image is focussed upon the slit a little above or below the position previously occupied by the first source, and then the second photograph is taken. In carrying out this procedure it will be seen that the draw-slides mentioned above will prove of excellent service.

A very convenient form of spectroscope is one in which a grating is substituted for prisms. A grating may be obtained which has been accurately ruled on a polished surface of glass or speculum metal. The former are used as transmission instruments, whilst in the latter case the spectrum is obtained by reflection.

In a prism spectroscope the dispersion increases with decrease of wave-length, and so the blue and ultra-violet regions appear more extended than the red and orange. In the case of a grating which produces the spectrum by diffraction, as the diffraction is a function of the wave-length, it will be found that the distribution of rays in the spectrum will be much more nearly proportional to their wave-length. Thus, for example, in the visible spectrum it will be found that the yellow rays occupy the middle position. For this reason the dispersion given by a grating is relatively greater in the red and yellow than that given by a prism spectroscope, and hence there is some advantage in using a grating for the study of these regions.

Owing to the difficulty of successfully ruling a grating the cost is necessarily rather high, but it has been found possible to produce excellent replicas at a very reasonable cost. These replicas are produced by making a celluloid cast of a first-class ruled grating. The casts are then mounted upon a flat glass plate, and may be used exactly in the same way as a ruled grating.

III. **Photography of the spectrum.** A few words may be said about the photographic plates to be used in spectrum work. For the blue and ultra-violet regions any good make of plate may be employed, but it is to be remembered that in general better definition is obtained with slow than with rapid plates. If very faint spectra have to be photographed, Wood advises the exposure of the plate for a few moments to a very weak light, such as that obtained from a small gas flame. The actual time for this exposure must be found by trial for the make of plate used, and in one case Wood found that 4 seconds exposure of the plate to the light from a gas flame turned down until the yellow tip is only 3 or 4 mm. high at a distance of 2 metres was necessary. This exposure may be made either before or after the spectrum photograph is taken.

For the red and yellow regions Wratten and Wainwright's allochrome, panchromatic, or spectrum panchromatic plates may be used according to the limits of sensitiveness required. The allochrome plate gives excellent results from the ultra-violet up to the beginning of the yellow. The sensitiveness of the panchromatic plate extends to about $\lambda=7000$, while the spectrum panchromatic extends to about $\lambda=8000$ Ångströms.

If it be required to photograph the regions of greater wave-length than $\lambda=8000$ A, special methods have to be employed for the production of plates sensitive to this region.

Three different methods have been used for this purpose. First Abney prepared special emulsions at a low temperature with which he coated the glass plates. This method has been made more practicable by Ritz. The second method depends on the inverse action of the infra-red rays upon an ordinary photographic plate, which previously has been solarised by exposure for a short time to a weak light. This method has been used by Millochau, who succeeded in obtaining photographic records up to $\lambda=10000$ A. The third method is that known as the phosphorophotographic method, and depends upon the power possessed by infra-red rays of destroying the phosphorescence of zinc sulphide. Bergmann, in using this method, exposed a zinc sulphide screen for 1–2 mins. to an arc light, a second screen of a saturated solution of cupric ammonium sulphate being interposed. The screen is then exposed to the spectrum for 2–8 mins., and then brought into contact with the photographic plate, which after 2 hours is developed. In this way it has been found possible to reach as far as 20000 A.

IV. **Recognition of lines and determination of wave-lengths.** In any work upon qualitative analysis by spectroscopic methods, or in the quantitative estimations described below, it is essential to recognise the lines in any known spectrum, which may most easily be carried out by a determination of their wave-lengths. This is simple enough for the lines in the visible spectrum when a direct reading wave-length spectrometer is used.

In the older form of spectrometer, in which the deviations of the lines are read, or their position on some arbitrary scale noted, it is necessary to reduce the values obtained to wave-lengths. This may be done either by the method of graphical interpolation or by the use of Hartmann's interpolation formula. In the former case the deviations of certain well-known spectrum lines, or their scale readings, are plotted against the wave-lengths on squared paper. When a sufficient number of such points are obtained a curve is drawn through them; the wave-length of an unknown line may at once be read from this curve if its deviation or scale reading is known. For drawing the dispersion curve in the visible region Collie has pointed out that a vacuum tube containing helium, hydrogen, and mercury vapour gives a number of lines eminently suited for the purpose. The wave-lengths and oscillation frequencies of the lines in this spectrum are as follows:—

		Wave-lengths	Oscillation frequencies
Helium	red	7065	14197
Helium	red	6678	14969
Hydrogen	red	6563	15232
Mercury	orange	6152	16250
Helium	yellow	5876	17014
Mercury	yellow	5790	17265
Mercury	yellow	5770	17329
Mercury	green	5461	18307
Helium	green	5016	19932
Helium	green	4922	20311
Hydrogen	blue	4861	20564
Helium	blue	4713	21211
Helium	violet	4472	22357
Mercury	violet	4359	22937
Hydrogen	violet	4341	23031

It will also be found that a vacuum tube containing neon shows a spectrum containing a great number of lines in the red, which are exceedingly convenient for the calibration of the red region.

It will be found that if instead of the wave-lengths the oscillation frequencies of the lines be used, the shape of the curve becomes flatter and easier to draw. By the oscillation frequency is meant the number of wave-lengths contained in 1 cm. *in vacuô*, *i.e.* the reciprocal of the wave-length reduced to vacuum. In order to reduce the wave-length of any line measured in air to its real value *in vacuô*, it is necessary to multiply it by the refractive index of air for the particular wave-length. In making this correction in actual practice it is simplest to add a small number to the wave-lengths. A table of these corrections can be readily constructed, and they lie between 2·5 Ångström at λ=8000, and 0·7 Ångström at λ=2000. Such a table is given complete in Watts' Index of Spectra, App. E, p. 51.

If it be desired to draw the calibration curve from photographic measurements it is simply necessary to measure the distances between the lines on the plate, starting from a chosen line at either end of the spectrum, and plot these against the oscillation frequencies or wave lengths.

As in this case the photographic record will no doubt include the ultra-violet region, the above list of wave-lengths will not, of course, be sufficient. A very convenient set of lines for this purpose is given in the spark spectrum of gold, and the following table contains the wave-lengths and oscillation frequencies of the principal lines of gold and silver, such as are given by gold of ordinary purity. As there are not many strong lines of gold in the red, orange, and green, one or two lines of lithium, sodium, and nitrogen have been included.

No.	Wave-lengths	Oscillation frequencies	Element and intensity

For the recognition of the lines in the spectrum and for a measurement of their wave-length Hartmann's interpolation formula will prove of great service. In its original form this formula is as follows:—

$$\lambda=\lambda_0+\frac{c}{(n_0-n)^{\frac{1}{a}}}$$

where λ_0, c, n_0, and a are constants, and n is the linear distance of the line measured from some line chosen as origin. Hartmann showed, however, that since a is nearly $=1$ it may be omitted, which simplifies the formula considerably. As may readily be seen, the values of λ_0, c, and n_0 may be obtained if the wave-lengths and scale readings of three lines in the spectrum be known. It is advisable, of course, that one of these lines be chosen near the middle of the region of the spectrum which is being dealt with, and that of the other two lines, one be chosen at the beginning and the other at the end of the region measured. When the values of the three constants have been found, the wave-lengths of any line can at once be calculated from its scale reading. Although the formula gives more accurate results when short lengths of the spectrum are being dealt with, yet it may be applied over a considerable range with very fair accuracy, and if it only be required to recognise the various lines in a spectrum, the accuracy then given is quite sufficient.

If, however, it is required to measure the wave-length of any new spectrum lines, or if for any other reason greater accuracy is required than can be obtained from Hartmann's formula, the measurement of the wave-length of any line may be found by a simple interpolation between two known lines in the comparison spectrum. Since in a prismatic spectrum the dispersion steadily increases as the shorter wave-lengths are approached, it is advisable in the interpolation to choose two standard lines of known wave-length which are near together, and, of course, one on each side of the line, the wave-length of which is to be measured.

A simple method of approximately determining the wave-lengths of lines from photographs of prismatic spectra has been devised by Edser and Butler. This method consists in photographing a series of interference fringes adjacent to the spectrum to be measured; these interference fringes are produced by Fabry and Perot's method, which consists in causing a beam of white light to pass through a film of air bounded by two parallel sides of half-silvered glass. When this light is examined in a spectroscope, a continuous spectrum is seen, crossed by a series of interference fringes. A sufficiently accurate interference apparatus can be made by taking two pieces of good plate-glass about 3 ins. square, which are each half silvered on one face; the plates are then carefully dried and mounted together, the two silvered faces turned towards one another. The plates are fastened together by a little wax placed all round the edges, when perfect adjustment can be obtained by simply pressing the plates together with the fingers. A preliminary adjustment for parallelism is made as follows: a spot of light or an incandescent electric lamp is viewed through the silvered surfaces; a long train of images due to multiple reflections is generally visible. These images are brought into coincidence, and then, on examining a sodium flame through the apparatus, interference bands will generally be visible. The final adjustment for parallelism is made with the help of these bands, which should be made as broad as possible. In carrying out this adjustment the film is held as close as possible to the eye, because for a parallel air film viewed normally the interference bands are formed at an infinite distance. The perfection of the results finally obtained will depend greatly on the accuracy of this adjustment.

The slit of the spectroscope is illuminated by a slightly convergent beam of light from an arc lamp, and the plates are placed in front of the slit, and as near to it as possible; under these circumstances the spectrum will be found to consist of a series of bright lines separated by black intervals. The best results will be obtained when the plates are in such a position that the slit is parallel to the direction of the interference bands seen with sodium light. The closeness of the bands depends upon the thickness of the film between the silvered surfaces. By means of draw slides, or screens upon the slit, these interference bands are photographed adjacent to the spectrum which is to be measured.

If the interference fringes on a photograph be numbered consecutively, starting from either end, the oscillation frequencies of all the fringes will be in linear proportion to their order number.

The oscillation frequencies of one or two lines at each end of the photograph are plotted against their readings on the interference fringe scale, and a straight line is drawn through the points thus obtained. From this straight line the oscillation frequency of any spectral line can be found at once from its scale reading.

V. **Methods of illumination.** Except in the case of phosphorescent spectra all substances are caused to luminesce when in the state of gas. The following methods of illumination are most usually employed: Flame, electric arc, electric spark, and high potential discharge through gases under reduced pressure.

(*a*) *Flame spectra.* Usually in the case of flame spectra the most convenient flame is that given by the Mecker burner. If it be possible to use an aqueous solution of the salt to be examined, a lasting effect is obtained by the use of the apparatus first designed by Mitscherlich, and which is shown in Fig. 6. The wick at the bottom is composed of fine platinum wires or quartz fibres. A little ammonium acetate added to the solution of the salt is useful in order to make it run well along the wick. In the case of solid substances Hartley recommends as support for the substance thin strips of cyanite or a mixture of carborundum and porcelain clay, which has been fired at a high temperature. It is also convenient in some cases to use a small spoon made of fused silica. Hartley also recommends feeding the burner with gas containing a little chloroform vapour in order to obtain a lasting chloride spectrum.

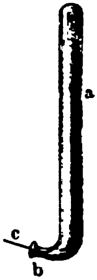

FIG. 6.

Again, a very convenient method of obtaining flame spectra is to introduce into the flame very finely-divided particles of the element itself or of the solution of a salt. In the case of the former, as has been shown by Hemsalech and de Watteville, the air supplied to the burner is passed through a small bulb in which is maintained either a series of electric sparks, or the electric arc between poles of the element to be investigated. In the latter case, the coal-gas supplied to the burner is passed through a flask containing a solution of the salt. This solution is made strongly acid with hydrochloric acid, and a few fragments of zinc are added. The bubbles of hydrogen thereby evolved carry with them into the burner a very fine spray of the solution. An alternative method is to use some form of 'vaporiser' or 'atomiser' by means of which the solution is broken up into very fine spray which is caused to mix with the illuminating gas before it enters the burner.

(*b*) *Arc spectra.* In the case of the electric arc, when the spectra are required of metals which are not easily fusible, the arc may be made between poles of the metal itself or the positive pole (which is the hotter) may be made of carbon. An alternative method is to use a carbon arc and put the substance to be examined in small portions into the crater formed in the positive pole. This, however, has the inconvenience of causing the arc to jump rather badly. A much steadier effect is obtained by using as the positive pole a cored carbon rod in the central hole of which has been packed the substance, the spectrum of which is to be examined. When carbon poles are used for the production of the arc spectra of substances it will, of course, be found that the spectrum shows the lines and bands due to carbon. These may be eliminated by comparing the photographs with one taken of the arc between two pure carbon poles.

(*c*) *Spark spectra.* The third method of illumination is to pass electric sparks from an induction coil or transformer either between electrodes of a metal or between beads of metallic salts which have been melted on to the ends of platinum wires or between an electrode of gold, platinum, or graphite, and the solution of a salt.

In the first case, it is advisable to use a condensed discharge, which may be produced by the introduction of a Leyden jar or plate condenser connected in parallel with the sparking apparatus. It may be pointed out that the most suitable capacity of condenser depends very largely on the size of the induction coil or transformer, and no very definite directions can be given. The condenser should be so chosen that the size of the spark obtained between iron electrodes in air is of the order of 2–3 mm. For the study of the spark spectra of melted salts de Gramont uses two platinum wires, one of which is mounted in a horizontal position, and the other is set above the first, making a somewhat narrow angle with it, so that the two extremities are close together. The two ends of the wires are heated in the Bunsen burner, and a small fragment of the required salt is melted on to the end of the upper wire. The sparks are then passed between the lower wire and the melted bead.

For the study of spectra of solutions a convenient form of apparatus is shown in Fig. 7. In this apparatus the lower platinum wire is surrounded by a narrow, thin glass tube up which the solution ascends by capillary attraction. Another form of sparking apparatus due to Hartley is shown in Fig. 8. In this the electrodes are made of graphite, which is cut into the shape of wedges about ½ in. long and ⅛th in. wide. The wedges are set with their edges parallel to one another, and to the collimating tube of the spectroscope. The wedges are attached to platinum wires and are fixed in glass tubes. The lower wedge dips into the solution, which ascends by capillary attraction up the deep grooves or scratches.

A third apparatus, especially designed for the investigation of quantitative spectra, was used by Hartley and by Pollock, and may be thus described. A piece of glass tube about 6 ins. long and with a capillary bore is bent into the form of a U-tube with the limbs of unequal length, and a small cup, like a thistle funnel, of about 2 c.c. capacity is blown at each end as shown in Fig. 9. A gold wire is then passed through the capillary of the tube so as to project a little above the rim of the lower cup, and a small piece of thin-walled capillary tubing is slipped over the end of the gold wire, and is just so long as to reach the top of the wire and thus draw up the solution and keep the top of the wire well wetted when sparking. It is necessary to employ fairly thick gold wire, and it may be found economical only to use a short piece of gold attached to a thin platinum wire sufficiently long to pass through the capillary. The electrode in the solution must be made the negative, and the upper or positive electrode may be held in any convenient manner, and the spark should not be too long.

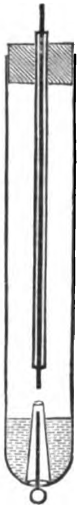

FIG. 7.

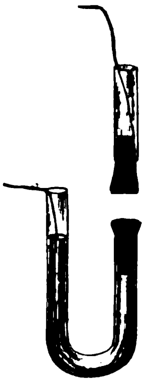

FIG. 8.

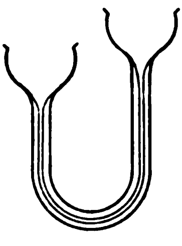

FIG. 9.

Two very convenient pieces of apparatus for obtaining the spark spectra of solutions without the use of metallic electrodes are described by Krulla, the principle being that the spark is made to pass between two jets of the solution. This method eliminates the spectrum lines of the metallic electrodes from the spectrum of the salt.

The phenomena which may be seen in a spark discharge are somewhat complex, for the condensed spark consists of different zones, there being a central part which is very brilliant and is surrounded by an aureole. A spectroscopic examination of the spark shows the rays emitted by the whole spark, aureole, and central portion, and also the rays which are emitted only by the central portion. These two different sets of rays can be recognised as long and short lines in the photograph of the spectrum.

Generally when dealing with spark spectra it is advisable to use a condenser, but in some cases, as will be referred to below, advantageous results are obtained by using the uncondensed spark discharge. It must not be forgotten that in any spark spectra will be found many of the spectrum lines of air. These latter are more pronounced, the less volatile is the substance under examination; for example, the air lines will be found to be very strong in the spectrum of the spark between platinum electrodes. These air lines may readily be eliminated from a spectrum by comparing it with the spectrum of the spark, say between platinum electrodes, when, of course, the lines common to the two spectra will be those due to air. It was shown by Hemsalech that the air lines may be entirely eliminated from any spectrum by introducing self-induction into the secondary circuit. A self-induction coil may be made quite readily by winding wire round a bobbin, the coil so prepared being put in series with the sparking apparatus. The amount of self-induction to be introduced of course varies with the size of the induction coil used. Such a self-induction coil for use with a large Ruhmkorff induction coil is 50 c.c. long, 5 cm. internal diameter, and contains 8 layers of wire each consisting of 150 turns.

(*d*) *Spectra of gases.* The most convenient method for the illumination of gases is to pass the discharge from the induction coil through them under a pressure of from 1 to 3 mm. The gas is enclosed in a vacuum 'tube,' which has two electrodes and a capillary portion, as first designed by Plücker. It will be found that the discharge through the capillary portion of the tube is exceedingly brilliant. If the ultra-violet region of the spectrum is required, either the whole vacuum tube may be made of quartz with no electrodes, or the discharge through the capillary may be viewed end-on through a quartz window.

For the methods employed for making and filling these tubes reference must be made to books on gas manipulation.

(*e*) *Phosphorescent spectra.* An important method of illumination, especially in the study of the rare earths, is that of the cathode streams producing phosphorescence in the substance under examination. It has been found as a result of researches by Crookes, Lecoq de Boisbaudran, Urbain, and others, that very many minerals and artificially-prepared substances give characteristic phosphorescent spectra, but this method of examination finds its chief practical use in connection with the separation of the rare earths from one another.

The rare earth under investigation in the form of oxide or sulphate is placed in a bulb tube provided with two electrodes consisting of flat plates of aluminium, the normals to which lie in the direction of the centre of the heap of material to be examined. Since the cathode rays leave the electrode normal to its surface, it is evident that this construction will give the maximum brilliancy. The exhaustion of the tube is carried to a very high point, the exact degree of exhaustion being judged by the maximum of phosphorescence obtained. For the examination of the spectrum the tube is set at a slight angle, so that the phosphorescent rays can be directed into the spectrograph. When the ultra-violet region is to be examined the phosphorescence tube is provided with a quartz window cemented on and through which the phosphorescent spectrum may be photographed.

VI. Absorption spectra. By an absorption spectrum is meant a continuous spectrum from which certain definite rays, or groups of rays, have been absorbed during the passage of the light through the substance to be examined. It would appear from this that the best source to use for absorption spectrum observations would be one giving a perfectly continuous spectrum. It must be remembered, however, that it is necessary in all quantitative observations of absorption to make accurate measurements of the position of the absorption lines or of the limits of the absorption bands. If, therefore, a continuous spectrum be used it will be necessary that some convenient method of wave-length determination be at hand. Several series of investigations have been carried out in which a source giving a continuous spectrum is used, but it will generally be found that the determination of wave-lengths of the absorption maxima is unsatisfactory and troublesome. By far the best method is to use a source which gives a spectrum consisting of a very great number of lines closely situated together, and not differing very much in their relative intensities. Such a source is a spark between carbon electrodes, which are thoroughly impregnated with the oxides of molybdenum and uranium, as described by Jones. The two carbon rods, about 1 cm. in diameter, are filed to wedge-shaped edges, care being taken that the edge of the wedge is at right angles to the axis of the rod. These carbon wedges are boiled in a solution of uranium nitrate and then dried and heated to dull redness. This process is repeated three times. They are then boiled in a strong solution of ammonium molybdate and again heated to dull redness, this process also being repeated three times. In mounting these electrodes, just as in the case of the spark spectrum described above, the wedges are set parallel to one another, and to the axis of the collimator tube.

The electric spark between cadmium electrodes has been used by Hartley and by Purvis as a source for absorption spectra observations. Although the cadmium spectrum consists of only a few very bright lines, yet the region between these lines is filled with a continuous background which serves extremely well for the observation of fine-line absorption. It must not be forgotten, however, that errors may be introduced if it happens that an absorption band lies very close to the position of one of the bright cadmium lines. For this reason, in dealing with fine-line absorption, it is advisable to use alternately two sources, the cadmium spark and one other, the second one being used merely for the purpose of finding whether any absorption lines are present at or close to the position occupied by the cadmium lines. Hartley has also used the spark between electrodes made of an alloy of cadmium, tin, lead, and bismuth, the metals being melted together in atomic proportions. This, however, does not seem to be so satisfactory as the spark between pure cadmium electrodes.

The use of one of these sources which gives a spectrum of bright lines is manifestly superior to a source giving only a continuous spectrum, because the bright lines, being of known wave-length, serve as land-marks from which the wave-lengths of the absorption lines or bands may be measured.

Owing to the enormous multiplicity of the lines in the uranium and molybdenum coated carbon electrodes mentioned above, some difficulty may be found in recognising these lines and finding their wave-lengths. This spectrum may, however, easily be calibrated by photographing in juxtaposition to it a spectrum containing a few lines of known wave-length, as, for example, the cadmium spectrum. If the photograph then be measured with a travelling micrometer the whole of the molybdenum and uranium spectrum can be calibrated with the help of Hartmann's formula already described. By matching this calibrated spectrum with the photograph of the same spectrum taken when the absorbing substance has been interposed, the limits of the absorption may at once be read off. Very frequently absorption spectrum measurements are expressed in oscillation frequencies and not in wave-lengths.

If it be desired to observe absorption bands or lines in the red and yellow regions of the spectrum, it will generally be found that emission spectra do not contain sufficient lines in these regions to justify their use for this purpose. Some other source must be sought for, and it has been found that very satisfactory results are obtained with interference fringes. These interference fringes are obtained simply enough by the use of the Edser and Butler interference apparatus described above. A source of light giving a continuous spectrum in the red and yellow is used, and by means of a condensing lens a slightly converging beam of light is thrown on to the interference plates, which are placed immediately in front of the slit of the spectroscope. Since the oscillation frequency of the fringes is very easily obtained they may readily be used for the observation of absorption bands.

Although for simple qualitative measurements of absorption in the visible region it may be sufficient to make visual measurements by means of a spectrometer, yet in any accurate work upon absorption it is necessary to determine the position of the maximum of absorption in the case of every absorption band, which is not necessarily its centre; furthermore, it is necessary when possible to determine the limits of concentration over which the absorption band persists. In such accurate work it is obvious that visual work must give place to photographic methods. In order to obtain the position of maximum absorption corresponding to any absorption band the concentration of the absorbing substance is steadily decreased. It will be found that the absorption band or bands become narrower and narrower until they finally vanish. In this way the head of the absorption may be obtained, and this corresponds to the position of maximum absorption in the case of each band. It will be found most convenient to examine the absorption of a compound by dissolving it in some suitable solvent, when the molecular concentration may be decreased simply by lessening the thickness of the solution examined. For this purpose may be used an adjustable absorption cell as shown in Fig. 10, which consists of two glass tubes which fit loosely one inside the other. Both of these tubes are ground flat at one end and square to the axis, and have a quartz plate cemented in each case as shown at A and B. C is a bulb tube sealed to the side of the outer tube, and serves to take up the solution when the thickness of the layer is decreased by pushing in the inner tube. At D a broad india-rubber band is slipped over the junction in order to keep it water-tight, and this may be about 1 in. broad. The outer tube is about 1 in. wide and 6 ins. long, and it has a millimetre scale etched upon it, this scale being so ruled that its zero division coincides with the inner side of the quartz plate A, and thus the reading of the inner side of the plate B upon the scale gives the thickness of the solution. The inner tube is preferably lined with black paper, so as to stop as far as possible the reflection of light from the glass walls. In actual practice a solution of known strength of the substance in a suitable solvent is made of some standard strength, say $\frac{1}{10}$th normal. This is then put into the cell which is adjusted so that the thickness of the layer is 30 mm., and a photograph is then taken of the source after passing through this thickness; the layer is then reduced to 25 mm., and a photograph again taken, this being repeated for the lengths 20, 15, 12, 10, 8, 6, 5, and 4 mm. If, as is most probable, the 4 mm. layer of the solution is not entirely diactinic, the solution is diluted ten times and the spectrum photographed through the same thicknesses as before. If necessary this may also be repeated for solutions of N/1000 and N/10000. Except in certain peculiar cases it will be found that there is no need to dilute beyond N/10000. The photographs thus obtained will give a complete record of the change of absorption to be observed in passing from 30 mm. of N/10 to 4 mm. of N/10000. If it be desired, of course, a normal solution of the substance may also be examined, though this in the case of organic compounds is very rarely necessary. The wave-lengths or oscillation frequencies of the absorption lines, or of the limits of the absorption bands, may be read in the case of these photographs either by comparison with a calibrated photograph of the spectrum of the source or by interpolation between any standard lines in the spectrum. These wave-lengths or oscillation frequencies are plotted against the equivalent concentrations of the substance under examination. Hartley, to whom we are indebted for most valuable work on the absorption of organic compounds, in his earlier papers used the equivalent volume of

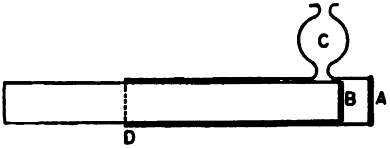

FIG. 10.

solution of a fixed quantity of the substance, and later an equivalent thickness of solution of fixed concentration. In the first case the effect of a given relative change in the amount of the substance was more marked at smaller than at greater concentrations, and in the second case exactly the opposite is true. If, however, the logarithms of the relative thicknesses be used, it will be seen that a given relative change in dilution or thickness will be represented by the same distance on the diagram, whatever be the actual strength of solution. In actual practice the logarithms of the relative thicknesses of the weakest solution used (in the above case N/10000) are put on the ordinates, and the measurements of the absorption limits on the abscissæ, and the line drawn through the points so obtained gives the absorption curve of the substance under examination. Such an absorption curve is shown in Fig. 11, which represents the absorption of acetyl acetone in alcoholic solution.

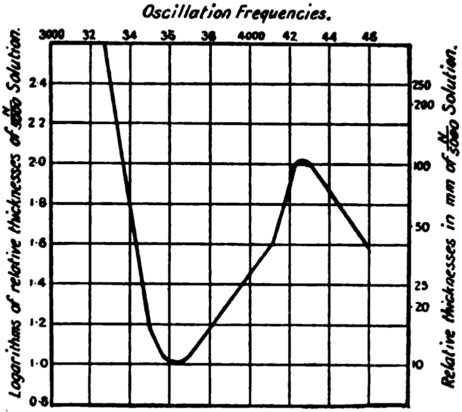

FIG. 11.

As will be shown later, the influence of a solvent upon the absorption exerted by a substance is often very marked, and it may prove of importance to observe the absorption of the substance in the absence of any solvent. This may either be done with the substance in the state of vapour or in the liquid state. Hartley and Purvis have both examined the absorption of the vapours of a number of organic substances, and the method adopted was as follows: A glass tube about 2 cm. wide and 20 cm. long, with quartz plates fastened at each end, is filled with the vapour of the substance by aspirating a current of air previously saturated with the vapour by bubbling it through the substance contained in a small wash bottle.

Since this method does not easily allow the concentration of the substance to be changed, which is necessary in order to obtain the complete absorption curve, a similar tube made of quartz with the ends sealed on may be substituted. To this quartz tube is attached a side tube connected with a small flask containing the substance, and the whole apparatus is exhausted to the highest possible point. The bulb containing the substance is now heated to certain known temperatures at each of which a photograph is taken, this being continued until sufficient concentration is reached. It must be remembered that in order to guard against any condensation of the substance in the quartz absorption tube this must be kept at a constant temperature, which is at least 30° higher than the highest temperature to which the substance is to be heated. The concentration of the substance in the quartz absorption tube may readily be calculated from the vapour pressure curve of the substance under investigation. These observations will give a complete record of the absorption of the substance similar to that obtained for solutions, and from which the absorption curve may be drawn.

For the absorption of pure organic compounds it is evident that very thin layers must be used, and Purvis has devised an apparatus for this purpose, in which a small quantity of the liquid in question is placed between two perfectly parallel quartz plates, and by means of a micrometer screw these plates may be brought closer and closer together, and the thickness of the layer read off at any time. With this apparatus the thickness of the layer may be reduced to 0·003 mm.

VII. **Application of spectroscopic methods to analysis.** Spectroscopic methods have found considerable application in many directions. Although in most cases the use of the spectroscope is restricted to the qualitative analysis of substances, yet it has been found possible to develope certain systems of quantitative analysis by its means. These applications may conveniently be treated under the three headings of emission spectra (flame, arc, and spark), phosphorescence, and absorption.

(*a*) *Emission spectra. Qualitative analysis.* Although in the qualitative spectrum analysis of a substance some knowledge may be gained if the substance give a flame spectrum, yet for complete analysis by the spectroscope recourse must be had to the arc or the spark as a means of illumination, preferably the latter.

In general, owing to its wider application, the spark spectrum is most suited to a qualitative analysis of substances, because they are more often sufficiently good conductors for the high potential current of a spark discharge. Then, again, arc spectra are not possible in the case of solutions. In dealing with solid substances such as, for example, native minerals, it will be found perfectly possible to obtain the spark discharge between fragments of such minerals. These small fragments may be attached by means of fine platinum wire to iron or steel wires, or may be held in small clips which are mounted in any convenient form of sparking apparatus by means of which the spark length can be varied.

In dealing with the spark spectra of solutions it is important that the solution be made the negative pole, and it is most convenient to use an induction coil giving a 2 or 3 in. spark in air. A considerable advantage is often gained by comparing the spectra given by the spark with or without a condenser. When no condenser is used it will be found that the spectrum shows the bands of nitrogen. The solutions of the chlorides of the alkaline earths, metals, and of certain rare earths show with the non-condensed spark, spectra of bands and lines. This is also true for chromium, iron, lead, bismuth, mercury, copper, silver, and gold. The chlorides of the alkalis, tin, antimony, zinc, cadmium, thallium, iridium, gallium, nickel, cobalt, and the platinum family give line spectra. The condensed spark gives almost entirely line spectra, but superposed on these will be the line spectra of air, platinum, and sometimes of chlorine. Considerable differences are often obtained between the spectra given by the spark with or without a condenser, and the unequal sensitiveness of the spectra often affords decided advantages. It is possible for this reason to detect the presence or the absence of various substances in very complex mixtures, which with the condensed spark give such complicated spectra as to make the individual lines very difficult to pick out.

On this account it is sometimes very useful to use a condenser, the capacity of which can be varied at will. Such a condenser can easily be made out of two glass tubes, one of which is sufficiently smaller than the other, so as to slide easily in and out. The larger tube may be about 2 ins. in diameter, and both the tubes are coated on the outside with tin-foil. It is advisable to have a wooden handle fitted to the inner tube, so that it can be moved without danger of touching the coatings with the fingers, and also to have the ends of the wider tube expanded a little, so as to guard against any damage to the inner coating when it is moved in or out.

It has been shown by de Gramont that if the condensed spark discharge be passed between fragments of minerals the spectrum shows bright emission lines, not only of their metallic components, but also of the non-metallic components in a number of cases, as, for example, chlorine, iodine, sulphur, phosphorus, arsenic, and antimony in the case of antimonates and thio-antimonates. In the spark spectrum of no mineral up to the present time have the lines of oxygen and fluorine been noted. We are indebted to de Gramont for an exhaustive study of this method of qualitative analysis of many minerals.

Among the conclusions drawn by de Gramont from his work may be mentioned the following: Those elements which are present only in very small quantities are easily detected. If the condenser is not used the spectra of the non-metals disappear and the metals themselves only show the brightest of the lines. Those minerals which are not good conductors but which are volatile in the spark give equally good results. Fused salts also show the spark spectra both of their metallic and non-metallic elements.

It has been shown by Urbain that minerals such as blende can be analysed spectrographically, using the electric arc. In one case he analysed 64 different samples of blende, and was able to detect quite easily the presence of germanium, gallium, and indium.

It is well known that the arc and spark spectra of the same element frequently differ very considerably. There have been found lines in the latter which are not present in the former. To these Lockyer has given the name of enhanced lines, and has, indeed, suggested that they are due to simpler forms of matter produced under the conditions of great stress existing in the spark. On the other hand, the flame spectrum, as a general rule, is much simpler than that of the arc spectrum, this being attributed to the fact that the temperature of the flame is lower than that of the arc. Again, each particular type of spectrum, whether flame, arc, or spark, is very sensitive to change in the exciting cause, especially is this true in the case of spark spectra, where the relative intensity of the lines is found to change very markedly when the capacity of the condenser or the amount of self-induction in the circuit is varied. It will be evident, therefore, that in such work as quantitative spectrographic analysis great care must be taken to keep the conditions constant throughout the whole series of experiments.

Detection of mercury in explosives. The basis of this method is the electrolysis of a properly prepared solution of the explosive, using a platinum wire as cathode. The platinum wire is then put into a vacuum tube and gently heated, when the mercury may at once be detected by its characteristic spectrum. If the explosive is completely soluble in the ordinary solvents, ether, alcohol, or acetone, 2 grms. of an average sample are dissolved in a suitable solvent and a sufficient quantity of sulphuric or hydrochloric acid is added to give a faintly acid reaction, and the solution is then electrolysed. If the explosive is only partially soluble 2 grms. are first extracted by decantation, the residue is then dried at a low temperature and evaporated with strong nitric acid to destroy all organic matter. It is then taken up with very dilute hydrochloric acid and electrolysed. The solution in the organic solvent is also electrolysed. Since the test for mercury is exceedingly delicate great care must be taken to avoid any contamination during the process of extraction and solution. It is best to use the same dish for solution and for electrolysis.

The electrodes are made of platinum wire 0·015–0·02 in. in diameter and 1 in. long. The dish is nearly filled and is carefully covered with glass or cardboard, the electrodes being passed through this cover. A current of 2 ampères at 10 volts is used, and may be continued all night. The cathode is then taken and carefully dried and dropped into the vacuum tube. This tube is about 2½ ins. long by ⅛th in. in bore. A platinum wire ½ in. long is sealed in at one end, and the other end is drawn out ready for sealing, but leaving sufficient room to allow the entrance of the cathode. The second electrode also is a platinum wire ½ in. long, and sealed in a small side tube. After exhaustion the tube is sealed off and the current from an induction coil passed through it. It is then gently heated, and the presence of mercury is at once recognised by the green line at 5461 Ångström, and also by the two yellow lines at 5790 and 5678 Ångström.

By this method the presence of as little as 0·000001–0·0000001 grm. of mercury may be detected.

The same piece of platinum wire must never be used twice, for it has been found impossible to remove the mercury by the action of heat so that it will not still continue to give the mercury spectrum in a vacuum tube. The amount of mercury present may be estimated quantitatively by placing the cathode in a test tube with a small quantity of iodine and gentl heating it. The mercury is converted into mercury iodide, which then may be treated in any convenient manner.

Quantitative analysis. Hartley has shown, in the first place, that the spark spectra of solutions of metallic salts show the lines of the metallic radicle, and further that the effect of diluting these solutions is first to weaken these lines and then to shorten them until they finally disappear. It has been found on further investigation that all the lines of a metal do not disappear at the same dilution, and further that, given the same conditions, the same lines always disappear at the same dilution. These investigations have been continued by Pollok and Leonard and by de Gramont, and the name of residual or ultimate lines has been given to those lines which persist the longest when the substance is diluted. The method adopted by Pollok, which is based on Hartley's investigations, is to use gold electrodes and to compare the photographs of the spectra given with a 10 p.c., 1 p.c., 0·1 p.c., 0·01 p.c., and 0·001 p.c. solution of a metallic salt. In taking any photograph the spectrum of the spark between the gold electrodes alone is photographed, using a long slit; then the length of the slit is shortened and the spark spectrum of the particular solution required is photographed without moving the photographic plate. In this way the gold lines may at once be recognised. By comparing the photographs taken at various dilutions of the salt the relative persistence of the various rays is obtained. The most persistent, that is to say, the residual lines, have not necessarily any connection with their intensity. It is evident that in the spectroscopic examination for the presence of traces of any element it is by these residual rays that an element may be recognised when present in very small quantities. Inasmuch as it is quite possible, and has indeed been done in very many cases, to determine the dilutions at which the various lines disappear, it may be seen that we have herein a quantitative method of spectrum analysis.

When photographs of the various dilutions of the solution of a particular metal have been taken, the next step is to observe the lines of that metal, which appear at each particular dilution. For the sake of convenience, Hartley indicates the persistence of the various lines by means of the letters of the Greek alphabet in the following way. By ω lines only seen in a 0·001 p.c. solution, by ψ those seen in a 0·01 p.c. solution and not in a 0·001 p.c. solution, by χ those lines seen in a 0·1 p.c. solution but not in a 0·01 p.c. solution, and by φ those seen in a 1 p.c. solution but not in a 0·1 p.c. solution, then by σ those seen in a strong solution and not in a 1 p.c. solution, whilst by τ he denotes those lines which are seen in the metallic spark, but not in any solution.

In actual analysis, therefore, it is only necessary to compare the spectrum photographs taken of the unknown solution with the photographs of the particular metals in the various dilutions, whence the percentage of each particular metal in the substance under examination may be arrived at.

It is hardly necessary to point out that in every photograph the conditions of exposure must be the same, and also in examining the solutions that exactly similar apparatus and electrodes be employed.

The apparatus recommended by Pollok for this particular purpose has already been described in the section dealing with spark spectra. A condenser should be used, and if it be desired to remove the air-lines a self-induction coil may also be inserted.

As a result of the method described above the gold lines may be easily recognised, and the wave-length of the other metallic lines may be obtained by interpolation between the gold lines, using either an interpolation formula or an interpolation curve.

A very large number of these quantitative observations have been made by Pollok and by Leonard on the spectral estimation of the elements, but as yet the investigations are not sufficiently complete to warrant their detailed description as a basis of quantitative spectrographic analysis.

This method can be applied to the quantitative analysis of minerals and alloys; for example, de Gramont has shown that it is possible to estimate by this method the silver in specimens of galena.

Hartley describes the application of this method to the quantitative analysis of alloys; for example, old and rare coins, which, as he points out, saves the cutting and destruction of the coin. He checked his results by making an alloy of the same composition as the coin as found by the spectrographic method, and proved that the spectra of the two were in every way identical. In one case he found 13·96 p.c. of lead, 72·35 p.c. of copper, 12·70 p.c. of zinc, and 0·85 p.c. of iron. He afterwards found that these figures were correct by the ordinary methods of chemical analysis.

Methods have been devised for the quantitative estimation of lithium, sodium, and potassium depending on the persistence of the characteristic lines in the flame spectrum of these elements. For example, Ballman found that if a solution of lithium chloride be diluted until the lithium line ($\lambda = 6708$ Å) disappears, then there is contained in every 3345 c.c. of the solution 0·001 gr. of the lithium salt.

Mottram has devised a method of quantitative estimation of potassium and sodium, which he applies to the analysis of animal tissues and blood. He uses a direct vision spectroscope, with a fixed slit in front of which a piece of cobalt glass is fixed. A Bunsen burner is used, guarded with a blackened metal cylinder having a hole in one side through which the flame is viewed and a slit through which a platinum spoon can be introduced. This Bunsen burner is provided with a platinum gauze nozzle, and in order to keep the gas pressure constant a toluol manometer is used for measuring the pressure and a gas tap with a long arm attached for delicate adjustments. The following precautions were found necessary. The distance at which the spectroscope and cobalt glass is fixed in front of the metal cylinder surrounding the flame must always be the same. The position of the spoon in the flame must be constant, and in Mottram's experiments it was so placed that the bottom of the spoon was just above the apex of the blue inner zone of the flame. The gas pressure was kept very constant as measured by the difference in heights of the toluol columns in the manometer (0·3 cm.). The amount of diffused light in the room must be small and constant. It is best to carry out the experiments in a dark room lighted by an 8 candle-power electric lamp. The spectroscope must always be directed to the same part of the flame; it was directed above the spoon so that the continuous spectrum produced by the incandescent spoon was just invisible. The first definite observations should be postponed until the eyes become accustomed to the dull light of the room (about half an hour). The method for the estimation of sodium depends on the fact that different quantities of sodium sulphate when placed on the spoon and introduced into the flame take different lengths of time to burn off, the time being proportional to the amount. Mottram recommends the use in this case of a second cobalt glass. When the platinum spoon has been cleaned with strong hydrochloric acid and the blowpipe until the D line can no longer be seen through the two cobalt glasses, 0·02 c.c. of the solution under examination containing a known weight of the substance in which it is required to estimate the sodium is placed in the spoon. The D line, which at first is clearly seen, gradually fades until it disappears. The time is then noted, and this time is compared with a table which has been previously prepared when known weights of sodium sulphate were placed on the spoon under identical conditions. From this the percentage of sodium can be estimated.

Mottram gives a table showing the times taken by known quantities of sodium, which vary from 6½ minutes with 0·000001 gr. of sodium to 13 minutes at 0·000003 gr.

The estimation of potassium depends upon the least amount of potassium sulphate that will give the red (potassium line $\lambda=7699{\cdot}3$ Å). In Mottram's apparatus this amount was 0·0000002 gr. Only one cobalt glass was used in this case, and just as before 0·02 c.c. of the solution is placed in the spoon. If the potassium line is then seen, the solution is diluted and again examined, this being continued until the line just becomes invisible. This dilution corresponds, therefore, to 0·0000002 gr. of potassium in 0·02 c.c. of solution.

In the application of this method to the estimation of sodium and potassium in animal tissues and in blood, owing to the fact that carbon and acid radicles other than sulphate materially alter the constancy of the results, great care must be taken in these cases to destroy all carbonaceous matter and to ensure that the sodium or potassium is only present as sulphate.

Phosphorescent spectra. Amongst the many substances which show phosphorescence under the influence of cathode streams perhaps the most interesting are the rare earths. This phenomenon has been frequently used as a means of testing the progress of the fractional separation of the rare earths from one another. Every such method is based on the assumption that the phosphorescent spectrum is a characteristic property of each rare earth. This, however, is not the case, because it has been proved by Leonard and Klatt and by Urbain and his pupils that phosphorescence is a phenomenon characteristic of mixtures of two or more substances. No rare earth gives any phosphorescence when it is pure, and indeed it would seem that no pure substance whatsoever can phosphoresce. Urbain has shown that phosphorescence is a property of diluted matter, and that in order to obtain the phosphorescence of a substance it is necessary that it be mixed with a large quantity of some diluent. To the active principle of such mixtures has been given the name of phosphorogene, and for every pair of substances, phosphorogene and diluent, there is one definite mixture which gives an optimum of phosphorescence. On either side of this optimum, that is if the phosphorogene be either increased or decreased, the phosphorescence is weakened. Moreover, a phosphorescent spectrum as a rule contains several bands, and there is an optimum condition for each of these bands; also these conditions are not the same for all the bands in any one spectrum. It may happen that as the quantity of phosphorogene is increased in a given mixture the conditions are successively arrived at for giving the optimum for each of the bands in turn, with the result that the colour of the phosphorescence appears to the eye materially to alter. Generally speaking, the optimum condition corresponds to the presence of a very small quantity of the phosphorogene. It will be understood from this that the variations in the phosphorescence observed during the fractional separation of the rare earths, will be very varied as the optimum condition for each of the phosphorogenes present is passed. The extraordinary variations which can be obtained in the relative intensity of the various bands in any one phosphorescent spectrum explain why it has been thought by some people that each separate band is the characteristic spectrum of a single element.

Urbain's investigations have proved conclusively that this theory is completely untenable, and they also show the great care that must be exercised in the interpretation of any phosphorescent spectrum that is observed. At the same time, in the fractional separation of the rare earths, owing to the very small differences in their atomic weights, it is necessary to use some physico-chemical observations (such as spectroscopic) to characterise the elements.

In this connection may be used emission, absorption, and phosphorescent spectra, all three of which are given by the rare earths.

In carrying out any fractional separation on the rare earths, if the order number of the fraction is made the abscissa and the atomic weight the ordinate, the curve drawn through these points at the beginning of the fractionation will of course appear continuous and regular. As the fractionation advances the curves will begin to give indications of horizontal steps, which become more marked as the process is continued. These steps, as a rule, correspond to the existence of pure substances. They may, however, be mixtures similar to constant boiling mixtures in a distillation. It is evident from what has been said above, if these horizontal steps give any evidence of phosphorescence that they must correspond to a mixture, and that if they correspond to single pure substances they will not phosphoresce.

It will be seen, therefore, that although phosphorescence cannot be utilised as a test for the purity of a substance, yet it may within certain limits be of great value for the characterisation of an element. But for the complete identification of such an element it is necessary also to make use of its emission and absorption spectra.

Absorption spectra. Perhaps it may not be out of place before dealing with specific absorption spectra observations to define the limits of transmission of the various materials which are used in different branches of spectroscopy.

Substance	Transmits all rays between		
Heavy flint glass	2μ	and	0·3500μ
Flint glass	2μ	and	0·3300μ
Crown glass	2μ	and	0·3200μ
Light crown glass	2μ	and	0·3000μ
Quartz	4μ	and	0·2000μ
Calcite	2·2μ	and	0·2150μ
Fluorite	7·6μ	and	0·1230μ
Rock salt	18μ	and	0·2000μ

Frequently in constructing spectroscopes it is necessary to make use of a reflecting mirror of some kind. It may be pointed out that a silvered surface has very poor reflecting power in the ultra-violet region. The maximum of transmission by a silver layer lies between 3360 and 3100 Ångströms, and such a layer consequently cannot reflect light of this wave-length. A speculum metal surface, however, seems to have the power of reflecting ultra-violet light down to the shortest wave-length yet observed. Similarly a nickelled surface has excellent reflecting power in the ultra-violet region. Nickelled mirrors may easily be obtained by exposing the surface to be coated to the cathode streams from a nickel cathode in a high vacuum.

Absorption spectra of inorganic salts and their lakes with alkannin. Many metallic salts which give coloured solutions may be recognised by their absorption spectra. Those, however, which give colourless or only weakly-coloured solutions, with the exception of praseodymium, neodymium, erbium, samarium, holmium, thulium, europium, gadolinium, and dysprosium do not give sufficiently characteristic absorption for their recognition. It is possible, however, in many cases to convert these substances into compounds which give a characteristic absorption spectra, for example, manganese salts, which although rose coloured, give no characteristic absorption, but if they are converted into permanganates by oxidation with nitric acid and lead peroxide the absorption spectrum becomes highly characteristic. Similarly aqueous solutions of cobalt salts though red possess no characteristic absorption, but their solutions in the presence of concentrated hydrochloric acid give again a highly characteristic absorption.

Formánek has made a careful investigation into the absorption spectra of the lakes formed by metallic salts with the dye-stuff alkannin, which may be used in the qualitative testing for the presence of the metals. It is necessary to use a rather dilute solution of the alkannin in alcohol. The powdered alkanna root is extracted in the cold with 95 p.c. alcohol until a layer of the solution 10–12 mm. thick shows all the absorption bands sharply separated. About 5 c.c. of this solution are then put into a cell about 10–12 mm. thick and two or three drops of the neutral aqueous solution of the metallic salt are added. If after a short time no change in the spectrum is noticed a small drop of dilute ammonia is carefully added and the absorption spectrum observed. The salt solution must be perfectly neutral, and in case of the heavy metals great care must be taken in adding the ammonia to guard against any insoluble precipitate being formed. The solution of the alkannin in alcohol shows four absorption bands at the following wave-lengths 5637, 5443, 5227, and 4872 Ångströms. The addition of dilute ammonia to this solution changes it from red to blue, and it then shows only two bands at λλ=6428 and 5948. If the chloride of the metal is added to the neutral alcoholic solution of the dye-stuff the absorption changes in the case of the following metals, iron, aluminium, glucinum, yttrium, erbium, zirconium, thorium, vanadium, indium, molybdenum, nickel, copper, palladium, rhodium, and uranium. In the remaining metals no change is observed until after the addition of ammonia. In the table on p. 127 are given the maxima of the absorption bands obtained with the various metals.

Absorption of the oxides of nitrogen and ozone in the infra-red and their quantitative estimation. Warburg and Leithäuser have measured the absorption of N_2O_5, NO_2, N_2O_4, NO, N_2O, and O_3 in the infra-red, and find that all these gases exhibit very well marked and characteristic absorption bands between the limits 2·7 and 7μ.

The apparatus used was a fixed arm spectrometer with a single fluorite prism. The source of illumination was a Nernst lamp, and the absorption bands were detected by means of a vacuum bolometer, whilst the wave-lengths of the absorption bands were calculated from the known dispersion curve of fluorite.

In the following table are given the wave-lengths of the absorption bands, in each case the most important band being marked in heavy figures :—

Substance	Absorption maxima in μ						
N_2O_5	2·73	2·83	3·33	3·86	4·27	4·81	**5·81**
N_2O_4	5·695						
NO_2	3·38	**6·11**					
NO	5·24	5·40					
N_2O	2·79	3·54	3·86	4·02	(4·29)	**4·45**	
O_3	4·74						

The absorption of these gases can be utilised for the quantitative analysis of the gas mixtures which contain one or more of these gases, provided that their quantities are not too great. A 30-cm. long absorption tube is used, and it is necessary to determine the intensity of the absorption band in each case corresponding to definite percentages of the gas in question. These percentages should be so small that the partial pressure of the gas lies between 0·3 and 1 mm. When these relations between intensity, and absorption and partial pressure of the absorbing substance have been determined for all the above gases the estimation of the amounts present in any given gas mixtures may readily be found.

Element	Principal band	Secondary Bands		Remarks
Uranium	6870	6315	—	Without NH_3

Molybdenum	5845	5415	5040	Without NH_3
Glucinum	5820	5385	5008	Without NH_3

In making use of this method of investigation it is not advisable to use the metallic salts in too dilute a solution.

Absorption spectra of nitrogen peroxide in the visible region and its estimation thereby. Nitrogen peroxide, as is well known, exhibits a very characteristic absorption spectrum, which consists of a large number of fine lines in the visible region and a general absorption in the violet. Robertson and Napper have utilised this absorption for the quantitative estimation of small quantities of nitrogen peroxide in air or carbon dioxide. The absorption spectrum was photographed in each case with a spectrograph having a single dense flint glass prism. A Welsbach incandescent mantle was used as a source of light, and the absorption vessel was a glass tube 40 cm. long with the ends closed by glass discs which were attached by cement. The estimation of the nitrogen peroxide in any gas is done by comparison of the photographs taken of the absorption exerted by the gas, with a series of photographs of the absorption spectra of carbon dioxide or air containing known definite amounts of nitrogen peroxide. It was found possible to estimate quantitatively an amount of nitrogen peroxide as low as 0·05 p.c. within 0·02 p.c. In the case of greater concentrations of nitrogen peroxide the accuracy is about 0·05 p.c.

Quantitative estimation of the nitrogen evolved in the decomposition of gun-cotton and nitroglycerin. The above described method for the estimation of nitrogen peroxide has been applied to the Will test of decomposing gun-cotton and nitroglycerin.

The most satisfactory results in the case of gun-cotton, and also of nitroglycerin, were obtained by heating the substance in a measured current of pure carbon dioxide, and passing the gases through an absorption spectrum vessel as described above, and afterwards through a tube containing copper heated to redness. The gases from this decomposition tube were passed into potassium hydroxide solution and the total nitrogen measured. In the case of gun-cotton 2½ grms. are heated in an oil-bath to 135°, and a stream of specially pure carbon dioxide is passed at the rate of 1 litre per hour (controlled by observing the number of bubbles per minute in a small glass washing bottle containing sulphuric acid) through the vessel containing the nitrocellulose. The current of carbon dioxide containing the gases resulting from the decomposition of the nitro-cellulose is passed through the absorption spectrum tube and the spectrum photographed at intervals of a quarter of an hour. The gases are then passed through a combustion tube containing two spirals of reduced copper gauze and layers of Kreusler's copper oxide asbestos and reduced copper asbestos. The oxides of nitrogen are thereby reduced to nitrogen and the organic gases oxidised to carbon dioxide. The gas is then passed through a measuring burette containing strong caustic potash, and the volume of nitrogen is read at intervals. A curve is constructed showing the amount of nitrogen peroxide and of nitrogen evolved each quarter of an hour, and the character and slope of the curve is a measure of the stability of the sample.

Since certain preliminary experiments proved that water vapour has no influence upon the absorption spectrum of nitrogen peroxide, whilst the presence of liquid water causes a rapid absorption of this gas, great care must be taken not to allow any water to condense in the apparatus. It was found that about 40 p.c. of the nitrogen evolved by the gun-cotton is in the form of nitrogen peroxide.

In the case of nitroglycerin, Jena glass wool soaked in 0·3–0·5 grm. of nitroglycerin is placed in a horse-shoe shaped tube; this is closed by a stopper, which is greased and mercury-sealed. To each end of the horse-shoe is connected a spiral tube s_1 and s_2 in Fig. 12. The current of carbon dioxide may be passed down the right-hand spiral through the glass wool and up the other spiral or *vice versâ*, according to the way the three-way cocks are turned. The whole apparatus can be rotated round the axis, and, when starting, the spiral s_1 is immersed in an oil-bath of known temperature, and so the carbon dioxide receives a previous heating before it reaches the nitroglycerin. Spiral s_2 is protected by an asbestos sheet from the heat of the oil-bath, and is cooled by an air blast. Any volatilised nitroglycerin is condensed in this spiral. After a reasonable time has elapsed the apparatus is rotated through 180°. The two spirals now exchange their functions, and any nitroglycerin in s_1 is restored to the system. The gases are then passed, as described above, first through the absorption spectrum tube and then through the heated tube of copper and copper oxide. In order to guard against any presence of nitroglycerin in the gases they are made to pass through a worm cooled with ice immediately on leaving the decomposition apparatus. As in the case of gun-cotton, described above, the current of carbon dioxide passes at a measured rate and the nitrogen peroxide is spectroscopically estimated by the method described for that substance.

The decomposition of nitroglycerin was studied between the temperatures of 90° and 135°, and it was found that this decomposition proceeds in as uniform a manner as that of a stable gun-cotton. Further, the whole of the nitrogen is evolved as nitrogen peroxide. Between 95° and 125° the rate of decomposition is a function of the temperature, and is doubled for every increase of 5°.

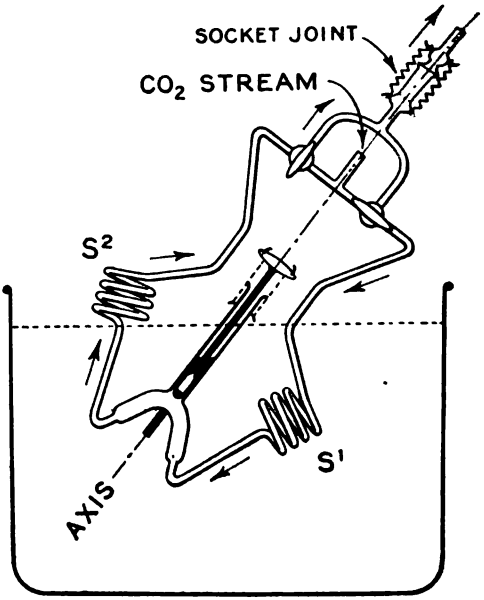

Fig. 12.

VIII. **Spectrophotometry.** In dealing with the quantitative analysis of substances which exhibit absorption two general methods may be employed. Firstly, the amount of an absorbing substance present in any given mixture may be determined by taking a photograph of the absorption exerted by the mixture, and comparing this with a series of standard photographs which have been taken of the absorption of the same substance at certain definite and known concentrations. That standard which exactly matches the absorption given by the unknown mixture will, of course, give the concentration of the absorbing substance in that mixture.

An example of this method has already been given above in connection with the estimation of nitrogen peroxide in the gases evolved on heating gun-cotton and nitroglycerin. It is manifest that exactly the same principle may be applied to substances in solution, provided that standard absorption records can be obtained of known concentrations of the same substance in the same solvent.

In the second method the amount of absorption exerted by the substance in a given mixture is determined quantitatively by means of a spectrophotometer, these observations being made at that region of the spectrum where the characteristic absorption by the substance occurs.

Before giving an account of the instruments and methods employed, a few words may be said about the laws of absorption and their application to quantitative analysis.

If light of intensity I enters an absorbent medium having a thickness equal to 1, the light which emerges will be reduced to $1/n$, and after passing through a second layer of equal thickness the intensity will be reduced to $1/n^2$. If the thickness of the layer be denoted by d, the intensity of the light will be reduced to $1/n^d$. From this it may be seen that as the thickness of the layer increases in arithmetical progression, the transmitted light will decrease in geometrical progression.

If, therefore, the intensity of the incident light be put equal to I and dI be the amount lost during its passage through a layer of thickness dx, we have $dI = -kIdx$.

If we integrate between the limits $x=0$, when the intensity of the incident light $= I_0$ and $x=d$, when the intensity is I, then it will follow that

$$I = I_0 e^{-kd} \quad . \quad . \quad . \quad . \quad (1)$$

where k is a constant depending on the absorbing medium and the wave-length of the light, and e is the base of natural logarithms.

Usually e^{-k} is denoted by the symbol a, and is known as the absorption coefficient, so that we may write

$$I = I_0 a^d \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and if $d=1$, we have $a = I/I_0$, so that a represents the fraction of the light which is transmitted by a layer of thickness I. This relation is known as Lambert's law. Bunsen and Roscoe expressed the absorption power of a given region of the spectrum in terms of the 'coefficient of extinction,' and defined this as the reciprocal of that thickness which causes the reduction in intensity of the light to $\frac{1}{10}$th of its original value. If this coefficient of extinction be expressed by α then, when in equation (2) $I/I_0 = \frac{1}{10}$, $d = \alpha$, therefore $a^{\alpha} = \frac{1}{10}$, whence $a = 10^{-\alpha}$.

Substituting this in the general equation (1) we have $I = I_0 10^{-\alpha d}$, and if I_0 be put equal to 1 then $-\log I = \alpha d$.

In actual practice it is simpler to use a layer of unit thickness ($d = 1$ cm.) when the coefficient of extinction can at once be obtained. For example, let us suppose that a beam of light is reduced to $\frac{2}{5}$ths of its intensity when transmitted through 1 cm. of an absorbing solution.

From this it follows that —

$$\alpha = -(\log \tfrac{2}{5}) = \log 5 - \log 2$$
$$\alpha = 0{\cdot}69897 - 0{\cdot}30103$$
$$\alpha = 0{\cdot}39794.$$

The determination of the extinction coefficient is therefore exceedingly simple.

In order to apply this to the quantitative estimation of absorbing substances we make use of the relation known as Vierordt's absorption ratio. According to Beer's law the absorption of a given solution is inversely proportional to the concentration, that is, if the absorption were observed of a given thickness of a solution of concentration c, the same absorption would be exhibited by half that thickness of a solution of concentration $2c$.

It follows, therefore, that in solutions of different strengths of the same substance the extinction coefficient is proportional to the concentration c.

If the concentrations of a series of solutions of the same substance be expressed by c, c_1, c_2, . . . and the corresponding coefficient of extinction by α, α_1, α_2, . . ., then it follows that $\frac{c}{\alpha} = \frac{c_1}{\alpha_1} = \frac{c_2}{\alpha_2} = A$. From this we have generally $c = \alpha A$, when A is called the absorption ratio. A may be determined once for all for any substance in the given solvent, and the concentration of a solution of the same substance in that solvent may at once be determined by finding the extinction coefficient and substituting it in the formula $c = \alpha A$.

It must be remembered, of course, that the above relation is only true for any one wave-length.

It is evident also that the above relation only holds good when a single absorbing substance is examined in a non-absorbing solvent, and that if two absorbing substances are present, such as occur when the solvent exerts absorption, or when two absorbing substances are dissolved in a diactinic solvent, the observations become a little more complicated. It is necessary in such a case to determine the extinction coefficient for light of two different wave-lengths. If, for example, we have a solution of two coloured substances of unknown concentration, x and y respectively, it is necessary to determine the extinction coefficient for two different parts of the spectrum. Let these be α and α_1 respectively. Then if A and A_1 and B and B_1 be the absorption ratios for the two substances at the two different wave-lengths, it follows that $\alpha = \frac{x}{A} + \frac{y}{B}$ and $\alpha_1 = \frac{x}{A_1} + \frac{y}{B_1}$.

Solving these two simultaneous equations we get $x = \frac{AA_1(\alpha B - \alpha_1 B_1)}{A_1 B - AB_1}$ and $y = \frac{BB_1(\alpha A - \alpha_1 A_1)}{AB_1 - A_1 B}$ from which, of course, the concentrations of the two substances may at once be calculated.

The measurements of the amount of light absorbed by or transmitted through substances such as are required for the determination of the extinction coefficient are made with a spectro-photometer, which is an instrument by means of which the relative intensities of two different beams of light may be compared at any required wave-length in the visible spectrum.

The Vierordt instrument consists in the main of an ordinary spectrometer, the slit of which is divided into two, an upper and lower portion, which are provided with separate micrometer screws for adjusting the width. If both halves of the slit are set at equal width, and are illuminated with a beam of white light, and in front of one half is placed the absorbing material, there will be seen in the eye-piece two spectra, one above the other, one of which is less intense owing to the absorption which has taken place. The difference in intensity between the two spectra at any given wave-length may be determined at once by decreasing the width of the half of the slit corresponding to the brighter spectrum until the two appear equal in the field of view of the telescope. If the original widths of the slit were, say 100, and the one half had to be reduced to 75 in order to establish equality, then clearly the relative intensities were as 4 : 3.

In order to guard against the eye being confused by the intensities of the spectral regions on either side of the region dealt with, the eye-piece is provided with adjustable screens in order to shut off all the rays except those actually to be compared.

There are, however, several points of importance which must be attended to in order to make accurate measurements, and these necessitate the apparatus being more complex than the above simple description would foreshadow. In the first place, the original idea of Vierordt depends upon the assumption that the intensity of illumination is directly proportional to the width of the slit. This cannot be true with a slit of the ordinary type in which only one jaw is movable, so that the slit widens unsymmetrically. This difficulty was surmounted by Krüss who substituted for the Vierordt double slit one in which both jaws of each slit are equally moved in opposite directions by the micrometer screws. Each slit of the instrument is, therefore, opened or closed symmetrically. Again, the intensity of illumination is only proportional to the slit-width when the latter is small. If, therefore, the difference in intensity between the two spectra is very large, it is not possible to measure this only by altering the slit-widths. The intensity of the brighter spectrum is first reduced by introducing a plate of neutral tinted glass, and the final adjustment made by altering the width of the slit. Several of these plates of tinted glass should be on hand, the absorption of which for the various spectral regions has been carefully determined.

In the second place it must be remembered that the loss of light suffered when a beam of light passes through an absorbing layer is not only that due to the absorption of the medium, but that a very appreciable amount is lost by reflection at the boundary surfaces. For example, if an absorption cell half full of the absorbing solution were placed in front of the slits of the Vierordt instrument so that the lower slit was illuminated by the light after passage through the absorbing layer while the upper slit received the light which passed through the upper and empty half of the cell, then the differences observed between the two spectra would not be that due to the absorption alone. The loss by reflection of the light would not be the same in the two cases, for, on the one hand, the reflection would be at a glass-solution surface, and in the other case it would be at a glass-air surface. As the indices of refraction for air and the solution are different the amount of loss by reflection would also differ. This difficulty may be removed by means of what is known as the Schultz corrector. This is a block of glass of the same quality as that of the walls of the cell and is shown at A in Fig. 13.

The internal thickness of the cell is made 11 mm., and that of the Schultz corrector 10 mm., and the depth of the latter is half that of the cell. The cell is filled with the absorbing solution and is set up in front of the slits of the instrument so that one slit receives the beam after passage through 1 mm. thickness of solution, and the other slit receives the beam after passage through 11 mm. If the cell and corrector are made of the whitest flint glass no appreciable absorption is introduced by the latter except in the extreme violet, whilst the difference in loss by reflection is reduced to a minimum.

The third point, and the most difficult of realisation, is the necessity that the two spectra should be in optical contact in the field of view. The eye is exceedingly sensitive to differences in intensity between two spectral images, provided that there is no sharply defined line of separation between them. It may be readily understood that however carefully the above cell be adjusted in front of the Vierordt slits, it will practically be impossible to obtain the two spectra in contact without a dividing line. In order to bring the two spectra into contact H. and G. Krüss applied the so-called Hüfner rhomb to the Vierordt instrument, the arrangement being shown in Fig. 14.

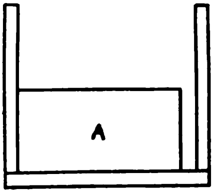

FIG. 13.

The two beams coming from the absorbing cell with the Schultz corrector enter the rhomb. and emerging thence they enter the slit and give two spectra in contact.

In the Vierordt instrument the intensity of the spectra is altered by varying the width of the slit, the assumption being made that the intensity is proportional to the slit-width, provided that this latter is kept small. Many forms of spectrophotometer have been devised from time to time, and a different method of altering the intensity adopted. In the Glan type the two beams are polarised at right angles to one another by suitable means, and they finally pass through a Nicol prism. A rotation of this will, therefore, decrease the intensity of one and increase the intensity of the other, and the relative intensities of the two may be calculated from the angle θ through which the Nicol is rotated, for $\frac{I}{I_0} = \tan^2 \theta$. In the Hüfner instrument only one beam is polarised, and the change in intensity is altered by the rotation of a Nicol prism as in the Glan instrument. In the older forms of the Hüfner instrument the brighter beam, that is to say, that light which has passed through the thinner layer of absorbing solution was polarised by reflection from two plane mirrors set at the polarising angle outside the slit. In

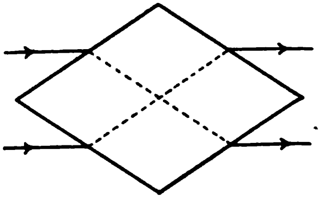

FIG. 14.

the modern form the beam of light after transmission through the thinner absorbing layer is passed through a Nicol prism, and then the two beams are brought into optical contact by a special rhomb similar to that shown in Fig. 14, for the Vierordt instrument. The intensity is changed by a second Nicol, the angular rotation of which can be measured, and, if again θ be the angle of rotation necessary to bring about equality of the two spectra in the field of view, $\frac{I}{I_0} = \cos^2 \theta$.

The Hüfner spectrophotometer has recently been much improved by Twyman, who has succeeded in reducing the experimental errors to a very small value indeed. Twyman points out that the principal source of error lies in the fact that the rays of light in passing through the dispersing prism system are partially polarised. For this reason the beam which does not pass through the Nicol prism outside the slit will become partially polarised, and, therefore, will lose in intensity when the second or analysing Nicol is rotated. As a matter of fact this error is corrected to a certain extent by the use of the Hüfner rhomb owing to the fact that the principal planes of this rhomb and the dispersing prism are at right angles to one another. Twyman shows that by the use of a rhomb made of the same glass as the prism, and so cut that the angle of incidence on the face of the rhomb is the same as that on the prism face, the error is entirely eliminated, for the polarisation caused by the two, rhomb and dispersing prism, are then exactly equal and in planes at right angles, and thus the two exactly counterbalance one another.

Further, the instrument is made with a constant deviation prism so that the telescope and collimator are fixed and the spectrum caused to pass across the field of view by the rotation of the prism, the principle being the same as that of the spectrometer shown in Fig. 4. The accuracy obtained with this improved form of spectrophotometer is exceedingly great and far superior to that obtained with the ordinary form of instrument. In actual practice the instrument is adjusted as follows. The best source of illumination is a Nernst filament lamp, and the rays from this are directed into the instrument, and the analysing Nicol prism is set at the zero reading. Owing to the necessary loss of light caused in the one beam by the polarising Nicol the two beams will naturally appear of different intensities. In order to correct this error a wedge of neutral tinted glass is mounted outside the slit in the path of the brighter beam. This wedge is slowly moved until the two spectra appear exactly equal in intensity in the field of view. The instrument is then in adjustment, and in determining the extinction coefficient of a given solution, the solution is put in an absorption cell with a Schultz corrector, and this is properly mounted in front of the polarising Nicol and slit. When the analysing Nicol has been rotated so as to bring the two spectra again to equality, and as stated above, the angle of rotation is θ, the ratio of the intensities of the two beams I/I_0 will be given by $\cos^2 \theta$.

In addition to the above-mentioned types of spectrophotometer, which are particularly adapted to the quantitative measurement of absorption since only one source of light is used, there have been several instruments devised more suited to the spectrophotometric comparison of two different light sources. These are more suited to spectropyrometry or the measurement of temperature by comparison of the emission spectrum of the body, the temperature of which has to be measured with that of some standard source. One of the most convenient of these instruments has been devised by Brace, and a diagrammatic arrangement is shown in Fig. 15. A and B are two exactly similar right-angled prisms which are cemented together. Before they are cemented, however, that surface of B which is to be cemented to A is heavily silvered, and this coating is carefully removed so as to leave a narrow horizontal strip across the centre of the prism face. The two prisms are then cemented together. One source is placed at C and the other at D, the rays from each passing through a slit and collimating lens. The rays from C are refracted at the first surface of A as shown, and pass through the junction of the two prisms above and below the silver strip. The rays from D enter the prism B and are reflected from the silver strip. Both beams undergo exactly the same amount of deviation, with the result that when brought to a focus a strip of spectrum from D will be seen between two strips of spectrum from C. When these are brought to equality the boundary lines between them disappear. The necessary variations in intensity may be brought about either by altering the slit-width, as in Vierordt's instrument, or by the use of a rotating sector with openings of known size placed in front of the light source.

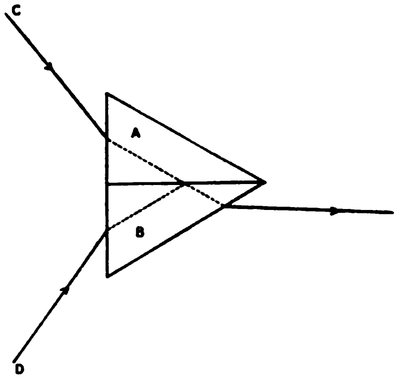

FIG. 15.

It is hardly necessary to point out that spectrophotometric measurements with ordinary instruments are limited to the visible region, and therefore only those substances the absorption bands of which lie in the visible region can be dealt with. Although H. A. Krüss has described a method by means of which two intensities in the ultra-violet can be photometrically compared by the use of a fluorescent screen, yet this seems to be incapable of extensive use, seeing that the brightness of the fluorescence is generally so small.

It would seem that the only method of

comparison is by photography. This comparison by photography must of necessity be very tedious, because it involves taking a series of photographs of the two spectra, the intensity of the standard spectrum being reduced by a known amount in each case. From a comparison of the resulting negatives the particular intensity of the standard required can be found.

The possible applications of spectrophotometry to the estimation of substances with absorption bands in the visible region, as may readily be understood, are very numerous. In the bibliography dealing with this section will be found references to many of these applications, for they are too numerous to describe in detail.

IX. **Qualitative and quantitative estimation of blood.** Blood contains the highly complex iron-containing crystalline colouring matter called hæmoglobin. This hæmoglobin has the power of readily linking itself to an atom of oxygen, which is in such a labile state that it can readily be given up and oxidise the waste products of the tissues of the body. While living blood generally contains both the oxygenated and the deoxygenated hæmoglobin, the former is essentially a constituent of arterial, and the latter of venous, blood. This labile oxygen may, therefore, be considered as the respiratory oxygen of the animal system. Hoppe-Seyler has shown that hæmoglobin is decomposed by acids, and by alkalis in the absence of air into hæmochromogen (sometimes called reduced hæmatin), and finally into hæmatin. This process is apparently a hydrolysis, whereby an albumen, globin, is split off. If in this process hydrochloric acid be used, an intermediary product known as hæmin is formed, which is the hydrochloride of hæmatin (see BLOOD). Again, if hæmatin is heated with concentrated nitric acid or is dissolved in concentrated sulphuric acid, it dissolves, giving a solution of hæmatoporphyrin. This substance contains no iron, the iron atom having been withdrawn as a ferrous salt from the hæmatin. According to Nencki and Sieber the following equation expresses the preparation of hæmatoporphyrin from hæmatin—

$$C_{32}H_{30}N_4FeO_3+3H_2O=C_{32}H_{34}N_4O_6+Fe.$$

Two reactions of hæmoglobin are of considerable importance, namely its oxidation and its reaction with carbon monoxide. When oxidised by a mild oxidising agent such as nitrites or potassium ferricyanide it is converted into a brown substance, methæmoglobin, the same substance being produced when hæmoglobin is exposed to air, as may be seen on the edges of wounds and on blood stains on cloth, &c.

The second reaction of hæmoglobin is the power which it possesses of absorbing carbon monoxide, a new compound being produced called carbon monoxide hæmoglobin. This is of great importance in dealing with cases of carbon monoxide poisoning.

The various derivatives of hæmoglobin may be prepared as follows: The blood is first defibrinated and diluted with 1 p.c. of caustic soda, when it is found to show the spectrum of oxyhæmoglobin. To reduce this back to hæmoglobin we may use freshly-prepared ammonium hydrogen sulphide, or better still, hydrazine hydrate, since in this case only nitrogen and water are formed

$$NH_2{\cdot}NH_2+O_2=N_2+2H_2O.$$

The addition of a few drops of concentrated potassium ferricyanide solution to diluted blood shows at once the spectrum of methæmoglobin.

If a drop of blood be warmed on a slide with one or two drops of glacial acetic acid and the mixture boiled over a small flame and then allowed to evaporate, the residue, when examined under the microscope, will show reddish-brown crystals of hæmin, known as Teichmann's crystals. Even an old blood stain gives the same, but better results are obtained in such a case if a small crystal of sodium chloride is added.

To prepare hæmin on a large scale, 1 volume of defibrinated and strained blood is added to 4 volumes of glacial acetic acid previously heated to 80°. As soon as the temperature has fallen to 55°–60°, the blood is again heated to 80°, and on cooling the crystals of hæmin separate out with characteristic silky lustre and dark-blue colour. These are allowed to settle for 12 hours, then decanted and washed with water, after which they are filtered off and washed with alcohol until the runnings are no longer coloured.

If the crystals are dissolved in very dilute caustic potash and then heated with dilute hydrochloric acid hæmatin is precipitated. This is then washed with water until free from chlorine.

Both hæmatin and hæmin dissolve in cold concentrated sulphuric acid to give hæmatoporphyrin, which is precipitated on the addition of water. The absorption spectra of the different colouring matters are as follows:—

Oxyhæmoglobin shows two absorption bands in dilute solution which coalesce into one band when the solution is more concentrated.

Formánek	5880–5650A	5550–5260A
Naumann	5890–5680A	5570–5270A (maximum at 5500)

In stronger solution one band at 5940–5180A.

Hæmoglobin. This only shows one band as a rule, though in very dilute solution a weaker band has been described as appearing on the red side.

Preyer (1871)	. 5980–5400A (maximum at 5520)
Gamgee (1880)	5950–5380A (maximum at 5500)
Formánek	. 5930–5700A and 5700–5400A.

Carbon monoxide hæmoglobin. Formánek describes two bands, 5810–5610A and 5500–5230A.

Methæmoglobin. The neutral or faintly acid solution is chocolate-brown, whilst when made alkaline with ammonia it turns red. The former shows a well-marked band in the red, and two others which are very weak and may not be seen. The latter gives a principal band nearer to the blue and two faint bands. The fainter bands in both cases seem to agree with those of oxyhæmoglobin.

Neutral or faintly acid bands, Formánek, 6400–6250A, 5780–5680A, and 5540–5300A.

Alkaline, Ziemke and Müller, 6050–5890A, 5890–5790A, and 5580–5350A.

Hæmatin. Alkaline solutions are red and acid solutions brown—

Alkaline solution (Naumann) . 6240–5750A.

Acid solution shows a principal band in the red and a weaker one—

Naumann . .6600–6300A and 5890–5270A.

Hæmatoporphyrin. Acid alcoholic solutions are purple to bluish-violet. Alkaline solutions are red to red with a violet tinge—

Acid, 2 bands (Naumann), 6060–5910A and 5890–5440A.

Alkaline, 4 bands (Formánek), 6330–6160A, 5890–5660A, 5200–5350A, and 5200–4980A.

For the quantitative estimation of blood the following values of the absorption ratios of oxyhæmoglobin, hæmoglobin, and carbonic oxide hæmoglobin may be given for the spectral regions specified (Hüfner).

Substance	Limits of spectral region	Absorption ratio
Oxyhæmoglobin . .	5650–5540A	0·002070
„ . .	5425–5315A	0·001312
Hæmoglobin . . .	5560–5540A	0·001354
„ . . .	5425–5315A	0·001778
Carbonic oxide hæmoglobin	5650–5540A	0·001383
„ „ „ .	5425–5315A	0·001263

In the detection of blood stains, such as may occur in medico-legal cases, the stain is either washed out with water or digested with warm 10 p.c. sodium carbonate solution. The spectrum is noted and then the solution is treated with a reducing agent, for example ammonium hydrogen sulphide or hydrazine hydrate, as described above, when the spectrum of hæmoglobin is formed. This is an exceedingly delicate test; shaking with air restores the original spectrum, but a fresh addition of the reducing agent reproduces hæmoglobin.

Again the hæmin and hæmotoporphyrin test described above can be employed. In the detection of carbon monoxide poisoning the blood shows the spectrum of carbonic oxide hæmoglobin. This is somewhat similar to the oxyhæmoglobin spectrum, but it is quite unaltered by ammonium hydrogen sulphide, and in this manner may be sharply differentiated.

X. **Optical Pyrometry.** An important application of the spectroscope lies in the measurement of the intensity of the radiation from an incandescent source by direct comparison with that of a standard, for by this means the temperature of the former may be arrived at. Generally this comparison is carried out for red light, because, in the first place, the colour of the light emitted by a body varies very considerably with the temperature, and in the second place it allows the measurements to be made at lower temperatures. It must be remembered that the intensity of the radiation emitted by an incandescent substance is not only a function of the temperature, but also that it depends upon the surface and composition of the substance. In dealing with the radiation from any substance it is necessary, therefore, to set up a standard in terms of which all radiation laws can be expressed. This was first done by Kirchhoff, who defined the absolutely 'black body' as that which would absorb every radiation without reflection or transmission. He pointed out that the radiation of the 'black body' is purely a function of the temperature. Although no substance is known the surface radiation of which is exactly equal to that of the 'black body,' yet it is possible almost to realise the condition by maintaining a vessel at a constant temperature, and observing the radiation from the inside through a small hole in one of the walls. For high temperatures a porcelain tube may be electrically heated to a known temperature (determined by a thermocouple) and the radiation from the central portion examined. Such an apparatus is used in the calibration of optical pyrometers. It follows that in the optical measurement of temperatures the instrument will always give the 'black body' temperature corresponding to the intensity radiation dealt with. This temperature will, of course, only be the true temperature of the incandescent body when the latter is behaving as a 'black body.' Such a condition may frequently be realised, as, for example, in the determination of the temperature of a furnace by the examination of the radiation from the inside of a porcelain or metal tube projecting into the furnace. If, however, the 'black body' conditions are not obtained the optical pyrometer will usually give a temperature lower than the true value. In technical processes this error may not be of great importance, as, for example, when it is only necessary to reproduce certain given conditions with accuracy at any moment.

Before dealing with the methods of working with the various forms of optical pyrometers it is necessary to speak of the laws of radiation. The Stefan-Boltzmann law states that the total radiation emitted by the 'black body' is directly proportional to the fourth power of the absolute temperature, and may be expressed as follows:—

$$I = k(T^4 - T_0^4),$$

where I is the total radiation from the black body at the absolute temperature T to the body at the absolute temperature T_0, and k is a constant. It is well known that as the temperature of a body changes the wave-length of the maximum of the radiation varies, and Wien concluded that, if λ_m be the wave-length of the maximum energy, $\lambda_m T = $ a constant. Combining this with the Stefan-Boltzmann law, Wien obtained the relation $I_{max} T^{-5} = $ constant, where I_{max} is the energy corresponding to the wave-length λ_m and T is the absolute temperature of the 'black body.'

Even although these relations were deduced for the 'black body' they hold good for other radiating surfaces, but, of course, the values of the constants are different. Wien's second equation is then modified to $I_{max} T^{-a} = $ constant.

Some further investigations of Wien led him to the following equation:—

$$I = b\lambda^{-5} e^{-\frac{c}{\lambda T}},$$

where I is the energy corresponding to the wave-length λ, e is the base of natural logarithms, T is the absolute temperature, and b and c are constants. Although it has been found that this expression does not hold good over long ranges of wave-lengths, yet it is sufficiently accurate for the ranges dealt with in optical pyrometry, and may be used for the calibration of these instruments. In practice the method of work with the optical pyrometer is as follows: Some standard of illumination is chosen, and the intensity of the red light of chosen wave-length emitted by the incandescent body is varied by some means until it becomes equal to that of the standard. For the calibration of this type of pyrometer Wien's third equation may be used—

$$I=b\lambda^{-5}e^{-\frac{c}{\lambda T}}.$$

This may be written—

$$\log I=\log b-5\log\lambda-\frac{c}{\lambda T}\log e$$

or

$$\log I=C+\frac{K}{T}$$

where $C=\log b-5\log\lambda$, and $K=-\frac{c}{\lambda}\log e$.

Evidently, since we are dealing with the radiation of only one wave-length, there is a linear relation between log I and 1/T. The instrument may be calibrated, therefore, from measurements of I at two known temperatures. A similar relation will hold good if the radiation be not that of the 'black body,' but the constants C and K will then be different.

In the Le Chatelier pyrometer the radiation from the incandescent source passes through an iris diaphragm, and is brought to a focus by a lens and examined through a screen of red glass with a Ramsden eye-piece. The rays from the standard of comparison pass down a tube at right angles to the first tube, and are reflected from a plane mirror into the eye-piece. The equality between the two radiations is produced by altering the aperture of the iris diaphragm. If the radiation from the incandescent body is too great one or more plates of tinted glass are introduced, the coefficients of absorption of which are known, and the final adjustment done by the iris diaphragm. The effective aperture of this diaphragm can be obtained from the scale reading.

In the Wanner pyrometer the principle is the polarisation of both rays, as in the case of the Glan spectrophotometer described above. The radiations from the two sources are focussed on to two adjacent slits, and then after being rendered parallel by a collimating lens they pass through a direct vision prism system. They then pass through a Rochon prism which resolves each beam into two portions polarised at right angles to each other. By means of a biprism and lens two red images oppositely polarised, one from each source, are focussed contiguous to each other on a third slit. The two beams then pass through a Nicol prism into the eye-piece. If the two intensities be equal, and the Nicol set at 45° with the plane of polarisation of each, both will appear of equal brightness. If, however, the two intensities be not equal, they may be equalised in the field of view of the eye-piece by rotating the Nicol. If the necessary angle of rotation of the Nicol is θ, the ratio between the intensities will be given by—

$$\frac{I_1}{I_2}=\tan^2\theta.$$

For the standard source of light in these instruments a Hefner standard amyl acetate lamp, a gasoline lamp, or an electric filament lamp fed with constant current may be used.

In the Féry instrument the total radiation from the incandescent object is measured. The rays are focussed upon a sensitive thermocouple, and the energy of radiation determined from the readings of a galvanometer connected with the thermocouple. In the calibration of this instrument the Stefan-Boltzmann law is employed. *V.* PYROMETRY.

XI. Absorption spectra and chemical constitution. In dealing with the absorption of radiant energy exerted by chemical substances it may be pointed out that the observations which have been made extend over a very long range. Whereas, perhaps, the most familiar results are those which have been obtained in the visible region, the observations have been pushed to the extreme limit of $\lambda=1200$A in the ultra-violet on the one hand, and on the other to a great distance in the infra-red ($\lambda=15000$A). Now, whatever may be the view taken of the origin of absorption bands, there is little doubt that selective absorption in the infra-red is due to a different cause from that of the absorption in the visible and ultra-violet regions. This may at once be understood from the fact that characteristic absorption bands in the infra-red may be traced to definite atomic groupings, while such is by no means the case as regards the ultra-violet absorption bands. It has been found that the OH group and the SO_4 group, for example, always exhibit characteristic absorption bands in the infra-red. Since the extreme infra-red region is beyond the limits of vision and of photographic sensibility it is necessary to employ a bolometer, radiometer, thermopile, or radiomicrometer, and to measure the intensities of the radiant energy at any given point of this heat spectrum by its means. although it may be remembered that, as has been said above, it has been found possible to obtain photographic records far beyond the limit of visibility.

A great number of observations have been made upon infra-red absorption by Abney and Festing, Spring, Puccianti, and others, but it can hardly be said that many conclusions can be drawn from the work of these investigators as regards the relation between absorption and constitution. Coblentz, however, has published some important results on infra-red absorption in relation to constitution. It was found by him that the following atomic groups exhibit characteristic absorption bands at the positions specified.

Compounds having the following groups	Show characteristic absorption bands at
CH_2 or CH_3 .	3·43, 6·86, 13·6, 13·8, and 14μ
NH_2 . .	2·96, 6·1–6·15μ
C_6H_6 . .	3·25, 6·75, 8·68, 9·8, 11·8, 12·95μ
NO_2 . .	7·47, 9·08 (?)μ
OH . .	3·0μ
NCS . .	4·78μ
SO_4 . .	4·55, 8·7, 9·1μ

where $\mu=0{\cdot}001$ mm.$=1000$ A.

A large portion of Coblentz's observations dealt with minerals and other compounds containing hydrogen and oxygen, and it was always found possible at once to determine whether the hydrogen and oxygen exist as water of crystallisation. Water exhibits absorption bands at 1·5, 3, 4·75, and 6μ, and these bands are always shown when the compound contains water of crystallisation. The band at 3μ is due to the OH group in the water, and if the compound only contains the OH group, and not water of crystallisation, this band only is observed. A single exception was noted, namely cane sugar, which shows distinct evidences of the water bands, and so the absorption would indicate that in this substance some of the hydrogen and oxygen exist as water and not entirely as hydroxyl or water of constitution. It is interesting that this substance is the only exception amongst a great number that were examined.

The chemical evidence against this conclusion is, of course, overwhelmingly strong, but at the same time the argument based on the presence of the absorption bands of water cannot be lightly laid on one side. Coblentz, in addition to cane sugar, has investigated the absorption of *d*-fructose, *d*-glucose, maltose, lactose, raffinose, and gum-arabic. Of these latter *d*-fructose is the only one which does not possess water of crystallisation, and, indeed, is the only one which shows no trace of the water bands. This disposes of the possible contention that the number of hydroxyl groups in the carbohydrate molecule might conceivably give rise to bands similar to those of water.

The results of the observation of the absorption of talc and serpentine were very interesting, and confirm the chemical conclusions, for talc shows no evidence of the hydroxyl band at 3μ, whilst serpentine shows a large band at this point. Coblentz concludes from his examination of a number of silicates that, as no characteristic band is traceable to them, the union of the silicate radicle is different in each mineral containing it.

The results obtained by Coblentz show very conclusively that the absorption bands in the infra-red are due to specific atomic groupings. In the case of absorption in the visible and ultra-violet regions it is equally manifest that the absorption bands cannot be attributed to groups of atoms as such, because the position and character of the bands are profoundly modified by a single substitution process. For example, benzene in alcoholic solution gives eight absorption bands in the ultra-violet, while nitrobenzene in the same solvent gives only the merest trace of a single broad band. On the other hand, phenol and aniline give very well-marked and broad absorption bands just beyond the visible region. No characteristic absorption, for example, therefore, can be attributed to the C_6H_5 group, seeing that the last three bodies differ so much in their absorption spectra.

It appears that selective absorption in the ultra-violet is due in the main to the presence of unsaturation in the molecule. For example, it has been found that a saturated hydrocarbon does not show any selective absorption. The paraffin hydrocarbons only exhibit general absorption, which extends further and further towards the red with increase of molecular weight. This is also true for the fatty acids and their esters, and for the alcohols derived from the paraffin series, although there is a slight increase in the general absorption in each case compared with the corresponding hydrocarbon.

The introduction of unsaturated groups tends to increase the amount of general absorption, and in some cases to cause the appearance of selective absorption in the ultra-violet region. Thus, for example, the ketone group in acetone and its homologues and in compounds of the type of acetylacetone and ethyl acetoacetate causes the appearance of well-marked absorption bands.

The same is true as regards the saturated hydrocarbons of the aromatic series, for *cyclo*-hexane does not show any more than slight general absorption. Similarly benzene hexachloride ($C_6H_6Cl_6$) only shows general absorption. On the other hand, benzene itself shows strong selective absorption with as many as eight absorption bands. Again naphthalene, phenanthrene, and other condensed ring hydrocarbons also show complicated banded absorption. The absorption of all these compounds tends to diminish and the bands to disappear as the compounds are reduced and become more saturated.

The substitution of one of the hydrogen atoms of the benzene ring by a halogen atom or group of atoms very profoundly modifies the absorption, and the type of spectrum now shown depends upon the nature of the substituent atom or atoms. Thus chlorobenzene shows seven bands which are in quite different positions from those of benzene. The substitution by methyl or any saturated radicle produces a spectrum showing one of the benzene bands, while the others are amalgamated into one broad band. The hydroxyl, amino, and other ortho-directing groups produce one broad and persistent band which is nearer the red than the bands of benzene itself. The nitro group, on the other hand, almost entirely obliterates the selective absorption of benzene and shows strong general absorption with only a very shallow band.

There seems to be no hard-and-fast rule as regards the type of absorption induced by the substituent group, for benzaldehyde shows a small band nearer the red than the one in nitrobenzene; and, further, benzene sulphonic acid shows several well-marked absorption bands.

The aromatic nitrogen bases, such as pyridine, quinoline, &c., all show well-marked absorption bands.

When the benzene ring is associated with groups possessing strong residual affinity such as, for example, is the case in azobenzene or in cinnamylideneacetone

$$C_6H_5\cdot CH:CH\cdot CH:CH\cdot CO\cdot CH_3$$

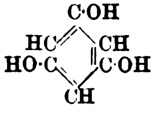
the position of the absorption bands, compared with those of benzene, is shifted towards the red, so that they may lie in the visible region, with the result that the compound appears visibly coloured. Visible colour may, therefore, be said to arise from the association together of unsaturated groups in the molecule. The benzene ring possesses a type of residual affinity that is peculiarly suited to this purpose, and so the aromatic compounds are more frequently coloured than the aliphatic compounds.

It does not seem to be absolutely necessary that the associated centres of unsaturation be present within the same molecule, for it is possible in certain cases to obtain the shift of the absorption bands into the visible region by the intimate mixture of suitable compounds, such mixtures frequently developing striking colours. Such intimate mixtures are produced by dissolving one substance in the other, when, as may be understood, the residual affinities may mutually influence one another in very much the same way as if they were present within the same molecule. It is manifest from this that the influence of the solvent is of extreme importance in absorption spectra observations, and it is a frequent occurrence to find that the absorption spectrum of a substance in one solvent is very materially different from what it is in the case of another solvent. Although great care must be taken, therefore, to guard against errors arising from the influence, yet it may at once be said that absorption spectra observations are capable of throwing great light upon the problem of chemical constitution, and there are now many cases known in which the constitution has been settled when the chemical evidence has failed. Further than this, it may be said that since the presence of absorption bands must be traced to the play of forces between the centres of residual affinity within the molecule, so there must be expected an intimate relation between absorption and chemical reactivity. This intimate connection has been proved in many cases, and it is not too much to hope that absorption spectra will serve to advance very materially the study of chemical reactions.

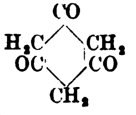
It has already been emphasised how important an influence the solvent may have upon the absorption spectrum given by a compound in solution, arising from the fact that the residual affinities of the two may form a combined system such as occur when such residual affinities are present within the same molecule. It follows at once that the conclusions drawn as regards the constitutions of compounds from the similarity of their absorption with that of their derivatives of known constitution can only be looked upon strictly as being definite for the compounds when in solution in the chosen solvent. This, however, for two reasons, need not cause apprehension, for, provided that the solvent used be one of no very decidedly marked residual affinity, there is no reason to expect that any error will be involved by the assumption that the constitution is the same for the pure substance itself. Alcohol is a very safe solvent to use, because, with perhaps the exception of hexane and heptane, it has the least effect upon the systems of residual affinities present in the molecules of the compounds dissolved in it. In all the cases given below alcohol was used unless another solvent is specifically mentioned.

Many cases are known in which it has been found possible to elucidate the chemical constitution of substances by comparing their absorption with that of an analogous compound of perfectly known constitution, and the following examples may be given :—

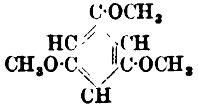
Phloroglucinol may be expressed by either of the two following formulæ—



or



as far as the chemical evidence is concerned. Now, the constitution of the trimethyl ether of phloroglucinol is known to be—



The absorption curves of phloroglucinol itself and the trimethyl ether are shown in Fig. 16, and it may be seen that they are almost exactly similar, and therefore there is no doubt that the two substances are of similar constitution. or, in other words, phloroglucinol must exist in the trihydroxy form.

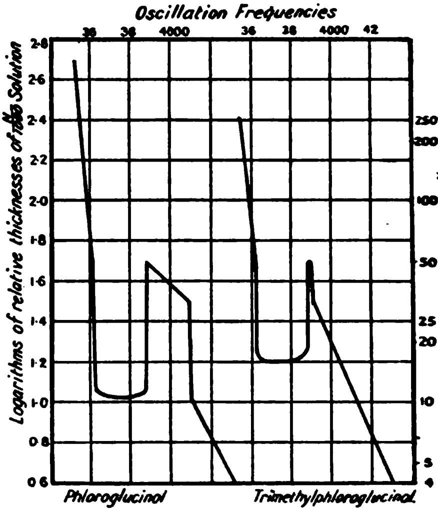


FIG. 16.

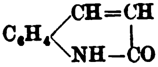
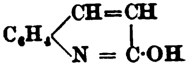
A second case is the proof of the constitution of carbostyril. Chemical evidence alone is not capable of differentiating between the two formulæ—



$$C_6H_4\left\langle\begin{matrix} CH=CH \\ | \\ NH-CO \end{matrix}\right.$$

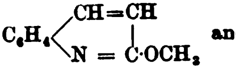
and



$$C_6H_4\left\langle\begin{matrix} CH=CH \\ | \\ N = C{\cdot}OH \end{matrix}\right.$$

The methyl ethers corresponding to the above possible formulæ are both known, namely,

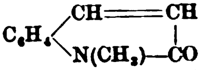
methylcarbostyril



$$C_6H_4\left\langle\begin{matrix} CH=CH \\ | \\ N = C{\cdot}OCH_3 \end{matrix}\right.$$

and

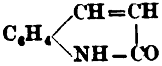
methyl*pseudo*carbostyril



$$C_6H_4\left\langle\begin{matrix} CH=\!=\!=CH \\ | \\ N(CH_3)-CO \end{matrix}\right.$$

The former of these is obtained by the action of methyl iodide and sodium hydroxide upon carbostyril in methyl alcohol solution, whilst the latter is prepared by the action of methyl iodide upon the silver salt of carbostyril.

The absorption spectra of the two ethers are shown in Fig. 17, and the absorption curve of carbostyril is practically identical with that of methyl*pseudo*carbostyril. It therefore follows that the constitution of carbostyril is to be represented by the formula



$$C_6H_4\left\langle\begin{matrix} CH=CH \\ | \\ NH-CO \end{matrix}\right.$$

Although it might be urged that both forms may be present in dynamic equilibrium, still, even if this were true, the amount of the ketonic form must be far in excess of the enolic form.

In exactly the same way the constitution of *o*-oxycarbanil was proved to be

$$C_6H_4\left\langle\begin{matrix} NH \\ O \end{matrix}\right\rangle CO$$

for the absorption curves show that its constitution is the same as that of the lactam ether.

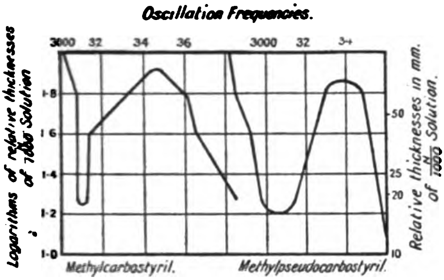


FIG. 17.

The constitution of the lactam and lactim ethers is known to be

$$C_6H_4<\overset{N(C_2H_5)}{\underset{O}{}}>CO \text{ and } C_6H_4<\overset{N}{\underset{O}{}}>C\cdot OC_2H_5$$

respectively.

The absorption curves of the two ethers is shown in Fig. 18.

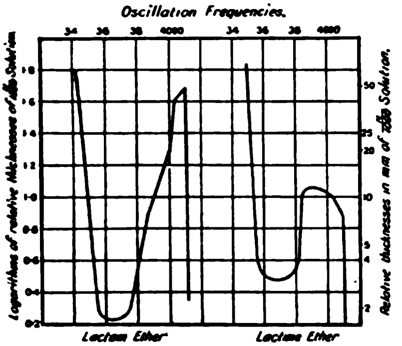

FIG. 18.

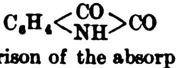
In a perfectly similar way isatin was proved to have the constitution represented by the formula—



$$C_6H_4<\overset{CO}{\underset{NH}{}}>CO$$

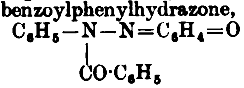
By a comparison of the absorption spectrum of cyanuric acid with those of the two possible methyl ethers, namely, methyl cyanurate and methyl *iso*cyanurate, it has been shown that cyanuric acid has a constitution analogous to the former substance. It may be pointed out, however, that none of these substances exhibit an absorption band, a fact which is not in harmony with a formula so analogous to that of pyridine and still more closely allied to that of dimethylpyrazine. It is, therefore, doubtful whether the constitution of cyanuric acid is rightly understood.

It may be seen at once that the above conclusions are based on the fact that no change in the absorption spectrum is produced when a methyl or ethyl group is substituted for a hydrogen atom. Although this has been shown to be true by Hartley in several cases which he examined, it is not true in every case. Exceptions are known, particularly in those cases where the hydrogen atom is labile or where the hydrogen atom is directly attached to the benzene ring. Basing his conclusions on somewhat similar evidence, Tuck has investigated the absorption spectra of the hydroxyazo compounds, and has been able to determine the constitution of these substances. In his first paper he dealt with benzeneazophenol and benzeneazo-*m*-cresol, both of which are *p*-hydroxyazo compounds. The absorption of these substances was compared with that of their benzoyl derivatives and their methyl ethers. The chemical evidence leaves no doubt that the methyl ethers and the benzoyl derivatives of these hydroxyazo compounds are true azo compounds, and that their formulæ are as follows—

Benzene azophenetole $C_6H_5{-}N{=}N{-}C_6H_4{-}OCH_3$
Benzoyl benzeneazophenol
$C_6H_5{-}N{=}N{-}C_6H_4{-}O{-}COC_6H_5$.

The close similarity between the absorption of the parent substances and that of the ethers and benzoyl derivative shows conclusively that these parent substances are true hydroxyazo compounds, and have formulæ of the type $C_6H_5-N=N-C_6H_4OH$, and not $C_6H_5-NH-N=C_6H_4=O$.

This conclusion is strengthened by the fact that the absorption of the corresponding quinone phenylhydrazone derivatives is quite different. The compound investigated was *p*-benzoquinonebenzoylphenylhydrazone, which has the formula



$$C_6H_5-\underset{\displaystyle CO\cdot C_6H_5}{\underset{|}{N}}-N=C_6H_4=O$$

In the case of the corresponding *o*-hydroxyazo-compounds Tuck found that these are *o*-quinone phenylhydrazones. The actual compounds examined were benzeneazo-*p*-cresol and *p*-tolueneazo-*p*-cresol, their methyl ethers and benzoyl derivatives. The absorption curves of the ethers agree with those of the ethers of the *para*-compounds and with that of azobenzene. This was to be expected, as the chemical evidence has proved them to be azo derivatives. The benzoyl derivatives, on the other hand, give very different spectra, and their curves show a very marked and close relationship with that of benzoquinone benzoylphenylhydrazone. There is no doubt, therefore, that these benzoyl derivatives are in the quinone hydrazone form. Since the absorption curves of the parent substances show a marked agreement with those of their benzoyl derivatives and considerable disagreement with those of their ethers, it may be concluded that the parent compounds are quinone hydrazones, and are derivatives, therefore, of *o*-benzoquinone $C_6H_5-NH-N=C_6H_4=O$.

One of the most important theories of the colour of organic compounds is that known as the quinonoid theory. It is well known that *p*-benzoquinone is a strongly yellow coloured substance, and the general theory has generally been held that visible colour of compounds, especially aromatic compounds, is to be explained by their having a quinonoid structure, that is, they contain the linking $=\!<\!\equiv\!>\!=$. It may be seen at once that this theory only takes account of visible colour. Now, every compound which exhibits selective absorption is coloured in the physical sense, and it would seem therefore that any attempt to connect visible colour with a particular structure need not necessarily be sound. It has already been stated that the association of residual affinities tends to shift the absorption bands towards the red, and it follows that if the centres of unsaturation are sufficiently strong in character and suitably associated, the absorption band can easily be caused to shift into the visible region with a result that the compound will become visibly coloured.

Evidently, therefore, there is no necessity for the assumption of the quinonoid structure in order to account for visible colour, though clearly such a structure may give rise to it. There is a tendency on the part of organic chemists to write a quinonoid structure wherever it is possible in order to account for visible colour; but it may be said at once that spectroscopic observations have shown that this quinonoid hypothesis is entirely unnecessary, and have indeed proved that the particular substances examined do not exist in the quinonoid form.

As a definite example of the association of residual affinity with the production of visible colour without any possibility of a quinonoid configuration, the diketone diacetyl may be quoted; the absorption spectrum of this substance is shown in Fig. 19, and owing to the association of the two CH_3CO groups, each of which alone shows selective absorption (compare the monoketones of the aliphatic series), the absorption band appears in the visible region and the substance is yellow. The case of camphor quinone is perfectly analogous. The following results show clearly that the quinonoid theory is entirely fallacious and unnecessary as regards visible colour.

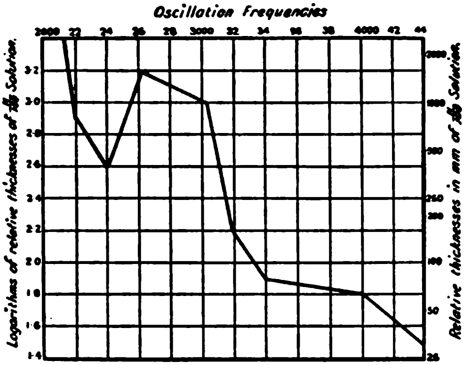


FIG. 19.

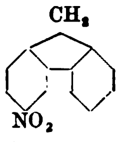
It was pointed out above that benzene and the condensed ring hydrocarbons of the aromatic series show complicated absorption spectra with many bands. There is little doubt from the chemical evidence that in the case of benzene the carbon ring is perpetually in a state of vibration, and it was suggested that the various absorption bands are in all probability due to phases in the configuration of the molecule produced by its vibrations. Although at the time only seven bands were described, while eight are now known, this does not invalidate the principle then put forward. It is evident that the vibrations of the molecule and the play of forces thereby resulting will be altered when the hydrogen atoms of benzene are substituted by other atoms or groups of atoms. This alteration may be due to two causes; firstly, the change in the vibration of the ring induced by the weight of the substituent group may play a part; and secondly, the change in the play of forces due to the mutual influence of the residual affinities of the benzene ring and of the substituent group must produce some effect. When the substituent group is of the ortho-directing type, such as OH or NH_2, the absorption band produced is always strongly marked, and is nearer to the red than are the bands of benzene itself. When phenol is dissolved in caustic soda solution, the increase in basicity resulting from the conversion of OH into ONa causes a still further shift of the band towards the red. An exactly similar shift towards the red is shown in the case of aniline when the basicity of the nitrogen atom is increased by the substitution of the amino hydrogen atoms by alkyl groups.

On the other hand, the substitution of the acid NO_2 group decreases very considerably the absorption of benzene, so that very small, if any, selective absorption is observed. This effect is due to the mutual influence of the benzene nucleus and the NO_2 group, which practically neutralise one another, with the result that a condensed system is formed, showing little or no selective absorption.

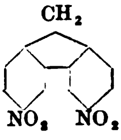
It would appear from the above that there must be almost perfect balance between the residual affinities of the C_6H_5 nucleus and the NO_2 group, and consequently the introduction of a second group into the benzene ring, and one which has an opposite character to that of the NO_2 group, will tend to destroy this balance with a result that the new compound will again show selective absorption.

This has been proved in the case of the three nitrotoluenes and the two mononitronaphthalenes, as well as for certain other compounds of the same type.

A very good test case was found in the mono-nitro and di-nitro fluorenes



and



for the former compound, where only one of the rings has a nitro group, should show a well-marked absorption band owing to the opening up of the closed system of the one ring by the residual affinity of the other. In the latter compound both rings have an NO_2 group, and as there is no unsaturated group present to open their systems up, this compound should exhibit no selective absorption. The absorption spectra of these two compounds agree perfectly with the prediction, for mono-nitrofluorene shows a strongly marked band, while the dinitro compound shows no band at all.

If the second group introduced into nitrobenzene be more markedly different from the NO_2 group, if, for example, the absorption of the nitroanisoles be considered, then the absorption bands are very decided, and are nearer to the red than in the case of the nitro-toluenes. The effect is still more marked in the case of nitroquinoldimethyl ether, which has two OCH_3 groups, for the absorption band is now so far shifted towards the red that the substance appears yellow to the eye.

An interesting point is to be noted with this compound, for its solution in hexane or a saturated hydrocarbon is colourless. This fact might at first sight tempt one to believe in a different structure for the compound in the two solvents alcohol and hydrocarbon. The absorption spectra of the two solutions, however, are very similar, the only difference being that the band is nearer the red in the case of the alcoholic solution. It happens that the band given by the alcoholic solution just lies within the limits of visibility, so the solutions appear coloured to the eye. The absorption band with the hexane solution lies just beyond the visible limit, and therefore the eye fails to detect any colour.

If, now, the second constituent group in nitrobenzene be still more strongly basic, the absorption bands of the resulting compounds will be still further shifted towards the red, with the result that these substances will be still more strongly coloured. Thus, for example, the absorption bands of *p*-nitrodimethylaniline is shown by the full curve in Fig. 20. It is evident from what has been said that this absorption band is due to the opening up of the condensed system of nitrobenzene by the strongly electropositive $N(CH_3)_2$ group. Almost exactly the same absorption as may be seen by the dotted curve in Fig. 20 is shown by para-nitroaniline itself, and consequently there is not the slightest possible doubt that the constitution of this body is the same as that of its dimethyl derivative. The constitution of the latter is of course $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>N{-}C_6H_4NO_2$ and therefore the parent substance must have the constitution $NH_2{-}C_6H_4NO_2$. This at once is opposed to the quinonoid theory. According to this theory, the constitution of the *o*- and *p*-nitranilines are to be represented by a quinonoid formula; that is to say, the formula of *p*-nitroaniline would be—

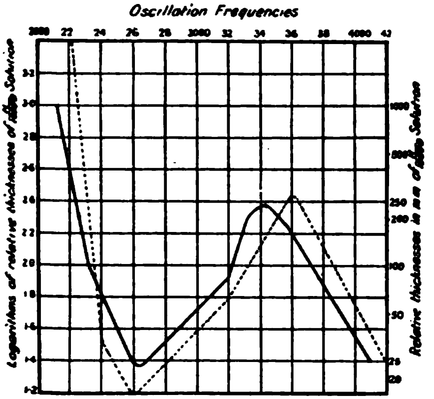


FIG. 20.

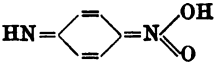


The quinonoid theory has also gained considerable support from the fact that *meta*-substituted compounds as a rule show less colour than that of the isomeric *ortho*- and *para*- bodies. As a static *meta*-quinone structure in a simple compound seems to be impossible the case for that structure of the *ortho*- and *para*-isomers was strengthened. Although it is true that the *meta*-compounds are less coloured, yet, generally speaking, their absorption curves show bands similar to those of the *ortho*- and *para*- substances, though they are less pronounced. As a result of this it is evident that the upholders of the quinonoid theory ought to accept a quinonoid structure for these *meta*-derivatives. As a matter of fact, however, the absorption band of *meta*-nitrodimethylaniline is distinctly nearer to the red than the band of *meta*-nitroaniline itself and so the substance is still more strongly coloured. This of course is due to the fact that the basicity of the nitrogen atom has been increased by the substitution of its hydrogen atom by the methyl groups, and the shift of the absorption band is exactly analogous to the shift observed on methylating aniline, as has already been noted.

The three nitroanilines and their dimethyl derivatives therefore show exactly analogous absorption, and clearly they must possess the same constitution.

The explanation of the absorption and colour of these six compounds must be the same, and so it must be concluded that all three nitroanilines cannot have a quinonoid structure.

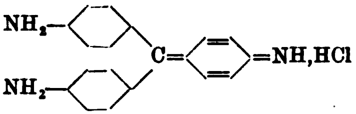
Exactly similar conclusions must be drawn respecting the constitution of the nitrophenols and their sodium salts. A comparison of the absorption of the nitrophenols with that of their corresponding methyl and ethyl ethers shows at once that the nitrophenols themselves are certainly not quinonoid. The change in colour observed when these substances are treated with sodium hydroxide must be due simply to the shift of the absorption band towards the red which is always produced when a phenol is converted into its sodium salt. As has already been said, phenol itself shows the same shift in its absorption, and, moreover, the absorption of sodium phenoxide is the same as that of aniline.

The similarity between the absorption of the sodium salts of the nitro-phenols and the corresponding nitro-anilines is very decided, and consequently there is no room for any doubt that the sodium salts of the nitro-phenols do not exist in quinonoid form. This conclusion is emphasised by the fact that the absorption spectrum of the nitro-phenols and their salts do not show that marked difference in character which would of necessity ensue if such a radical difference in constitution existed as required by the quinonoid hypothesis.

The quinonoid theory has been used to explain the colour of the alkali metal salts of such compounds as the nitro-benzene azophenols and the nitro-benzene azo-*a*-naphthols. The spectroscopic examination of these substances, using the same argument as detailed above, shows quite clearly that these substances do not exist in the quinonoid form. As conclusive evidence in support of this it is to be noted that *p*-benzoquinone azine—

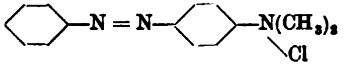
exhibits an absorption curve which is absolutely and entirely different from that given by any of the above compounds.

One of the most important applications of the quinonoid theory is the explanation by its means of the colour of the dye-stuffs. Perhaps the most familiar case is that of *para*-rosaniline hydrochloride with the suggested formula—



Similar quinonoid formulæ have been suggested for the other dye-stuffs of this type. Again, the same theory has been applied to the azo-dyestuffs which contain the azo-linking and one or more amino groups. Such a structure may be exemplified by that proposed for the hydrochloride of *p*-amino azo-benzene—

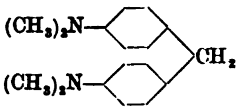
and in this case the formula has been supported by the fact that the absorption of the above salt bears no resemblance to that of—



so that the hydrochloride does not seem to exist in the form

Some investigations, however, into the influence of acid upon aromatic bases such as the aminoaldehydes and aminoketones show that the above quinonoid formulæ are unnecessary and improbable. It has been found that the addition of small quantities of hydrochloric acid to the alcoholic solution of these bodies produces a very marked coloration which gives rise to a new absorption band in the visible region. It is necessary that less than one equivalent of hydrochloric acid be added for the colour to be produced, and the addition of a further quantity of acid destroys the colour and forms the true hydrochloride. These colours are due to the formation of an intermediary phase through which the base passes before its conversion into the salt. This intermediary phase is perfectly stable in the presence of the small quantity of acid. In the case of a mon-acid base such as *p*-aminobenzaldehyde, ½ eq. of HCl produces the best results. With a di-acid base as Michler's ketone (tetramethyl diaminobenzophenone)—

one equivalent of acid is best. As it is known that the coloured compound is not a true hydrochloride, therefore in this latter case it must be concluded that the hydrochloric acid distributes itself equally between the two nitrogen atoms. The analogy with rosaniline hydrochloride is quite apparent, for in this salt the affinity of the acid radicle influences all the nitrogen atoms, and so the colour is due to the fact that the intermediate phase happens to exist as a stable crystalline substance. This view is borne out by the fact that the trihydrochloride has far less deep a colour than the monohydrochloride. Again, it must follow if this view be correct that it should be possible to produce a highly coloured intermediate phase of the leuco base of a dye by means of a suitable acid solvent. Such, indeed, can be done, for if the leuco base be dissolved in nitrobenzene the solution is highly coloured. For example, if the leuco base of malachite green



be dissolved in nitrobenzene the solution shows a magnificent red colour, which is discharged on dilution with alcohol.

Exactly the same arguments apply to the aminoazo colours, for in these bodies there are present at least two basic groups amongst which the acid radicle distributes itself with the formation of an 'intermediate phase,' which is a stable crystalline substance.

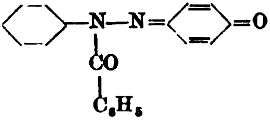
If a solution of azobenzene is treated with hydrochloric acid, the absorption spectrum will change, and a new absorption band will be obtained nearer to the red than that of azobenzene itself. The phenomenon doubtless is due to the same cause as in the case of the aminoaldehydes and ketones mentioned above, the only difference being that owing to the far less pronounced basic character of the nitrogen atoms a much greater concentration of acid is required. In the case of the aminoazo compounds when in acid solution a much less concentration of acid is required, since the amino group acts as a 'carrier,' and the affinity of the acid then is distributed between the amino and azo groups with the formation of the highly coloured intermediate phase. It has already been pointed out that the formula of the hydrochloride of aminoazobenzene cannot be expressed by the static formula—

but, as now may be understood, the formula is preferably to be written—

The quinonoid formula

may be ruled out, of course, because the absorption spectrum given by aminoazobenzene hydrochloride bears no resemblance to that of either of the similar substances which are known to possess a quinonoid structure, namely,

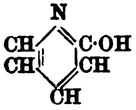
and



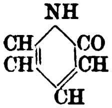
These two substances have already been dealt with above.

These foregoing arguments might be extended considerably and applied to many other compounds, the colours of which have been explained by the quononoid hypothesis, but sufficient has already been said to show that this conception is either entirely negatived or rendered quite unnecessary and improbable in every case where the spectroscope has been applied. In the bibliography dealing with this particular branch of spectroscopic work a very complete list of papers is given, and perhaps a seeming discrepancy may be pointed out so as to guard against a possible misconception. In the earlier stages of the investigation dealing with the absorption of the nitrophenols and the nitranilines the results obtained were interpreted as being in favour of the quinonoid theory, and it was not for some time that the conclusion was definitely arrived at that these previous arguments were unsound. This recantation, together with the definite proofs in favour of the views detailed above, was published in 1910.

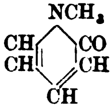
The absorption spectrum of pyridine and its derivatives give some considerable support to the view advanced above of the vibrations of the ring in the aromatic compounds. As was first shown by Hartley, pyridine gives an absorption band with its head at $\frac{1}{\lambda}=3900$, and the addition of hydrochloric acid to the solution enormously increases the depth or persistence of the band without changing its position. Later observations show that this is also true with the picolines and with lutidine. The vibrations present in the benzene ring are modified and restrained by the residual affinity of the nitrogen atom, which has been substituted for one of the carbon atoms of benzene, and when this residual affinity is almost entirely removed by the addition of an excess of hydrochloric acid the restraint is considerably reduced, and the vibrations become less restricted. The constitution of the three pyridones or hydroxypyridines was determined from their absorption in the following way. In the case of the α compound it was found that an alcoholic solution shows a well-marked band, and the addition of hydrochloric acid only shifts the band a little nearer to the ultra-violet without increasing its persistence. Furthermore, the addition of sodium ethylate does not shift the position of the band. The substance cannot therefore be phenolic in character; that is, it cannot have the formula



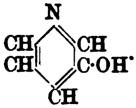
for if it had this constitution, sodium ethoxide would shift the band towards the red, as always happens with phenols; and further, since such a compound would be a true pyridine derivative, hydrochloric acid would increase the persistence of the absorption bands. Clearly, therefore, the formula must be



a conclusion which is confirmed by the close analogy of the absorption spectrum of N-methyl 2-pyridone—

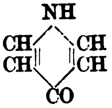


Exactly the converse is true in the case of the β-isomeride, for the absorption band of this compound is shifted towards the red by sodium ethoxide, and the effect of hydrochloric acid is very markedly to increase its persistence. The compound, therefore, must be phenolic, and a true pyridine derivative; that is, it has the formula



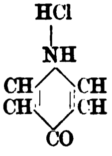
Moreover, the position of the absorption bands shows considerable analogy with those of phenol itself.

The γ-isomeride is peculiarly interesting, the compound showing an absorption band which is entirely removed by the addition of sodium ethoxide. This observation is analogous to the case of the aliphatic monoketones. The inference may be drawn from this that the substance is ketonic and has the formula



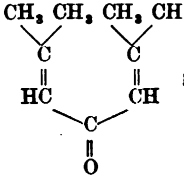
This is strikingly confirmed by the action of hydrochloric acid, which entirely alters the absorption, as may be seen from the full curve (Fig. 21), where the dotted curve is that of the γ-pyridone itself.

The hydrochloric acid should lock the compound in the form



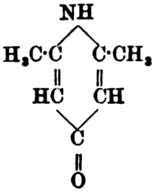
and as the CO group is between two ethylenic linkings a new absorption band should be produced.

It was found that phorone, in which this linking occurs

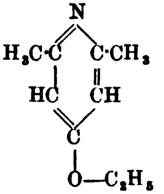


gives a very similar absorption. Clearly, therefore, the pyridone formula is confirmed.

Exactly similar conclusions are to be drawn from the absorption curves of γ-lutidone—

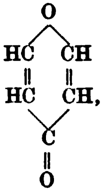


and here confirmatory evidence was forthcoming in the fact that γ-ethoxylutidine—

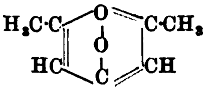


shows no absorption band, and therefore must have an entirely different composition from the parent lutidone.

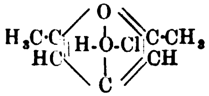
Somewhat similar arguments have to be applied to the elucidation of the constituents of the pyrones and certain applied compounds. It is well known that the pyrones do not form oximes or phenylhydrazones, and Collie pointed out that this fact could not be reconciled with the ordinary formula for the pyrones, for example,



and he suggested the bridged ring structure for dimethylpyrone—



The absorption curves of pyrone itself, dimethyl pyrone, and tetramethylpyrone show no absorption bands, but only a slight step-out, as is shown by the full curve in Fig. 22. The absorption curves of the hydrochloride do not even show this step-out, as can be seen from the dotted curve (Fig. 22). It is not possible to reconcile these observations with the ordinary formula, which contains a CO group between two ethylenic linkings, but they are just what would be expected from Collie's bridged formula, in which case the formula of the hydrochloride would be



and the step-out in the absorption curve of the dimethylpyrone itself may be traced to the residual affinity of the oxygen atom in the bridge, which is neutralised by the addition of the hydrochloric acid molecule. The addition of sodium ethoxide to the alcoholic solution of these bodies introduces a great change in the absorption, as can be seen from the dot-and-dash curve in Fig. 22, which is that of dimethylpyrone in the presence of 87 equivalents of sodium ethylate. This curve is very strikingly similar to that of γ-lutidone in the presence of hydrochloric acid, and as the chemical evidence shows

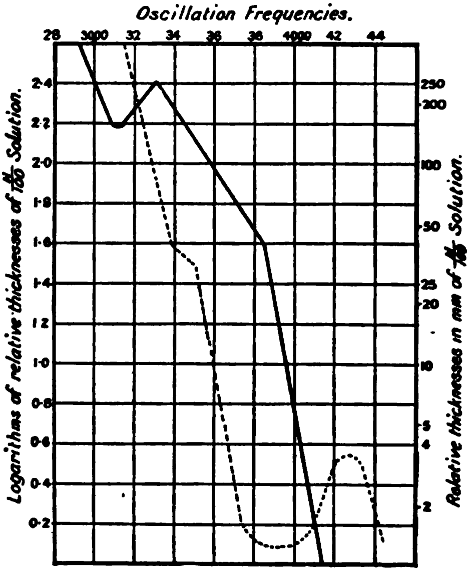


FIG. 21.

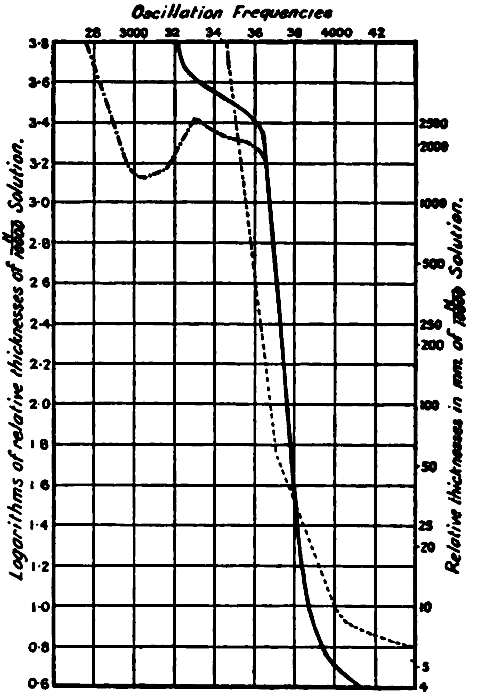

FIG. 22.

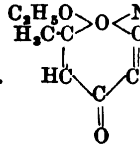
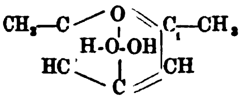
that an addition compound of dimethylpyrone and sodium ethoxide is formed, this suggests at once an analogous constitution for that compound, viz.

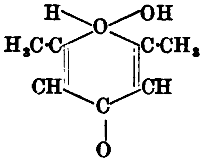


The addition of caustic soda to an aqueous solution of dimethylpyrone gives an entirely different absorption. It is well known that dimethylpyrone in aqueous caustic soda solution gives the sodium salt of diacetylacetone, and indeed the absorption curve of dimethylpyrone under these conditions approximates to that of diacetylacetone in aqueous alkali, so no doubt a considerable quantity of this substance is formed.

The determination of the constitution of diacetylacetone is complicated by the fact that the substance might have one of the following constitutions:—



1.



2.

$CH_3—CO—CH_2—CO—CH_2—CO—CH_3$

3.

and of these (1) is at once ruled out by the fact that diacetylacetone in no case shows an absorption resembling that of dimethylpyrone hydrochloride. In order to gain some idea of the absorption likely to be given by formula (3), tetracetylethane—

$$\begin{matrix}CH_3—CO\\CH_3—CO\end{matrix}\!>CH—CH<\!\begin{matrix}CO—CH_3\\CO—CH_3\end{matrix}$$

was examined in neutral and alkaline solutions. The constitution of this body is perfectly well known, and it was to be expected that its absorption will be analogous to the open chain form (3) of diacetylacetone. It was found that there was a strong similarity between the absorption of the diacetylacetone in water and tetracetylethane. The conclusion follows at once that in aqueous solution diacetylacetone exists in the open chain form.

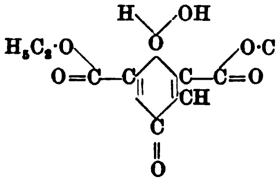
The alcoholic solution of diacetylacetone is different, for it exhibits a very broad absorption band. This band, however, extends over the regions occupied by the band of the open chain form of the substance and by the band of the sodium ethoxide compounds of the dimethylpyrones.

It may be concluded, therefore, that in alcoholic solution diacetylacetone exists as a mixture of the forms (2) and (3), and this conclusion is strengthened by the fact that the addition of sodium ethoxide to the alcoholic solution causes the broad band to be resolved into two bands, one of which is the same as that of the sodium ethoxide compound of dimethylpyrone and the other is that of diacetylacetone in aqueous alkali solution.

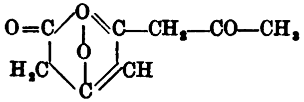
From similar arguments it was found that the colourless solution of ethyl xanthochelidonate in chloroform corresponds to the form—

$C_2H_5O\cdot OC—C(OH)=CH—CO—CH=C(OH)—COOC_2H_5$

whilst the yellow alcoholic solution contains also the closed form—

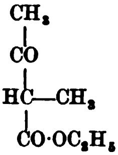


Finally, the results obtained in the examination of the absorption of dehydracetic acid and some closely allied substances would seem to argue that Collie's formula for this substance is the correct one, viz.—

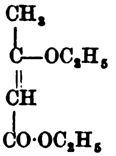


The simplest organic compounds at present known which exhibit selective absorption are the aliphatic ketones and allied compounds of the type of ethylacetoacetate and acetylacetone.

A few words may be said about these compounds, because the substitution of the hydrogen atom by the methyl group here induces a marked change in the absorption curves. A comparison of the absorption of ethyl acetoacetate with the well-known alkyl derivatives ethyl methylacetoacetate (I.) and ethyl β-ethoxycrotonate (II.)

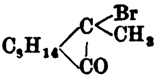


(I) and



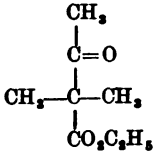
(II)

showed that the parent substance does not agree in its absorption with either of the two derivatives. Substances (I.) and (II.) do not show any absorption band in alcoholic solution, whilst ethylacetoacetate alone shows a tendency towards a band, and in presence of one or two equivalents of sodium ethoxide shows a well-marked band. From this it was concluded that ethylacetoacetate in alkaline solution is in a state of dynamic equilibrium, and that the absorption band is due to the reversible process  and also that the strongly marked band of acetylacetone in neutral solution is due to a similar process. Since that time investigations along two different lines have necessitated a slight modification in the above explanation of the absorption band. In the first place, it has been shown that all tautomeric changes of the above type are very much slower than is required by the above theory; and secondly, that absorption bands are shown, too, when such tautomeric equilibria are impossible, as, for example, in *αα′*-substituted camphor derivatives



$C_8H_{14}<\begin{matrix}C<\begin{matrix}Br\\CH_3\end{matrix}\\ |\\ CO\end{matrix}$

There is no doubt, however, that ethylacetoacetate can react either in the ketonic or the enolic form corresponding to I. or II. above, and also that there can be no doubt that the difference in the absorption of the body from that of the two fixed derivatives I. and II. is to be attributed to this cause, although it cannot be said that the absorption band is due actually to the dynamic equilibrium. Some recent and as yet unpublished experiments have shown that the compound I. and the still more rigidly ketonic substance



$$\begin{matrix} & CH_3 & \\ & | & \\ & C{=}O & \\ & | & \\ CH_3— & C & —CH_3 \\ & | & \\ & CO_2C_2H_5 & \end{matrix}$$

exhibit a well-marked band in presence of a great excess of sodium ethoxide, whilst the compound II. shows a band in presence of excess of acid. From this it is evident, were such evidence required, that the band cannot be due to tautomerism alone. It must originate in the mutual influence of the residual affinities of the alkali or acid upon I. or II., as the case may be. The extreme ease with which ethyl acetoacetate gives a band with alkali therefore must be connected with the ease with which this compound can pass from the ketonic into the enolic form and *vice versâ*.

Since acetylacetone gives an absorption band when dissolved in alcohol alone, it follows that the keto-enol change is even more easily brought about than in the case of ethyl acetoacetate. The absorption band in these compounds, then, is a measure of the amount that the closed systems are opened up by the influence of the solvent, and in certain respects may be considered as being analogous to that of the weak aromatic bases discussed above.

Although the absorption band is not due to the presence of a tautomeric equilibrium, yet the difference in the ease with which the absorption band can be developed forms a measure of the labile character of the hydrogen atom in the parent compound. For this reason, although a new explanation of the origin of the absorption band is introduced, it may readily be understood that spectroscopic results give a method of testing the presence of a labile or potentially labile hydrogen atom.

E. C. C. B.

SPECULAR IRON ORE *v.* IRON; also HÆMATITE.

SPECULUM METAL. An alloy of 1 molecular proportion of tin and 4 of copper and a small quantity of arsenic, used for making the mirrors of reflecting telescopes.

SPEISS *v.* COBALT.

SPELTER *v.* ZINC.

SPERMACETI *v.* WAXES.

SPERMACETI, VEGETABLE, *Insect wax v.* WAXES.

SPERM OIL *v.* OILS, FIXED, AND FATS.

SPERMIN *v.* SYNTHETIC DRUGS.

SPERRYLITE. A mineral of interest as being the only naturally-occurring compound of platinum. It is the diarsenide $PtAs_2$, and forms minute, tin-white crystals, which are cubic with the same degree of symmetry as iron-pyrites (FeS_2). It was found in 1889 as a loose crystalline powder, filling small pockets in decomposed pyritic ore at the Vermillion gold mine in the Algoma district (22 miles west of Sudbury), Ontario. The platinum detected in small amounts (0·006–0·24 p.c.) in the pentlandite and nickeliferous pyrrhotite of Sudbury, Ontario, is perhaps present as sperrylite. A few minute crystals of sperrylite have been isolated from the platiniferous copper ore (covellite) of the Rambler mine in Medicine Bow Mountains, Wyoming. Other localities are in North Carolina and British Columbia, but the mineral is always of very sparing occurrence. The frequent presence of traces of platinum in sulphide ores of nickel and copper is, however, a promising indication for future discoveries (*v.* F. W. Clarke, Data of Geochemistry, Bull. U.S. Geol. Survey, No. 330, 1908, 610).

L. J. S.

SPESSARTITE *v.* GARNET.

SPHACELINIC ACID *v.* ERGOT OF RYE.

SPHÆROSIDERITE *v.* CHALYBITE.

SPHENE *v.* CALCIUM; also TITANIUM.

SPIEGEL-EISEN *v.* IRON.

SPIKENARD OIL (*Valeriana celtica* [Linn.]) is a thick yellow oil with an odour resembling that of valerian and hazelwort oils. It has sp.gr. 0·9693 at 20°; $[\alpha]_D - 42°$ saponification value 62·5; ester value (after saponification and acetylation), 71·9. It contains palmitic acid and a sesquiterpene, b.p. 255°, sp.gr. 0·9359 at 20°, $[\alpha]_D - 30·88°$ (J. Soc. Chem. Ind. 1909, 1272.

SPINACH, *Spinacia oleracia* (Linn.). Several varieties are known. The leaves are used as a vegetable.

Average composition (König)—

Water	Protein	Fat	Sugar	Other N-free extract	Fibre	Ash
89·2	2·7	0·5	0·1	3·5	0·9	2·0

About half the total nitrogen exists as real proteid, and the N-free extract includes about 0·9 p.c. of pentosans.

Spinach is remarkable for the high proportion of iron which it contains, largely in the form of organic compounds.

König gives, as the composition of the ash—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
16·6	35·3	11·9	6·4	3·4	10·2	6·9	4·5	6·3

Serger (Chem. Zentr. 1906, i. 1668) found that winter spinach contained from 86 to 89·5 p.c. of water, 9·5 to 13·3 p.c. of combustible matter, and 1·9 to 3·1 p.c. of ash. 100 grms. of the dry substance contained, on the average, 0·104 grm. of iron. From 100 grms. of fresh winter spinach, dilute alcohol extracted 4·3 grms. of substance which contained 0·179 p.c. of iron and gave 26·23 p.c. of ash, while the residual material yielded 8·7 grms. of dry substance containing 0·066 p.c. of iron, and gave 9·18 p.c. of ash. A considerable amount of the iron was also present in the matter extracted by a mixture of benzene, chloroform, and ether from the fresh leaves.

The amount of iron in spinach may be considerably increased by the addition of ferric oxide to the soil (Czadek, Chem. Zentr. 1904, i. 832).

For the great increase of crop resulting from the use of sodium nitrate and other artificial manures, *v.* Dyer and Shrivell, J. Roy. Hort. Soc. 1903, 27, part 4). H. I.

SPINEL (*Spinelle*, Fr.). A double oxide of magnesium and aluminium or a magnesium aluminate, $MgO{\cdot}Al_2O_3$ or $MgAl_2O_4$, crystallised in the cubic system. The name is also applied to a large isomorphous group of cubic minerals with the general formula $R''R_2'''O_4$, where $R''=Mg, Fe, Zn, Mn$, and $R'''=Al, Fe, Cr, Mn$. Other members of this group are magnetite, chromite, franklinite, gahnite (*qq.v.*). Spinel proper is of importance as a gem-stone. When red it is known as 'ruby-spinel,' 'spinel-ruby,' or 'balas-ruby,' and is often mistaken for the true ruby or corundum (*q.v.*), from which it is distinguished by its optically isotropic character, lack of pleochroism, and lower sp.gr. (3·6–3·7) and hardness (8). Large numbers of small, water-worn crystals are found in the gem-gravels of Ceylon. These are octahedral in form and often twinned on a face of the octahedron (hence the term spinel-twin for this type of twinning). Blue spinel ('sapphire-spinel') is much less common; stones of excellent quality have been made artificially (*v.* Gems, artificial). Spinel is much used for the jewelled pivot-supports of clocks and watches. L. J. S.

SPIRIT OF AMMONIA *v.* Ammonia.

SPIRIT OF HARTSHORN *v.* Ammonia.

SPIRIT OF SALT *v.* Hydrochloric acid.

SPIRIT OF WINE *v.* Alcohol.

SPIRIT VARNISHES *v.* Varnishes.

SPIROSAL. Trade name for the glycol ester of salicylic acid $OH{\cdot}C_6H_4{\cdot}CO{\cdot}OCH_2{\cdot}CH_2{\cdot}OH$. A colourless oily liquid, b.p. 169°–170°, at 12 mm. Soluble in water, alcohol, and ether, and readily miscible with oils (*v.* Salicylic acid and Synthetic drugs).

SPLENIN *v.* Synthetic drugs.

SPODUMENE (*Triphane*, Fr.). A member of the pyroxene group of minerals consisting of lithium and aluminium meta-silicate $LiAl(SiO_3)_2$, and crystallising in the monoclinic system. This formula requires 8·4 p.c. of lithia, but, owing to partial replacement by potash and soda, analyses show only about 5–7 p.c. The mineral is occasionally mined as a source of lithium salts. Sp.gr. 3·1–3·2, hardness 6½–7. The name 'spodumene' (from ***σποδούμενος***, something burned to ashes) has reference to the ash-grey colour shown by the common, opaque material. Transparent crystals are, however, colourless or often beautifully coloured, and are cut as gem-stones. These are strongly pleochroic, but they have the disadvantage of readily splitting, owing to the presence of a perfect prismatic cleavage. Clear yellow (rarely blue) fragments come from the gem-gravels of Brazil. Bright emerald-green crystals, coloured by a trace of chromic oxide, are found sparingly, together with beryl (emerald), in gneiss at Stony Point in Alexander Co., North Carolina; this highly-prized gem-variety is known as 'hiddenite' (or sometimes erroneously as 'lithia-emerald'). 'Kunzite' is another gem-variety of a delicate lilac or violet shade of colour, which has recently been found in the pegmatites at several places in San Diego and Riverside Counties in California and at Antsirabe in Madagascar. Large prismatic crystals of dull spodumene are well known from Huntington (formerly Norwich) in Massachusetts, whilst in the Etta tin mine at Harney Peak in the Black Hills of South Dakota enormous crystals, measuring as much as 42 ft. in length and with a cross-section of 3 by 6 ft., have been found; 37 tons of spodumene have been, it is said, mined from a single crystal (F. L. Hess and R. C. Wells, Amer. J. Sci. 1911, 31, 433). L. J. S.

SPRUCE OCHRE. *Brown ochre v.* Pigments.

SQUILL. (*Scilla*; *Scille*, Fr.; *Meerzwiebel*, Ger.)

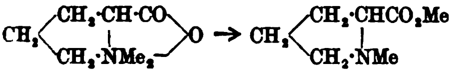
The fleshy bulb of *Urginea Scilla* (Steinheil), a liliaceous plant found on the shores of the Mediterranean (Bentl. a. Trim. 281). It has been employed in medicine from ancient times as a diuretic and expectorant. The bulb, already dried, is imported into this country mostly by way of Malta. Under the microscope the cells of its modified leaves are seen to be loaded with mucilage, in which numerous needle-shaped or square prismatic crystals of calcium oxalate are suspended (Flück. a. Hanb. 690).

The mucilage of squill contains a *gum*, which is precipitated by basic lead acetate, an *uncrystallisable sugar* (Flück. a. Hanb.) and *sinistrin* $C_6H_{10}O_5$ (Schmiedeberg, Zeitsch. physiol. Chem. 3, 112; Ber. 12, 704). The sinistrin of Schmiedeberg is probably a distinct substance from the constituent of dahlia root described under the same name by Marquart (Annalen, 10, 91). After removal of the gum from squill mucilage, by treatment with basic lead acetate, milk of lime is added, when an insoluble calcium compound is formed, from which free sinistrin may be liberated by carbonic acid. It is purified by successive solution in water and precipitation by alcohol. Sinistrin is a white amorphous powder, soluble in water, insoluble in alcohol, is lævorotatory (*cf.* Kühneman, Ber. 8, 387), and does not reduce Fehling's solution. Diastase is without effect upon it, but by boiling with dilute acid it is converted into lævulose and inactive glucose. The 'scillin' of Riche and Rémont (J. Pharm. Chim. [v.] 2, 291) appears to be nearly related to sinistrin.

By treating an alcoholic extract of squill with tannic acid, a compound is obtained containing the bitter and more active constituent of squill. This has not been satisfactorily isolated, although under the name of *scillitin* or *sculein* it has been much investigated. *See* further Mandet (Compt. rend. 51, 87), Schroff (Neues Rep. Pharm. 14, 241), Righini (Rep. Pharm. 63, 87), Tilloy (J. Pharm. Chim. 12, 635; [iii.] 23, 406), Vogel (Sitz. Ber. K. Akad. Wien. 6, 101), Lebourdais (Ann. Chim. Phys. [iii.] 24, 62), Marais (J. Pharm. Chim. [iii.] 30, 130), Landerer (Rep. Pharm. 47, 442). A bitter pulverulent compound, *scillain*, has, however, been obtained by Jarmersted, which, in its physiological action, resembles digitalin (J. 1879, 914). It is a glucoside, difficultly soluble in water but soluble in alcohol. The names 'scillipicrin,' 'scillotoxin,' and 'scillin' have been applied commercially to condensed pharmaceutical preparations of squill (Merck, Pharm. J. [iii.] 9, 1038). A. S.

STACHYDRINE $C_7H_{13}NO_2$. *Methyl betaïne of hygric acid*, or *dimethyl betaïne of a-proline*, is an alkaloid which was discovered by Planta and Schulze in 1890, in the tubers of *Stachys tuberifera* (Naudin) (Ber. 1893, 26, 939). It is also the chief basic constituent of the leaves of bitter orange (*Citrus Aurantium* [Linn.]) (Jahns, *ibid.* 1896, 29, 2065). It has been synthesised by converting ethyl hygrate into its methiodide and then treating the latter with silver oxide (Schulze and Trier, *ibid.* 1909, 42, 4654).

Stachydrine forms colourless, transparent crystals, which deliquesce in air and become opaque at 100° through loss of water of crystallisation. It melts at 210° and may be identified by its characteristic *aurichloride*, m.p. 225°, and by the fact that when heated in a glass tube, the vapours evolved turn a pine splint moistened with sulphuric acid, red (Schulze and Trier, Zeitsch. physiol. Chem. 1910, 67, 59). When heated with potash stachydrine evolves dimethylamine, and when distilled under reduced pressure it yields 66 p.c. of the isomeric dimethyl hygrate, thus—



$$CH_2\left\langle\begin{matrix}CH_2\cdot CH\cdot CO\\ |\\ CH_2\cdot NMe_2\end{matrix}\right\rangle O \rightarrow CH_2\left\langle\begin{matrix}CH_2\cdot CHCO_2Me\\ |\\ CH_2\cdot NMe\end{matrix}\right.$$

together with some trimethylamine and a little hygric acid (Trier, *ibid.* 324).

The *platinochloride* (in 3 forms), the *hydrochloride*, *sulphate*, *oxalate*, *picrate*, *nitrate*, and the *ethyl* derivatives have been prepared.

For further literature on the constitution and salts of stachydrine, *see* Planta and Schulze, Arch. Pharm. 231, 305; Engeland, *ibid.* 1909, 247, 463; Zeitsch. physiol. Chem. 1910, 67, 403; Schulze and Trier, *ibid.* 1909, 59, 233).

STACHYOSE, *Lupeose*, *v.* Carbohydrates.

STAGNIN *v.* Synthetic drugs.

STANNATES. Compounds of stannic oxide with bases (*v.* Tin).

STANNIC ACID *v.* Tin salts and oxides.

STANNITE or **Tin-Pyrites** (*Zinnkies*, Ger.). A sulphide of tin, copper, and iron, or a sulphostannate, Cu_2FeSnS_4, which has occasionally been found in sufficient amounts to be mined as an ore of tin (27·6 p.c. Sn). The iron is often partly replaced by an equivalent proportion of zinc (0–9 p.c.). Crystals are of rare occurrence; they are scalenohedral-tetragonal, with the same degree of symmetry and very nearly the same angles as copper-pyrites ($CuFeS_2$), but by twinning they give rise to pseudo-cubic forms. The crystallised material is iron-black with a bright metallic lustre (sp.gr. 4·45); but the massive mineral is usually yellowish or bronze-coloured (hence the miner's name bell-metal-ore), owing to an intimate intermixture with copper-pyrites. Stannite was formerly found in some quantity in several of the Cornish tin mines (*e.g.* Wheal Rock at St. Agnes; Carn Brea), and has also been mined at Borah Creek in New South Wales and Zeehan in Tasmania. Crystallised stannite has been found in some of the silver-tin mines of Bolivia (L. J. Spencer, Min. Mag. 1901, 13, 54). L. J. S.

STANNO-FLUORIDES *v.* Tin salts and oxides.

STAR ANISE, OIL OF, *v.* Oils, essential.

STAR SAPPHIRE *v.* Corundum.

STARCH (Lat. *Amylum*; Fr. *Amidon*, *Fécule*; Ger. *Stärke*, *Stärkemehl*, *Farina*).

1. *Occurrence.* In some form or other starch is one of the most widely-diffused substances in organic nature, occurring more or less abundantly in every plant that has, up to the present time, been examined. It is found in larger quantities in some families of plants than in others, and occurs in different parts in different plants; for instance, it is always found in great abundance in the seeds of all the cereals, as well as of the *Leguminosæ*, in the stems of various species of *Sagus* and *Cycas*, in the roots of many plants belonging to the family of *Euphorbiaceæ* and *Zingiberaceæ*, and in the tubers of the potato, canna, and cassava.

Starch is also found under varying conditions in different parts of the same plant; for instance, it is found in the green leaves of all plants during the daytime, the proportion varying according to the weather and time of day. It is generally present in greatest quantity towards the evening and least in the morning, whilst during the night the starch almost or completely disappears from the leaves, especially during the summer months. Starch is also found in the pith of trees and shrubs and in the various woody tissues; but its presence in these parts, as in the leaves, is not constant and equal, the same tissues at certain seasons being fully charged with starch and at others almost entirely devoid of it.

2. *Nomenclature.* In this country the term 'starch' appears to be applied generally to that obtained from all sources, with the name of the substance from which it is prepared usually prefixed to it, such as 'potato starch,' 'wheat starch,' 'rice starch.' In a few instances the affix starch is dropped, as in 'sago,' 'arrowroot,' or the product is known by some name given it in commerce, as 'tapioca,' 'tous-les-mois.'

In France the term 'fecula' (*fécule*) is applied to the starch obtained from roots and tubers, such as potato, manioc, arum; from stems, such as sago; and from fruits and seeds, as horsechestnut, acorns, &c.; whilst the starch obtained from all the cereals is defined as

TABLE I.—*Relative proportions of starch per cent. in various plants.*

—	Krocker	O'Sullivan

amidon or starch. Most of these products are known in Germany as 'farina.'

3. *Physical characteristics.* To the naked eye pure starch presents the appearance of a white glistening friable powder, having a harsh feel when rubbed between the fingers, without taste or smell, is uncrystallisable, and undergoes no change under ordinary atmospheric conditions. Under the microscope it is seen to consist of granules of various forms—in most cases, however, more or less ovoid—and differing widely in size, form, and appearance, dependent on the source whence they are derived. According to Payen, they may vary in size from 0·002 mm. in diameter to 0·185 mm. These wide differences are the principal means by which the various kinds of starch may be differentiated one from another as they occur in commerce.

TABLE II.—*Diameters of the commoner varieties of starch granules.*

Starch from	Millimetre
Rhizomes of *Canna gigantea*	0·175
,, ,, *Maranta arundinácea* (arrowroot)	0·140
Tubers of potato	0·140

Buckwheat	0·009
Parsnip	0·007
Seeds of beetroot	0·004

It must be noted, however, that the size of the starch granules varies very considerably in different plants, being in some immeasurably minute, as in certain species of cactus; in others, as in the potato and tous-les-mois, attaining a comparatively large size, the several grains being readily visible with a simple lens.

In the same plant—and, indeed, often in the same cell—the size of the starch granules will be found to vary, being chiefly dependent on the relative age of the grains, so that when measures of starch grains from various sources are given they must be taken only to represent an average; but although the dimensions of the starch granules produced by any one species of plant are by no means constant, yet none of them depart very widely from this average, and so by reference to such a standard the starch granules of different plants may readily be differentiated microscopically one from the other by an expert.

4. *Formation of starch in the living plant.* Starch granules in the growing plant are formed in the homogeneous solid substance (protoplasm) of the chlorophyll corpuscles. They are at first visible as mere points, and gradually increase in size, so that eventually they may so completely fill up the space of the chlorophyll corpuscle that this may be represented by a mere covering film, and at last almost entirely disappear. These starch granules are sometimes extremely minute and very numerous, and so closely packed together as to fill the cell cavity, as in the case of rice and oat, whilst in other instances they are of much larger dimensions, so that only a comparatively small number of them are to be found in each cell.

Starch granules only grow and increase in size so long as they are in contact with the protoplasm and are exposed to light at a favourable temperature in the presence of carbon dioxide. Hence the formation of starch in the leaves of the growing plant must be regarded as a product of assimilation, and may be supposed to take place somewhat in the following manner. It is well known that carbohydrates can be oxidised to aldehydes, and arguing from this Baeyer suggested (Ber. 3, 63) that formaldehyde is the immediate product of assimilation, and by its condensation gives rise to the polymeric substance glucose—thus: $(CH_2O)_6=C_6H_{12}O_6$, and hence to the anhydride of it, starch. If this be the process which actually occurs in the plant, the function of chlorophyll is simply the decomposition of carbon dioxide into carbon monoxide and oxygen (Vines, Chem. Soc. Trans. 33, 375). That such is the case would appear from experiments recorded by Bokorny (Chem. Zentr. 1888, 858; 1891, 120), who found that algæ (*Spirogyra majuscula*), when placed in a culture solution containing 0·1 p.c. methylal, or 0·1 p.c. of sodium hydroxymethyl sulphonate, and 0·1 p.c. K_2HPO_4, and allowed to remain in air free from carbon dioxide and exposed to the light, contained, at the end of five days, very considerable quantities of starch, the sodium hydroxymethyl sulphonate being broken up into sodium sulphite and formaldehyde, which by condensation becomes converted into carbohydrate.

Brown and Morris (Chem. Soc. Trans. 1893, 623), in repeating experiments carried on by Bölim and A. Meyer, found that the chlorophyll granules not only form starch by the process of assimilation, but can also elaborate starch from nutritive solutions of certain sugars. It is difficult to imagine that a complex substance such as starch is the first product formed in the process of assimilation, and evidence goes to prove this. The rôle starch takes in the living plant is that of a reserve material, and the fact of its being of a colloidal nature gives weight to the fact. When required as nutriment for the plant it is rendered soluble by the agency of enzymes, *e.g. diastase*, and converted into readily diffusible sugars.

Under favourable conditions of assimilation the leaf cells are supplied with more than sufficient freshly assimilated materials in the form of sugars, and this excess of material is deposited as starch. The starch is only called upon when assimilation ceases. These authors concluded that cane sugar is probably the first sugar to be synthesised and may be regarded as the starting-point of all the metabolic changes taking place in the plant. It has the function in the first place of a temporary reserve material, and accumulates in the sap when the processes of assimilation are proceeding vigorously. When the degree of concentration reaches a certain limit starch commences to be elaborated by the chloroplasts, the starch forming a somewhat more stable and permanent reserve material than the cane sugar, which can be drawn upon when the more easily metabolised cane sugar has been partially used up.

The investigation of E. Fouard on the colloidal properties of starch (Compt. rend. 1907–1908, and Int. Cong. App. Chem. 1909) caused him to modify some of the views held by Brown and Morris on the functions of the living plant in respect of its starch. His examination of the mineral constituents of starch reveals the existence of mineral matters consisting chiefly of acid or basic phosphates, and in view of the action of acid and basic salts on the coagulation of the starch solution pointed out by A. Fernbach (Ann. Brass. et Dist., 1908, 11, 481–486), and of the fact that the vegetable cell contains a juice with variable reaction, it seems probable that the phosphatic impurity in the starch may play an important part in the changes of condition of the latter, and in its migrations within the vegetable organism.

He holds that the hypothesis that starch must be hydrolised to the condition of sugar before it can migrate is no longer necessary, since an opalescent pseudo-solution, when filtered through a collodion membrane, yields a clear filtrate containing starch in a state of perfect solution, which may be the form in which the migration of starch goes on in the plant.

5. *Structure of starch granules.* Starch granules, when examined under the microscope with a sufficiently high power, are found to consist of a series of distinctly stratified concentric layers, the outer ones being denser than those nearer the nucleus or hilum, which appears as a dark spot and generally occupies an eccentric position. This is well seen in potato starch. Occasionally two or more nuclei appear in one granule, and concentric layers may be observed surrounding each, as in the case of the haricot bean. The outer layer is the oldest in point of growth; the starch granule, according to Nägeli, increases in size from without inwards, so that each interior layer is younger and less compact than the one which immediately surrounds it; and since these layers are for the most part of variable thickness they cause the granule to deviate gradually in form from the originally spherical nucleus and assume a more or less ovoid form.

The investigations of R. Whymper (VII. Int. Cong. App. Chem. 1909) on the action of heat, mineral acids, and diastase, on the starch granule, support the theory of Nägeli. The fact that the small immature granules are not so easily attacked as the larger ones strengthens the view that the layers form internally during growth, the older ones expanding to make room for those newly formed, and consequently as the starch granules become larger, the outer layers become thinner and more easily penetrated by attacking agents.

Starch granules when intact are absolutely unacted on by cold water, and this was attributed, according to the earlier theories, to the presence of a protective coating of a different constitution to the other part of the granule. Water is absorbed to a very large extent by the interior contents of the granule, but none of the substance, which is to the highest degree colloidal, is able to diffuse into the surrounding medium.

If, however, the outer layer of the granule be ruptured by attrition, water is rapidly absorbed, the cell contents become swollen to a very great extent, and a small quantity of matter goes into solution. By treating the ruptured starch grains repeatedly with water, the whole of the cell contents may be removed, whilst the outer coating remains behind in the form of extremely thin layers; treated with a solution of iodine this outer coating gives a dirty yellow colour, whilst the cell contents are coloured an intense blue; this reaction, which is most characteristic of all starches, will be referred to again later on.

For many years the substance forming the outer layer of the starch granule has been known as starch cellulose, and the interior contents as granulose. They can be separated from each other in the following several ways: (*a*) by digesting the granules for several days with a saturated solution of sodium chloride containing 1 p.c. of hydrochloric acid, the cellulose remaining undissolved; (*b*) by digesting starch with saliva at 45°–55°, thus dissolving the granulose only; (*c*) by the action of certain schizomycetes which decompose the granulose of starch paste and leave the cellulose untouched; and (*d*) by the action of malt extract on starch paste in the cold (5–6 grms. starch per 100 c.c. water).

In the latter case limpidity is produced in a few minutes, the liquid is filtered, and the residue, which consists of starch cellulose, is washed well with cold water. Starch cellulose obtained in this way is perfectly insoluble in cold water, or in water heated up to 80°C.; it is not acted upon by diastase in the cold, nor up to 60°. By boiling with water it is converted to a great extent into soluble starch; a portion of it, however (about one-fifth), resists the repeated action of boiling water, but is readily dissolved in a dilute solution of potassium hydroxide, from which the greater portion of it can be re-precipitated by the addition of acetic acid. If, however, the alkaline solution be heated to boiling, the whole of the cellulose is slowly converted into soluble starch. Well-washed potato starch contains from 2 to 5 p.c. of cellulose. A considerable amount of attention has been directed to the structure of the starch granule, and the theory of Nägeli has been somewhat modified.

A. Mayer throws doubt on the existence of starch cellulose in the starch granule. He considers the granule to be homogeneous, for he points out that the delicate transparent skeletons left when the gelatinised granules are acted on by saliva, dilute acids, &c., are produced by the action of the reagent on the starch, and are identical with amylodextrin. The writers incline to the view that starch granulose differs from starch cellulose in being less dense in consequence of containing less water of hydration.

Maquenne and Roux (Ann. Chim. Phys. 1904, [viii.] 2, 109–135; 1906, [viii.] 9, 179–220) brought forward fresh views on the structure of the starch granule which would seem to be contrary to those of Nägeli and others that natural starches are a mixture of granulose and amylocellulose or starch cellulose, the latter being in a sense regarded as extraneous to the actual constituents of the starch granules. Maquenne and Roux stated that amylocellulose in different states of condensation forms the principal constituent of granules (about 80–85 p.c.) in admixture with another substance to which they asserted the viscosity of starch paste is due, and which they called amylopectin. This latter substance is of a mucilaginous nature, gives no colouration with iodine, and is dissolved, but only very slowly saccharified, by diastase, producing non-reducing sugars only.

Amylocellulose or amylose, as they prefer to call it, separates when starch paste or starch solution is allowed to stand. It is partly soluble in boiling water, and completely so in water at 150°; its solutions are devoid of gelatinising power, and give a blue colouration with iodine, being converted by diastase almost instantly and quantitatively into maltose. Amylocellulose can exist in a liquid form by heating under pressure to 150°–155°, or can be made to separate out, by cooling the concentrated solution, in granules resembling natural starch (reversion).

Fernbach and Wolff (J. Inst. Brew. 1904, 10, 216) showed that cereals contain an enzyme—amylo-coagulose—which causes a very rapid reversion of starch paste or solution to solid starch, having properties identical with amylose.

Z. Gatin-Gruzewska (Compt. rend. 1908, 146, 540–542) claimed to have separated amylopectin and stated that it forms the envelope of the starch granule, and consists of a series of sacs fitting one into the other, which are insoluble in cold water, but swell up in hot water, forming gelatinous pastes; it constitutes 40–45 p.c. of the starch.

Amylopectin gives an opalescent solution with alkali and water, which has an optical rotatory power of $[\alpha]_D$ +221°; the solution gives a purplish-blue colour with iodine, less intense than amylose.

Amylose dried to a fine powder partially dissolves in cold water, and entirely in hot water, giving opalescent solutions which give a clear blue colour with iodine; it dissolves rapidly in the presence of small quantities of alkali, and has an optical rotatory power in such solution $[\alpha]_D$+184·4°.

Maquenne (Compt. rend. 1908, 146, 542) states that the amylopectin isolated by Gatin-Gruzewska was impure and still contained amylose insoluble in boiling water. He holds the view that amylopectin and amylose cannot be regarded as homogeneous, but must consist of a complex mixture of homologous or differently condensed products. There is a likelihood that in the natural formation of the starch granule the amylopectin is derived from amylose by condensation just as amylose is derived from sugars. This gradual transition would explain the difficulty of separating these two substances, as there appears to be no sharp transition between the group of slightly soluble amyloses occupying the end of the series, and that of the least resistant amylopectins.

A. Fernbach (Ann. Brass. et Dist. 1908, 11, 481) is of opinion that solid starch should be regarded as a coagulated substance, which in nature has probably passed from the state of apparent solution to the solid form, and all the changes that starch can undergo without chemical alteration should be regarded as changes of this or the opposite kind. The conversion of solid starch into starch-paste or with so-called soluble starch is, in a sense, a change of the latter kind; the partial reversion of starch-paste to a solid substance is a change of the former kind. Attention is drawn to the fact that natural starches, like malt extract, are acid to phenolphthalein and alkaline to methyl orange, and he considers that the properties of starch depend almost exclusively on the nature and proportion of the accompanying mineral substances. These conclusions are based on the results of his investigation on amylo-coagulose, the enzyme present in cereals which coagulates starch-paste, which he found to have a maximum activity in a medium which is neutral to phenolphthalein.

Under polarised light starch assumes a most characteristic appearance. When examined under crossed Nicol prisms the field remains dark, but each granule assumes a glistening grey appearance, as if self-luminous, and is marked with a black cross. If, then, the object be slowly rotated in the field of view, the cross will remain fixed with regard to the field, one pair of its arms being parallel to the principal plane of the polariser, and the other parallel to the principal plane of the analyser. If next the object be allowed to remain stationary, and the polariser or analyser be rotated, the cross will rotate with it, but with only half the angular velocity; if, next, a thin plate of selenite be introduced between the polariser and the object, and whilst the Nicols are crossed, most beautiful chromatic effects may be obtained.

6. *Chemical properties.* Starch is absolutely insoluble in cold water, alcohol, ether, or any other known solvent.

Ordinary air-dried starch usually contains about 18 p.c. of water, which may be entirely driven off by heating for some time in a current of dry air at a temperature of 100°–105°. Under this condition starch appears to be a most highly hygroscopic substance, which rapidly absorbs moisture from the air until it regains its original 18 p.c.; if exposed to a damp atmosphere it is capable of absorbing as much as 35 p.c. of moisture.

The specific gravity of air-dried starches varies considerably, the variation being mostly due to the moisture content. Starches that have been freed from water have not absolutely the same specific gravity, anhydrous potato having a value 1·650, and anhydrous arrowroot 1·5648.

7. *Action of heat.* Freed completely from moisture, starch may be heated to a temperature of 160° without undergoing any change; at temperatures higher than this it becomes coloured, and is partly converted into dextrin. If, however, ordinary air-dried starch be heated to 160° it quickly undergoes decomposition, becoming converted to a greater or less extent into dextrin and reducing sugars, the action varying with the particular kind of starch used (*v.* DEXTRINS).

Experiments were made by the writers as to the effects of heat on different varieties of starch. Potato, sago, and rice were heated to 190° for two hours, cooled down, dissolved in cold water, and the specific rotatory powers of the solutions taken. Potato and sago starch were entirely decomposed under these conditions, and their solutions showed a specific rotatory power of $\alpha_D = 154{\cdot}3$ for potato, and $\alpha_D = 193{\cdot}3$ for sago; rice starch appears to offer great resistance to the action of heat, being only partially decomposed at the above temperature.

According to Schubert (Monatsh. 1884, 472), the starch granule, under the influence of high temperature, is altered in such a manner that those layers which are rich in granulose are at once converted into soluble starch and dextrin, whilst the principal portion of the layers rich in cellulose only undergo this transformation after a time. When starch which has been subjected to a high temperature is treated with cold water, the soluble starch, dextrin, and other products of decomposition go into solution, and an organised residuum is left, which resembles the form and structure of the original granule, and contains small quantities of unchanged granulose.

By dry distillation starch yields carbon dioxide, gaseous hydrocarbons, water, acetic acid, and empyreumatic oil, and leaves a porous cinder.

On distilling dry starch with lime in the proportion of 1 to 4 it yields acetone, mesityl oxide, a series of ketones, and various condensation products of acetone (Horvat, Chem. Zentr. 1887, 38).

By distillation with manganese dioxide and dilute sulphuric acid it yields carbon dioxide, aqueous formic acid, and furfural.

In the open fire it softens, swells up, evolves choking vapours, and finally burns with a bright flame.

Distilled with hydrochloric acid and manganese peroxide, it yields, among other products, trichlorinated acetic aldehyde and pentachlorinated propionic aldehyde.

8. *Action of hot water.* When starch is brought into contact with hot water the contents of the granules, owing to a large absorption of water, swell up enormously; and, at a temperature varying according to the variety of starch, ultimately rupture the outer layer, forming a viscous liquid which is known as 'starch paste.'

The different varieties of starch gelatinise with hot water at very different temperatures, as is seen in the following table by Lintner (Brauer und Malzer Kalendar, 1889), which gives the temperatures of complete gelatinisation for the commoner varieties of starch:—

TABLE III.

Starch from	Temperature at which complete gelatinisation takes place
Potato	65°C.
Maize	75°C.
Barley	80°C.
Wheat	80°C.
Rye	80°C.
Rice	80°C.
Kilned malt	80°C.
Green malt	85°C.
Oat	85°C.

This table gives the temperatures at which the various starches gelatinise completely in the pure state. In the crude condition a much higher temperature is necessary.

Under the action of boiling water the starch granules do not all swell up and burst at once—the younger ones being attacked first, the older last. This progressive action of heat can be very well observed when potato starch has been suspended in 12–15 times its weight of water, and gradually heated on the water-bath; hardly any change is apparent up to 55°, at 57° the younger granules begin to show signs of rupture, and as the temperature rises this process of swelling and bursting of the contents through the outer wall of the granule goes on increasing, the earliest-formed granules being the last to give way, until, at a temperature between 65°–70°, a thick viscous liquid, of uniform consistency, is obtained.

According to Bruckner (Monatsh. 4, 889), starch paste and granulose are identical, and no sharp distinction can be drawn between swollen starch granules and starch paste; thus at 46° potato starch swells distinctly, at 59° it begins to lose its form, and at 62·5° it is converted into a paste and shows no trace of its original form.

On cooling, starch paste contracts and becomes, when very thick, a firm solid mass, which, after standing a short time, cracks; its maximum contraction is reached at the freezing-point, when a separation of the water and starch takes place to a certain extent. Upon raising the temperature, the water which had been frozen out does not again combine with the starch, and may be drained away, whilst the consolidated starch paste remains as a felty mass which, when dry, has the appearance of mother-of-pearl (Payen).

Wide differences in the viscosity of this paste are observed, depending not only upon the variety of starch employed, but also upon the treatment to which the starch is subjected during the processes of purification and drying.

According to Brown and Heron (Chem. Soc. Trans. 35, 596), starch which has been treated with dilute potash and acid in the process of purification produces a paste of less viscosity than the same starch which has not been so treated; they also find that great variations in the consistency of the resulting paste are produced by slightly altering the manner of drying.

These facts are of importance, seeing that the technical value of a starch in certain industries depends entirely upon the viscosity produced by it when acted upon by boiling water.

Potato starch is used in large quantities for sizing and stiffening yarn and cloth, so that it is of importance to the manufacturer to obtain that sample of starch which will make the stiffest cloth and which has the greatest tenacity. In order to determine this, the following method has been recommended by O. Soare and P. Martens (Zeits. Spiritusind, 1903, 26, 436–437). An immersion body is constructed of a circular brass plate, 22 mm. in diameter, to which a brass wire is fixed vertically at the centre, having a mark at a distance of 3 cm. above the disc, and terminated by a hook at the top. The starch paste is prepared by weighing out 7 grms. of starch into a beaker of 200 c.c. capacity provided with a small metal spoon. The whole is tared, and 164 c.c. of boiling water are added with continuous and gentle stirring all the time. This may be effected either immediately or after immersion in a boiling water-bath for 2, 5, or 10 minutes. This spoon is then removed and the brass disc supported by a clamp is immersed in the paste exactly up to the mark; 10 c.c. of olive oil are poured over the surface to prevent the formation of a hard skin by evaporation, and the whole is left at rest for 20 hours at a temperature of about 17·5°. A hand balance, one of the pans of which has been replaced by a counterpoise, is attached to that of the disc. On the other scale pan an uninterrupted stream of sand is discharged at a uniform rate of about 9 grms. a minute, until the disc is torn from the paste. The weight of the sand is then taken as a measure of the stiffness of the paste. Experiments showed that the time during which the paste was heated at the boiling-point had a considerable influence on the results. Certain starches, especially those with a high gelatinising-point, such as wheat and maize starches, did not attain their maximum stiffness until they had been boiled for several minutes; on the other hand, certain potato starch pastes had a maximum stiffness without heating, any heating beyond that necessary to produce the maximum stiffness, caused a rapid decrease in stiffness. The values of the various samples showed a tendency towards equalisation by prolonged heating.

H. Cappenberg (Chem. Zeit. 1910, 34, 218–220) has designed a viscosimeter for starch pastes in which a spherical weight of standard dimensions is drawn upwards through a column of the paste of fixed height and temperature, the time occupied in doing this, under the pull of a known load in grams, being noted. A series of trials are made with a regularly decreased load, these being tabulated for comparison, as single observations with a fixed load are useless for this purpose. In comparing starches it was found that pastes containing 5 p.c. of potato starch and 9 p.c. of wheat starch gave coincident figures, and it may reasonably be assumed that for these samples the thickening powers were in that ratio.

Erwen (J. Soc. Chem. Ind. 1907, 26, 501–502) makes solutions in the cold with the help of sodium hydroxide, and determines their viscosities in a Redwood viscosimeter. The weighed sample of starch is shaken continuously with 230 c.c. of cold water, and 15 c.c. of a 10 p.c. solution of sodium hydroxide with the addition of enough water to bring the whole up to 250 c.c., until the solution begins to thicken. It is allowed to stand until the next morning before measurement. When close attention is paid to constancy of procedure the method is claimed to give concordant results with the same starch, whilst different starches and different brands of the same starch are easily differentiated.

As has already been stated, starch paste is composed of granulose or amylose, which exists in a state of partial solution, and starch cellulose or amylopectin, a mucilaginous substance to which the viscosity of the paste is due. The sp.gr. of starch paste, as determined by Brown and Heron, is 1·66 at 15·5°. It is one of the most perfect colloids known, as, since its solution-molecule is extremely large, its passage through the fine pores of filter-paper is very difficult. It rotates a ray of polarised light strongly to the right, but owing to the want of transparency in the liquid, the determination of its specific rotatory power is exceedingly difficult, it being impossible to obtain good observations with solutions of even very pure starch containing more than 1 grm. of substance per 100 c.c. The mean of Brown and Heron's observations from solutions of this strength give $\alpha_j=208°$, but it is possible that this number is too high, owing probably to the presence of a small portion of soluble starch, which evidently possesses a higher rotation, for the above authorities state that if a dilute solution of starch paste (1 grm. per 100 c.c.) be boiled for 30 minutes the liquid becomes more transparent, and at the same time an increase in the rotation is observed.

9. *Soluble starch.* Under certain conditions starch undergoes a peculiar modification, by which it is rendered completely soluble in water from which it can be precipitated as a brilliant white flocculent substance by alcohol, or if the solution be somewhat concentrated and allowed to stand some time a white granular precipitate slowly separates out. Under these conditions, the precipitate is always found by microscopic observation to be made up of minute particles, entirely without structure and without action on polarised light. Lintner found, however, that when a dilute solution is submitted to a low temperature, it is possible to obtain this precipitate in the form of sphærocrystals.

Although but sparingly soluble in cold water (not more than 2 or 3 grms. per 100 c.c. ever going into solution), it readily dissolves in water at 60°–70°, and separates out again on cooling as a white flocculent amorphous precipitate. To this substance has been given the name 'soluble starch.'

When washed with alcohol and dried the precipitated starch becomes very friable, but after once being dried is almost completely insoluble in water.

When starch paste is largely diluted with water and boiled for some considerable time, a portion of it goes into solution and may be easily filtered off. A similar reaction may be brought about more rapidly if starch with about ten times its weight of water be heated under pressure up to 130°–150° (Stumpf, Bied. Zentr. 1880, 457). Under these conditions the greater portion of the starch is rendered soluble, and corresponds to the solutions of Maquenne and Roux's so-called amylose which enters into solutions at this temperature.

The same effect may be brought about by treating potato starch with a 5–10 p.c. solution of hydrochloric acid for 7–10 days (Lintner, J. pr. Chem. 1886, 34, 378); the starch granules are then washed until free from acid, and on treating with boiling water, dissolve completely without the production of the usual viscid paste. This extraordinary change in the properties of the granules is not accompanied by the slightest change of structure, and the altered granules have the same appearance under the microscope and the same influence on polarised light as the unaltered starch.

Soluble starch may be prepared, according to O'Sullivan, as follows: Starch paste is acted on with the least possible quantity of the cold water extract of malt, previously heated to 75° for 30 minutes, or with diastase solution, or with dilute sulphuric acid (sp.gr. 1·120) at 75°, and further action stopped as soon as limpidity is produced by raising the liquid quickly to the boiling-point if diastase or malt extract be employed, or by adding barium carbonate if sulphuric acid has been used, until neutrality is produced. The liquid is then filtered and evaporated until a slight skin begins to form on the surface; when the soluble starch falls out on cooling as a brilliant white precipitate. This is allowed to rest for a few days, and then treated with cold water, with which it is washed well upon a filter. It is purified by dissolving it in as small a quantity of boiling water as possible, and again filtering, if necessary using a hot-water funnel. On cooling, the soluble starch separates from the filtrate as before.

Perhaps the readiest way of preparing soluble starch is that recommended by Zulkowski (Chem. Zentr. 1888, 1060), who finds that starch dissolves in hot glycerol and is converted into the soluble modification; this, in turn, if the action be continued, becoming transformed into erythrodextrin and achroodextrin, with the production at the same time of reducing sugars. 60 grms. of dry-potato starch are heated for half an hour with 1 kilo. of glycerol at a temperature of 190°, then cooled down to 120°, and the soluble starch precipitated by the addition of two or three times its volume of strong alcohol. If necessary, the precipitate may be further purified by dissolving again in the smallest possible quantity of boiling water, and reprecipitating therefrom with 90 p.c. alcohol.

Soluble starch has been prepared by treating starch granules with a 1 p.c. solution of caustic soda (Wroblewski, Ber. 1897, 30, 2108); and Syniewski has also prepared it by treating potato starch suspended in water with sodium peroxide (*ibid.* 1897, 30, 2415). This product is soluble in cold water up to 12·5 p.c., and dissolves in hot water in any proportion. Soluble starch prepared in this way, however, appears to be quite distinct from that prepared according to Lintner's method.

Pure soluble starch prepared by the methods of Lintner and O'Sullivan, when in solution, rotates a ray of polarised light strongly to the right. Brown and Morris find its specific rotatory power to be $[\alpha]_{j3\cdot86}+216°$, $[\alpha]_{D3\cdot86}+195°$. Lintner gives it as $[\alpha]_D+200°$, and Brown, Morris, and Millar give a value in 2·5–4·5 p.c. solutions at 15·5° of $[\alpha]_D+202°$.

E. Fouard has carried out some interesting investigations with regard to starch solutions and soluble starch, but space does not permit any further description (*cf.* Compt. rend. 1908–1909; Seventh Internat. Cong. App. Chem. 1909).

Soluble starch has no action whatever on Fehling's solution, and, like starch paste, its solution is coloured an intense blue with iodine.

10. *Action of alkalis.* When a moderately-strong solution of potassium or sodium hydroxide is added to starch paste, the previously opalescent liquid is rendered perfectly transparent without any alteration taking place in its viscosity. This increase in transparency is due to the solution of the suspended starch cellulose by the alkali. The specific rotatory power is at the same time considerably lowered, but resumes its original value if the alkali be neutralised by acetic acid. These facts point to the production of a definite compound of starch with potash or soda. An interesting feature in this reaction is that, after acidification, the solution remains transparent, and possesses all or nearly all the viscosity of the original starch paste (Pfeiffer and Tollens, Annalen, 1882, 210, 285; Brown and Heron, Chem. Soc. Trans. 35, 596).

When starch is treated with an alkaline

solution the granules swell up and form an exceedingly tough viscous mass, which readily dissolves in water, forming a solution in no way differing from that produced by the action of alkali on starch paste.

Symons (Pharm. J. [iii.] 13, 237) has investigated the process of swelling of starch granules under the action of heat at different temperatures, and of alkaline solutions of varying strengths, and concludes that the process of swelling through the action of these widely-differing agents is one and the same, and, as a result of his experiments, proposes a method whereby the several varieties of starch may be detected by their behaviour with dilute alkaline solutions of definite strength.

The most suitable are solutions of caustic soda of 0·5–1·5 p.c. 0·1 grm. of the starch is repeatedly stirred up with 1 c.c. of the particular soda solution, and, after 10 minutes, examined under the microscope.

Ammonia solution, either dilute or concentrated, has no action whatever on starch or on starch paste.

If a trace of starch be added to a solution of a salt of ammonia, and then a solution of sodium hydroxide drop by drop, the starch remains unchanged until the whole of the ammonia salt has been decomposed; but the least excess of soda causes immediately an expansion of the starch granules.

Tables IV. and V. give the results of Symon's experiments for various starches.

TABLE IV.—*Action of heat on starch granules.*

Variety of starch	Order of relative size of granules	Few granules swollen at	Majority of granules swollen at	All granules swollen at
		°C.	°C.	°C.

Starch exhibits a peculiar reaction with ammoniacal copper solution. Dry starch readily absorbs cupric oxide from ammonio-cupric oxide solution, and decolorises the liquid, the action being more rapid if the starch has previously been slightly moistened. Starch paste acts in a similar manner. A deep-blue compound is formed, from which water, and even dilute ammonia, remove only traces of copper. Repeated washing, however, with strong ammonia eventually removes every trace of copper (Guignet, Compt. rend. 109, 528).

Dilute hydrochloric acid immediately decomposes this compound, forming cupric chloride, which may be readily removed by washing with water, leaving the starch granules intact.

After prolonged digestion with strong ammonia in the cold, the granules swell up and become converted into the soluble modification.

TABLE V.—*Action of dilute NaHO on starch granules.*

Variety of starch	Order of relative size of granules	Few granules swollen with	Majority of granules swollen with	All granules swollen with
		p.c.NaHO	p.c.NaHO	p.c.NaHO

On heating the compound of cupric oxide and starch with water at 80° the starch gelatinises, forming with the cupric oxide a beautiful blue viscous liquid.

Starch possesses the property of combining with other bases than sodium and potassium. If to the transparent colourless jelly formed by acting on starch with sodium hydroxide, a 7 p.c. aqueous solution of calcium chloride be added, double decomposition takes place, and a thick, white, insoluble mass is formed, which is a compound of starch with calcium. A series of compounds of starch with other bases may similarly be formed, in which the starch cannot be detected by means of iodine. The starch in such compounds is, however, immediately set free by acids (Payen).

Starch is completely precipitated from a dilute aqueous solution by a solution of lime in sugar-syrup. The composition of the precipitate varies according to the quantity of lime added. With baryta and strontia water similar compounds are formed (C. J. Lintner, Zeitsch. angew. Chem. 1888, 232).

11. *Action of acids.* A swelling of the starch granules, similar to that occasioned by sodium or potassium hydroxide, is produced immediately by all mineral acids, and by some organic acids, *e.g.* tartaric and citric acids, after being in contact for some time. No swelling is produced by acetic or oxalic acids, no matter how concentrated their solutions may be.

When air-dried starch is triturated with concentrated sulphuric acid considerable heat is evolved, and, after a short time, complete carbonisation takes place. If, however, the starch be previously freed from moisture, on addition of the acid the granules swell up and form certain mucilaginous compounds of the general formula $C_{6n}H_{10m}O_{5n-x}(SO_4)_x$, which are soluble in water, and rotate a ray of polarised light strongly to the right. When boiled with alcohol they lose all the sulphuric acid, leaving a modified form of starch. Upon neutralising the aqueous solution with bases, uncrystallisable salts are formed (Hönig and Schubert, Monatsh. 6, 768).

When diluted sulphuric acid 1 : 2 to 1 : 4 is added to air-dried starch, a swelling up of the granules takes place, and the mass becomes thick and viscous. On standing some hours the viscosity disappears, the iodine reaction showing the presence of soluble starch only; but on standing for some days this becomes gradually hydrated to maltose, and finally to dextrose.

Nitric acid yields with starch various products, depending on the strength of the acid, temperature, and duration of the action.

When starch is boiled for some time with moderately concentrated nitric acid (sp.gr. 1·200) it is completely converted into oxalic acid. Cold concentrated nitric acid (sp.gr. 1·520) added to starch causes the granules to swell up, first into a viscous mass, which after a short interval becomes quite limpid; if now water be added to this solution, according to Braconnot (Annalen, 7, 245), a white powder is precipitated which when dry explodes upon being struck. This substance has been termed *xyloïdin*, and has the same composition as the corresponding compound of cellulose.

If, however, the solution of starch in nitric acid be allowed to stand, water precipitates less and less of xyloïdin, and at last none, whilst a substance resembling saccharic acid remains in solution (Pelouze, Compt. rend. 7, 713).

When starch is heated with a mixture of nitric acid and fuming sulphuric acid containing some 2–3 p.c. of free SO_3 at a temperature of 45°–50° a starch nitrate having a formula $C_{12}H_{12}(NO_2)_8O_{10}$, and containing about 16·5 p.c. of nitrogen, is formed. It is an orange-coloured highly explosive powder, and is soluble in ether-alcohol.

Strong hydrochloric acid added to dry starch causes the granules to swell, and in a very short time to become a thick, semi-translucent, viscous mass. If to this a large quantity of cold water be added, a milky fluid results, which consists entirely of the soluble modification. If, however, the swollen mass be allowed to remain for a few days, the soluble starch will be found to have entirely disappeared, whilst at the same time the viscous mass becomes perfectly limpid, and separates into two layers, the lower one consisting of the products of decomposition of the granulose—namely, achroodextrin, maltose, and dextrose—whilst the upper layer consists exclusively of starch cellulose.

If, however, the action of very dilute (1–2 p.c.) mineral acids, such as sulphuric or hydrochloric, upon ungelatinised starch in the cold be allowed to continue for some considerable time (two months or more), the granules gradually become disintegrated, a portion becoming converted into dextrose and going into solution, whilst the residual substance retains little or nothing of the original form of the starch granule. Concurrently with these changes, the iodine reaction undergoes considerable modification, the original deep-blue colour gradually giving place to purple, and this, through reddish-purple and reddish-brown, to a pale yellowish-red, which is not further modified, even if the starch remain in contact with the acid for some years. This residual substance, after being washed with cold water until free from acid, is completely soluble in hot water, from which it may be precipitated by alcohol in the form of a brilliant white powder, which is highly crystalline in appearance when the precipitation has taken place slowly. This, under the microscope, is seen to consist of sphæro-crystals made up of thin needles or plates arranged radially, and so closely resembling the sphæro-crystals of inulin that the two substances cannot be distinguished by microscopical examination alone. This substance has been termed amylodextrin by Nägeli. It gives an intense reddish-brown colouration with iodine (Brown and Morris, Chem. Soc. Trans. 55, 449).

The further action of acids on starch differs very considerably according to the degree of concentration, temperature, and pressure.

When starch is heated to boiling with very dilute acids (2 p.c.), little or no formation of paste takes place, the starch being rapidly converted first into soluble starch, then into dextrin and maltose, and, if the action be sufficiently prolonged, finally into dextrose. If this action be stopped at various stages by neutralising the acid with calcium or barium hydroxide, and the filtrates examined at a very early period, the liquid will be found to consist almost entirely of a solution of soluble starch. Later on, this disappears, giving rise to dextrin and maltose; and, according to Brown, Morris, and Moritz (Eng. Pat. 19003, 1889), to a series of intermediate bodies known as maltodextrins. A little later, dextrose makes its appearance, and this continues to increase at the expense of the maltose already formed, the dextrins and maltodextrins being successively hydrated to this body, until finally dextrose only is found in solution. If, however, the action be carried to this extreme point, the dextrose in its turn is acted upon by the acid, giving rise to condensation products, caramel, and other humous substances (Valentin, Jour. Soc. Arts, 24, 404; Scheibler and Mittelmeier, Ber. 23, 3060).

At temperatures higher than 100°, or under pressure, the above changes take place very rapidly. Tables VI. and VII. give some idea of these relative changes.

12. *Action of chlorine, bromine, and iodine.* Chlorine gas has no action on starch granules either in the dry state or when moistened with water, but when passed through thin starch paste for some hours the viscosity disappears, the greater portion of the granulose becoming converted into soluble starch and erythrodextrin; this action takes place slowly in the cold, but quickly at a high temperature.

Bromine colours starch granules yellow, but does not seem to form any definite compound, as the yellow colour disappears on repeatedly washing the granules with water.

Very little action is produced on starch paste by bromine in the cold, but if heated on the water-bath for some time the starch paste is liquefied and converted into the soluble form.

The most characteristic reaction for starch, wherever it occurs, is the production of a deep-blue colouration with a solution of iodine. This colouration is imparted by the iodine to the granulose in the intact starch granules as well as when in the condition of starch paste and of soluble starch. This iodine reaction was discovered as far back as the year 1813 by

Stromeyer, and has been the subject of much investigation since then.

When an aqueous solution of iodine is added to starch paste an intense deep indigo-blue colouration is produced. This blue colouration—which is a most characteristic test for starch, not being produced by any other known body—is due to the formation of a definite chemical compound, or probably more than one compound, of iodine and starch granulose, and is provisionally termed iodide of starch.

It is best prepared by adding an excess of iodine to a thin solution of starch; iodide of starch then separates out as a blackish-violet powder, which, when washed, to free it from excess of iodine, and dried, presents the appearance of a black shining mass exhibiting a coppery lustre. Perfectly dry iodide of starch may be heated for several days to a temperature of 100° without undergoing decomposition; it may, therefore, be regarded as a very stable body. In the presence of moisture, however, it is decomposed, with, if heated in closed vessels, formation of hydriodic acid, whilst, if it be heated in open vessels, part of the iodine is volatilised, the remainder being converted into hydriodic acid.

Iodide of starch is also formed when dry starch and an alcoholic solution of iodine are triturated in a mortar, provided the alcohol contains water; with absolute alcohol a brown colour is produced, which, on addition of water, changes to blue. Iodide of starch is not formed when iodine vapour is passed over dry starch, but by using moist starch the iodide is formed; from this it would appear that water is necessary to the formation of iodide of starch (Stocks, Chem. News, 56, 212; 57, 183).

It is also formed from a mixture of potassium iodide and starch paste by the action of such reagents as liberate iodine from its compounds. Such are chlorine, bromine, nitric acid, strong sulphuric acid, ferric chloride, potassium permanganate, &c., all of which cause the characteristic blue colour to appear. The blue colour of iodide of starch is destroyed in presence of excess of chlorine or bromine, owing to the formation of iodine chloride or bromide.

Starch granules have a greater attraction for iodine than unorganised starch. Hence a cold clear solution prepared from crushed starch granules, and coloured blue by iodine, is completely decolorised by adding whole starch granules; similarly starch granules attract iodine more energetically than dextrin (Bruckner, Monatsh. 4, 889–912).

Iodide of starch is soluble only in a large quantity of water, but as ordinarily prepared from starch paste it is an opaque mass, and when examined under the microscope presents the appearance of blue flocculent masses of the iodide floating about in the liquid portion. In this state the blue colour is destroyed by heat (Stocks, Chem. News, 56, 212; Tomlinson, Phil. Mag. [v.] 50, 168), but the change is gradual, the liquid becoming first greenish, then yellowish, and finally colourless, and if at this point it be allowed to cool the blue colour does not again appear, although it does so if the heating be discontinued at the yellowish stage and the liquid be allowed to cool; this decolorisation is due to the formation of hydriodic acid.

When iodide of starch does not contain an excess of iodine, alcohol, ether, carbon disulphide, or benzene fail to extract any iodine from it; if, however, the iodide be heated with alcohol it becomes rapidly decolorised, ethyl iodide being formed at the same time.

The colour produced by iodine and starch grains has been found to vary slightly with the nature of the starch, potato starch giving a deep blue, whilst wheat starch gives a colour inclining somewhat to violet.

The exact composition of starch iodide has not been definitely settled. According to F. Mylius, iodide of starch contains 19·69 p.c. of iodine, and has the formula $(C_{24}H_{40}O_{20}I)_4HI$; whilst F. Seyferth finds 18·56 p.c. of iodine, formula $(C_{24}H_{40}O_{20})_6I_7$; and G. Rouvier fixes the iodine content at 19·6 p.c., and formula $(C_6H_{10}O_5)_{16}I_5$.

Syniewski deduces the formula of the iodide from his experiments, making use of his formaldehyde amylodextrin

$$[(C_{54}H_{90}O_{45}+1\tfrac{1}{2}H_2O)I_3]_4,$$

which corresponds with 20·5 p.c. of iodine. He suggests that the iodine probably attaches itself to the terminal CH_2OH groups (see The Constitution of Starch, v. Syniewski, Annalen, 1902, 324, 212–268).

Harrison (Chem. Soc. Proc. 1910, 26,

252–253) has put forward a new theory to explain the starch-iodine reaction. He finds that the presence of iodides is not necessary for the formation of starch iodide, but the depth of colour is increased by the presence of any salt or weak acid. The gradual addition of alcohol changes the blue to violet, red, orange, and yellow, the reverse change taking place on dilution with water. The same colour change is produced by carefully heating the blue solution, the reverse phenomena being observed on cooling.

He shows that all the iodine can be removed from starch iodide by washing with pure water, and draws the conclusion that the blue solution of iodine and starch is a colloidal solution of iodine, the starch acting as a protective colloid.

13. *Action of other reagents.* Potassium permanganate exercises a powerful reducing action on starch, but instead of dextrin a series of gummy acids are produced, which reduce Fehling's solution only to a very slight extent. Powdered potassium permanganate is added to a 2½ p.c. starch paste; much carbonic acid is evolved, and manganese dioxide precipitated. The solution is filtered, neutralised with acetic acid, concentrated lead acetate solution added, the resulting precipitate washed with hot water, decomposed with hydrogen sulphide, the solution concentrated and poured into absolute alcohol, when a curdy precipitate is formed. This is washed with absolute alcohol and ether, and dried *in vacuô* over sulphuric acid. The bodies formed possess dextrorotatory powers, which vary according to the quantity of permanganate employed, and give reactions with iodine from reddish-violet, through reddish-brown, to brown. The elementary analysis of a product which was not coloured by iodine agreed with the formula $C_{12}H_{22}O_{11},C_{12}H_{20}O_{10}$ (Lintner, Zeitsch. angew. Chem. 1890, 546).

Formaldehyde cause the starch grains to gradually swell to a thick jelly, which ceases to give a colouration with iodine, becoming limpid after several days, and capable of filtration after a few months. This filtrate, when allowed to evaporate spontaneously, solidifies to a crystalline mass, which is a compound of starch and formaldehyde and polymerised formaldehyde. When warmed both free and combined formaldehyde volatilise, leaving a substance which gives a blue colour with iodine, and which, on analysis, gives values agreeing with the formula

$$[C_{54}H_{90}O_{45}+1\tfrac{1}{2}H_2O]_4,$$

and which Syniewski considers to be identical with his amylodextrin. The action of formaldehyde in a concentrated solution of starch is considered to be a carbinol hydrolysis, the product 'formaldehyde amylodextrin' being hydrolised with extreme ease (*v.* Syniewski, Annalen, 1902, 324, 201).

When chloroform is added to a solution of starch in zinc chloride and allowed to remain three months the whole of the starch is converted into dextrin.

When starch paste is treated with chloroform a soluble modification of starch similar to that obtained by the action of hydrochloric acid is formed, and on heating a mixture after some months the starch dissolves and separates as a fine paste on cooling.

On shaking 1 part of starch with 100 parts of a solution of chloral hydrate (10 parts water to 7 parts chloral hydrate) an almost clear viscous solution is obtained, which does not give a blue colouration with solid iodine or a solution of iodine in chloral hydrate.

Tannic acid gives a flocculent leathery precipitate with starch paste, as well as with soluble starch, which is soluble in boiling water but is reprecipitated on cooling.

14. *Action of enzymes.* Certain enzymes exert a most powerful action on gelatinised starch, as well as on some of the varieties of starch in the raw state. Of these, the most active are the diastase of malted barley, the saliva, and the pancreatic juice.

If the action of a solution of any one of these ferments on starch paste be watched, the first effect produced will be complete liquefaction of the paste, and the production, in an incredibly short space of time, of a perfectly limpid liquid. At this instant, if the liquid be tested with iodine, a reaction for pure soluble starch may be observed; immediately following this comes the saccharification of the soluble starch. The blue colour produced by iodine disappears, giving place to a reddish-brown colour, indicating the presence of erythrodextrin, which in turn becomes transformed into achroodextrin, when iodine ceases to impart any longer a colour to the liquid. At the same time, concurrently with the disappearing of the starch, the proportion of sugar goes on increasing, and continues to do so for a considerable time after the iodine has ceased to show any reaction.

Although starch in some form or other enters so largely into the food of man and beast, it was not until early in the last century that it received any attention from the hands of chemists. Since that time, however, much attention has been bestowed upon the changes which it undergoes under the influence of heat, acids, and certain vegetable and animal extracts, and much valuable information has resulted therefrom.

Considering the very important part which starch plays in several industrial processes on the one hand, and how a careful study of its various transformations serves to throw very considerable light upon many questions connected with vegetable, as well as animal, physiology, it will, perhaps, not be altogether out of place to give, as briefly as possible, a history of the transformations of starch from the earliest up to the present time.

15. *History of starch transformations.* In the year 1811 Vauquelin discovered that when starch is heated to a high temperature it is converted into a substance completely soluble in water, and which resembles gum arabic in many of its physical properties. In the following year Vogel found that a similar substance is formed when starch is acted upon by hot dilute acid. About the same time, Kirchoff discovered that starch, when boiled with dilute sulphuric acid, yields a crystallisable sugar; and two years later, in 1814, the same chemist observed that a similar transformation is brought about by the action of the vegetable albumin of grain, and also that the action of this substance is much intensified by subjecting the grain to the malting process.

The gummy substance produced from starch by the action of dilute acid was first carefully examined in 1833 by Biot and Persoz, who gave to it the name of *dextrin*, from the property which it possesses of rotating a polarised ray of light strongly to the right.

Biot and Persoz did not look upon dextrin as a decomposition product of starch, but considered it rather as consisting of the contents of the starch granules freed from their outer coating by the action of the acid. Payen and Persoz—sharing the same view as to the formation of dextrin from starch by the action of an infusion of malted grain, and which they attributed to the presence of a particular transforming agent—named it *diastase*, from its supposed property of separating the interior of the starch granules from their outer envelope. They were the first chemists who prepared dextrin from starch by the action of diastase, and describe it as a substance soluble in cold water and in weak alcohol, and as not coloured by iodine. A few years later Payen stated that the specific rotatory power of his dextrin was equal to that of starch, and that its elementary composition was indicated by the formula $C_6H_{10}O_5$.

He also came to the conclusion that the dextrins produced by the action of dilute sulphuric acid, diastase, and heat respectively were simply physical modifications of one and the same substance.

Up to the year 1860, dextrin was considered as occupying an intermediate position between starch and sugar, the starch being first converted into dextrin, and this, by subsequent hydration, into sugar. But at this period, Musculus brought forward evidence to prove most conclusively that dextrin and sugar are not successively formed products, but are produced simultaneously by a splitting up of the starch molecule. This theory, which met with strong opposition at first, is now generally admitted to be in the main correct.

The dextrin described more in detail by Musculus in 1865 was a body not coloured by iodine, and did not reduce Fehling's solution. It now began to be recognised amongst chemists that there are at least two dextrins derivable from starch—the one coloured red by iodine, and the other giving no colouration with that reagent. These were described by Griessmayer in 1871 as dextrin I. and dextrin II., and in the following year O'Sullivan distinguished them as α and β dextrin. These are now more generally referred to as erythrodextrin and achroodextrin respectively, names first proposed by Brücke in 1872 as indicative of their behaviour with iodine.

In a series of most interesting and important researches extending from 1872 to 1876 (Chem. Soc. Trans. 25, 579; 29, 479; 30, 125), O'Sullivan proved most satisfactorily that the sugar produced by the action of diastase or acid on starch is not, as had up to this time been generally supposed, dextrose, but is a sugar of the saccharose type, having a considerably higher specific rotatory power than dextrose, and a much less reducing action upon Fehling's solution.

This body had been previously isolated, as far back as the year 1819, by De Saussure, who, however, merely described its crystalline appearance. It was prepared in 1847 by Dubrunfaut, who, from its optical properties, recognised it as a distinct sugar and named it *maltose*. His observations, however, obtained but little notice at the time of their publication, and appear to have been entirely forgotten until the re-discovery of maltose by O'Sullivan in 1872 (Chem. Soc. Trans. 25, 579). This investigator also gave the results of his examination of the dextrins prepared by the action of diastase and of acid upon starch. These results led him to the conclusion that the dextrins from both sources possess the same specific rotatory power of $[\alpha]_j = +213°$, and have an elementary composition corresponding to the formula $C_6H_{10}O_5$, and although he did not succeed in obtaining any of the dextrins absolutely free from a reducing action on Fehling's solution, yet he adduced good evidence to show that in a state of purity they would possess no reducing action. Both of these dextrins are slowly converted into maltose by the action of diastase.

In 1875 Bondonneau, apparently unaware of the previous work of O'Sullivan, described three dextrins, which he denotes as α, β, and γ dextrins respectively. The first of these corresponds to O'Sullivan's α dextrin and Brücke's erythrodextrin, whilst β dextrin appears to be an achroodextrin. Both of them possess a much lower specific rotatory power than O'Sullivan's, doubtless owing to not being as completely purified. There can now be no doubt that his γ dextrin was nothing more or less than maltose, and as Bondonneau regarded the reducing sugar formed throughout to be dextrose, it is easy to understand that he should fall into such an error with regard to his γ dextrin.

The properties of dextrin and maltose having been thus definitely established, and it having been shown conclusively that these two substances were the only products obtained by the action of diastase upon starch paste under ordinary conditions, the attention of investigators was turned to the influence of time and temperature upon the reaction by which these substances are produced, so that in the history of starch transformation a new field of research was opened up in 1876 by O'Sullivan (Chem. Soc. Trans. 30, 125). According to this investigator, starch granules which are intact are unacted upon by diastase or the cold water extract of malt; gelatinised starch, however, either in the cold or at temperatures up to 72° is readily transformed. He also established the fact that the transformation of starch into dextrin and maltose is not a gradual act of hydration, the dextrin appearing first and the maltose afterwards, but that the two bodies are formed simultaneously, and in certain proportions according to the conditions under which the starch molecule splits up. On this assumption, the splitting up of the starch molecule by diastase takes place according to certain definite equations, the relative proportion of the decomposition products depending upon the temperature at which the transformation takes place, so that, starting with soluble starch, it is possible to obtain a series of equations, each succeeding one containing a molecule less of dextrin and a molecule more of maltose than the one immediately preceding it until we arrive at the final equation. According to O'Sullivan, the following reactions take place:—(*a*) When starch is acted on by malt extract at any temperature below 63°, if the solution be immediately (5–10 minutes) cooled and filtered, the product invariably contains maltose and dextrin in proportions closely agreeing with 67·85 p.c. of the former and 32·15 p.c. of the latter; $K=44\cdot1$, $[\alpha]_j=170\cdot6°$, and this reaction is represented by O'Sullivan's equation A.

$$\underset{\text{Starch}}{(C_{12}H_{20}O_{10})_6}+4H_2O=\underset{\text{Maltose}}{(C_{12}H_{22}O_{11})_4}+\underset{\text{Dextrin}}{(C_{12}H_{20}O_{10})_2}$$

(*b*) When starch is acted on by malt extract at any temperature between 64° and 68°–70°, if the solution be immediately cooled and filtered the product invariably contains maltose and dextrin in proportions agreeing closely with 34·54 p.c. of the former and 65·46 p.c. of the latter; $K=22\cdot4$, $[\alpha]_j=191\cdot8°$, and corresponding to the equation B.

$$\underset{\text{Starch}}{(C_{12}H_{20}O_{10})_6}+2H_2O=\underset{\text{Maltose}}{(C_{12}H_{22}O_{11})_2}+\underset{\beta\text{ Dextrin}}{(C_{12}H_{20}O_{10})_4}$$

(*c*) When starch is acted on by malt extract at temperatures from 68°–70°C. to the point at which the activity of the transforming agent is destroyed, if the solution be cooled and filtered at the end of 5–10 minutes, the product contains maltose and dextrin in proportions agreeing closely with 17·4 p.c. of the former and 82·6 p.c. of the latter; $K=11\cdot3$, $[\alpha]_j=202\cdot8°$, and corresponding to equation C.

$$\underset{\text{Starch}}{(C_{12}H_{20}O_{10})_6}+H_2O=\underset{\text{Maltose}}{C_{12}H_{22}O_{11}}+\underset{\alpha\text{ Dextrin}}{(C_{12}H_{20}O_{10})_5}.$$

O'Sullivan considers that the formula for soluble starch must be at least six times the $C_{12}H_{20}O_{10}$ molecule, and that it, as well as the dextrins which are produced from it by the action of diastase, are a series of bodies of the same molecular weight in which the difference in their behaviour to this agent must be accounted for by a difference of relation in the arrangement of the molecules to one another, probably in solution alone.

In 1879 Brown and Heron (Chem. Soc. Trans. 35, 596), whilst confirming to a large extent O'Sullivan's results, came to the conclusion that the transformations of starch are to be represented by at least ten equations, of which they considered that their experiments substantiated at least four well-defined molecular transformations, by far the best-defined and most stable being the reaction obtained when starch paste is heated with malt extract at 60° for 30 minutes,

$$K_{3\cdot86}=49\cdot3,\ [\alpha]_{j3\cdot86}=162\cdot5°.$$

The next fixed point is that of the disappearance of the iodine reaction for erythrodextrin when starch paste is transformed with malt extract heated to 66°. This takes place when $K_{3\cdot86}=25\cdot0$ and $[\alpha]_{j3\cdot86}=188\cdot5°$ or thereabouts, and is very constant with varying quantities of malt extract.

The next strongly-marked reaction is that obtained with malt extract heated to 75°, the numbers obtained being $K_{3\cdot86}=18\cdot9$, $[\alpha]_{j3\cdot86}=195°–196°$.

The highest stable transformation is obtained by the action of malt extract heated to 66° and made very slightly alkaline with sodium hydroxide, the same reaction being also marked in all transformations above 66° by the appearance of the maximum iodine colouration for erythrodextrin, the numbers for this transformation $K_{3\cdot86}=12\cdot7$ and $[\alpha]_{j3\cdot86}=202°–203°$ are very nearly those of O'Sullivan's equation C.

It was also found that when higher conversions are treated with unheated malt extract at 50°–60° they are very rapidly converted into the lower form $K_{3\cdot86}=49\cdot3°$, $[\alpha]_{j3\cdot86}=162\cdot5$, at which points these factors remain for a time constant.

Brown and Heron conclude that the dextrins are not metameric but polymeric bodies; those corresponding to transformations of high optical activity being of greater molecular complexity than those yielded by transformations of lower optical activity, the latter being produced from the former by a partial act of hydration with consequent elimination of maltose. About the same time Musculus and Gruber (Bull. Soc. chim. [ii.] 30, 69) brought forward a similar theory. They look upon starch as a polysaccharide, having for its formula $n(C_{12}H_{20}O_{10})$, and undergoing under the influence of diastase successive hydrations and decompositions.

As the result of their experiments Brown and Heron were led to adopt the formula $10(C_{12}H_{20}O_{10})$ for soluble starch.

The first action of the transforming agent upon this complex and unstable molecule results in the removal by hydration of one of the groups of $C_{12}H_{20}O_{10}$, thus producing maltose, whilst the remaining nine groups, $C_{12}H_{20}O_{10}$, constitute the first dextrin of the series, erythrodextrin *α*. This dextrin, in its turn, on further hydration splits up into a molecule of maltose and erythrodextrin *β*, consisting of eight $C_{12}H_{20}O_{10}$ groups, and so in this way the degradation of the original molecule proceeds, until by successive stages of hydration the lowest equation is reached. The following table represents these transformations:—

TABLE VIII.

No. of Transformation	Maltose	Dextrin	$[\alpha]_{j3\cdot86}$	$K_{3\cdot86}$
Soluble starch .	0	0	216·0	0
Equation 1 .	10·4	89·6	209·0	6·4

Maltose . .	100·0	0·0	150·0	61·0

In 1879 Herzfeld (Ber. 1879, 2120) found that in addition to maltose and dextrin a third substance, maltodextrin, was under certain circumstances formed by the action of diastase upon starch paste. This compound was regarded by him as being intermediate between achroodextrin and maltose; it was insoluble in alcohol of 90 p.c., and completely fermentable by yeast, possessing a specific rotatory power $[\alpha]_j=171\cdot6$, $K=23\cdot5$. It was further investigated by Brown and Morris (Chem. Soc. Trans. 47, 527). They found that when the action of malt extract on starch paste is limited there is always found amongst the products of transformation, besides maltose and dextrin, a third substance which is more soluble in alcohol than the dextrins, and has a specific rotatory power of $[\alpha]_{j3\cdot86}=193\cdot1$ and a cupric reducing power of $K_{3\cdot86}=21\cdot1$, corresponding to an apparent composition of 34·6 p.c. maltose and 65·4 p.c. dextrin. It is completely hydrated to maltose by the action of malt extract at 50°–60°.

Maltodextrin is not fermentable by yeast (*S. Cerevisiæ* of the high fermentation), but is slowly hydrolysed into maltose and thus rendered fermentable by certain forms of saccharomyces of the secondary fermentation (*S. Pastorianus*, *S. ellipticus*). Brown and Morris considered that maltodextrin was not, as supposed by Herzfeld, a mere hydration product of achroodextrin, but was produced from starch and the polymeric dextrins by the fixation of a molecule of water upon the ternary group $(C_{12}H_{20}O_{10})_3$, of which there could not be less than five in the starch molecule, which resulted in the separation from the dextrin residue of maltodextrin

$$C_{12}H_{22}O_{11}.$$

This by the fixation of two more molecules of water gave rise to freely fermentable and crystallisable maltose.

Further experiments in connection with this subject have induced Brown and Morris to alter their views with regard to the dextrins (Chem. Soc. Trans. 53, 610; 55, 450, 462; Trans. Lab. Club. 3, 81), which they consider are, after all, not polymeric but metameric, and from their investigations they have built up the following hypothesis, which appears to them to be more in accord with the facts than any other yet propounded.

The starch molecule may be pictured as consisting of four complex amylin groups arranged round a fifth similar group constituting a molecular nucleus.

The first action of diastase is to break up this complex group and liberate all the five amylin groups. The central amylin nucleus, consequent on a closing up of the molecule, withstands the further influence of hydrolysing agents, and constitutes the stable dextrin of No. 8 equation. The four outer amylin groups are capable, when liberated, of being rapidly and completely converted into maltose by successive hydrolyses through a series of amyloïns or maltodextrins, the number of which is only limited by the size of the original amylin group.

In 1891 C. J. Lintner (Zeit. ges. Brau. 1891, 284) discovered a sugar amongst the products of starch hydrolysis, which yielded an osazone readily soluble in hot water, and melting at 152°–153°, which he called iso*maltose*.

Subsequently Lintner and Düll found that after the maltose had been removed from the products of starch conversion by fermentation, they were able by repeated precipitation with alcohol to resolve the unfermented matters into dextrin and *iso*maltose, no trace of an intermediary dextrin being found. They describe iso*maltose* as an intensely sweet tasting body having an optical rotatory power in a 10 p.c. solution $[\alpha]_D+139°–140°$ and $K=50\cdot63$. Their hypothesis of starch, transformed with diastase, starting from soluble starch, is as follows:—

I. $(C_{12}H_{20}O_{10})_{54}+3H_2O$
$=3[(C_{12}H_{20}O_{10})_{17}\cdot C_{12}H_{22}O_{11}]$.

II. $3[(C_{12}H_{20}O_{10})_{17}\cdot C_{12}H_{22}O_{11}]+6H_2O$
$=9[(C_{12}H_{20}O_{10})_5\cdot C_{12}H_{22}O_{11}]$.

III. $9[(C_{12}H_{20}O_{10})_5\cdot C_{12}H_{22}O_{11}]+45H_2O$
$=54C_{12}H_{22}O_{11}$ = Isomaltose.

IV. $54C_{12}H_{22}O_{11}$ = Maltose.

They considered that this action proceeded irregularly, some of the soluble starch molecules being broken down much more rapidly than others, the presence of maltose and the higher dextrins in high-angled transformations being explained by this means.

In 1892 Schifferer, working on the same lines as Lintner, practically confirmed his views with regard to *iso*maltose.

In 1893 Lintner and Düll described the properties of several bodies which they had isolated from the products of starch transformation after long and tedious fractionation with alcohol of different strengths. These were as follows:—

Amylodextrin. A loose white powder slightly soluble in cold water, readily soluble in hot water. $[\alpha]_D=+196$, does not reduce Fehling's solution, and gives a deep colouration with iodine, and is the principal constituent of soluble starch. The formula is given as $(C_{12}H_{20}O_{10})_{54}$.

Erythrodextrin. This body is readily soluble in water $[\alpha]_D=+196$, reducing power, R 1=1 p.c. that of maltose, and gives a reddish-brown colour with iodine. The formula given is

$$(C_{12}H_{20}O_{10})_{17}\cdot C_{12}H_{22}O_{11},$$

and it is formed from amylodextrin as follows:

$$(C_{12}H_{20}O_{10})_{54}+3H_2O=3[(C_{12}H_{20}O_{10})_{17}\cdot C_{12}H_{22}O_{11}]$$

Achroodextrin I. This dextrin is soluble in water; $[\alpha]_D+192$, reducing power R.10=10 p.c. that of maltose, and gives no colouration with iodine. The formula given is:

$$(C_{12}H_{20}O_{10})_5\cdot C_{12}H_{22}O_{11},$$

and it is formed from erythrodextrin as follows:

$$3[(C_{12}H_{20}O_{10})_{17}\cdot C_{12}H_{22}O_{11}]+6H_2O$$
$$=9[(C_{12}H_{20}O_{10})_5C_{12}H_{22}O_{11}].$$

Achroodextrin II. Only found in very small quantities in transformation products by the action of diastase $[\alpha]_D=+180$, reducing power R 24=24 p.c. that of maltose.

In 1895 Ost (Chem. Zeit. 1895, 1501) investigated the dextrins in a starch transformation, and isolated a dextrin having a rotatory power $[\alpha]_D=+180°–183°$, and reducing power R 28–33, and gave as its formula $C_{36}H_{62}O_{31}$. This he believed to be identical with Lintner and Düll's achroodextrin II., and to be contained in Brown and Morris' maltodextrin $[\alpha]_{D3\cdot86}+171°$ (R=34). He made the observation that it was improbable that dextrins of absolute purity could be prepared, as it is extremely probable that they may undergo some little change during the process of isolation.

In 1895 Ling and Baker (Chem. Soc. Trans. 1895, 43, 702) published the results of their investigations on the *iso*maltose discovered by Lintner, which threw much doubt on the existence of this product.

Working with diastase prepared from air-dried malt on the same lines as Lintner and Düll they obtained a substance having a sweet but by no means intensely sweet taste, with an optical rotatory power of $[\alpha]_{D3\cdot86}+144\cdot5°$, and $K=48\cdot59$. It yielded an osazone having a m.p. between 160° and 170°, and the results of its ultimate analysis and its molecular weight gave figures which indicated a disaccharide. When submitted to the action of diastase it showed an optical rotatory power of $[\alpha]_{D3\cdot86}$ $+131\cdot2°$, and $K=57\cdot64$, these changes not being accompanied by any change in the specific gravity of the solution. They concluded that Lintner's '*iso*maltose' was a mixture of maltose and a simple dextrin, having the formula

$$C_{12}H_{22}O_{10}+H_2O.$$

When working with diastase obtained from high-dried malt they obtained a substance yielding an osazone having a melting-point identical with Lintner's *iso*maltosazone, which analysis showed to be an osazone of a trisaccharide. They also found a certain amount of glucose was produced in transformations with diastase obtained from kiln-dried malts.

In a later paper, Ling and Baker (Chem. Soc. Trans. 1895, 43, 739) showed that the osazone obtained from the so-called *iso*maltose could be fractionated by recrystallisation into portions having melting-points corresponding to maltosazone and a substance which analysis indicated to be a disaccharide, and which they regarded as impure maltosazone. The presence of glucose was always detected in starch transformations with diastase from kiln-dried malt, but the osazones from the transformation products soluble in 90 p.c. alcohol were characteristic of Lintner's *iso*maltose, and gave analytical results between those required for the osazone of a disaccharide and that of a trisaccharide. It thus appeared as if a trisaccharide was a product of the action of diastase from kiln-dried malt. As an explanation of this they suggest that the trisaccharide might be formed by the condensation of a molecule of a simple dextrin with one of glucose under the influence of phenylhydrazine.

Brown and Morris, also in 1895 (Chem. Soc. Trans. 1895, 43, 702), published results of their investigations which threw doubt on the existence of *iso*maltose, first pointing out that it does not conform to their 'law of definite relation.' This law was the outcome of H. T. Brown's work in conjunction with others up to this date, and was as follows: The composition of the mixed products of a starch transformation by diastase or of any fractionated portions of such products can always be consistently interpreted in terms of maltose, having an opticity of $[\alpha]_{j3\cdot86}+150°$, and a reducing power of $K_{3\cdot86}$ 61, and a non-reducing dextrin having an opticity of $[\alpha]_{j3\cdot86}+216°$.

Lintner's *iso*maltose has an optical activity equivalent to $[\alpha]_j+156°$ and K 48·8. According to the law this optical rotatory power requires a reducing power of K 55·3; and a reducing power of K 48·8 requires an optical rotatory power of $[\alpha]_j+163\cdot2$. They came to the conclusion that *iso*maltose could be split up by fractionation, fermentation, &c., in such a manner as to indicate that it was a mixture of maltose and bodies of the amyloin type.

A study of the osazone led them to the belief that it was maltosazone modified in its crystalline structure and melting-point by the presence of an impurity, and they were able to compel maltosazone to crystallise in the *iso*maltose form by the addition of a trace of an amorphous product of the reaction. They found that 50–60 p.c. of *iso*maltose was fermentable, and their investigations led them to believe that the matter fermented was maltose, and the unfermented portion approaches very closely in composition that of an amyloïn containing two amylon groups and one amylin group.

In the same year Ost (Chem. Zeit. 1895, 1501), following the instructions of Lintner and Düll, made an attempt to isolate *iso*maltose. He found that their methods were not satisfactory, and after removing the maltose from the alcoholic extracts by means of crystallisation, he obtained osazones from the residue similar to those said to be characteristic of *iso*maltose, but which on further investigation proved to be maltosazone. He confirmed Ling and Baker's views, that mixtures of maltose and dextrin, when heated together, produced an osazone simulating *iso*maltosazone. No osazone was obtained in starch transformations where the whole of the maltose had been removed by fermentation, and from those in which a portion of the maltose had been left unfermented he obtained osazones similar to *iso*maltosazone. Ost's conclusions agreed with those of Ling and Baker, and Brown and Morris in that *iso*maltose has no real existence, and that the *iso*maltosazone of Lintner and Düll is modified maltosazone.

He came to the conclusion, after an investigation into the products of starch transformation by diastase, that starch itself has the composition $(C_{12}H_{20}O_{10})_n$, n indicating a large but unknown number. He freely criticises the results and theories put forward by previous workers, holding the non-reducing dextrin of Brown and Morris to be non-existent, and that their law of 'definite proportion' is not always fulfilled even in their own experiments, and is certainly not in the achroodextrin II. which he had prepared. He considers that the theory of Brown and Heron should have been entirely abandoned instead of being altered to the amyloin theory after maltodextrin and amylodextrin had been recognised as individual substances. He threw doubt on the molecular weight determinations, especially those of the higher dextrins, and regarded erythrodextrin as a mixture of starch and achroödextrin.

Mittelmeier (Zeitsch. angew. Chem. 1895, 552) put forward a theory based on his investigations that the starch molecule under the action of diastase is split up into two amylodextrins, which he terms primary and secondary erythrodextrin. The primary erythrodextrin is rapidly converted into maltose in the time that the secondary reached the stage in which it gives a red colouration with iodine, in this way he explains the presence of the highest dextrins and maltose in the same starch conversions. The optical rotatory power of these erythrodextrins is about $[\alpha]_D+170°$; they both reduce Fehling's solution and form osazones. Under the influence of diastase primary and secondary achroodextrins are obtained.

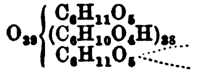
In 1897 Ling and Baker (Chem. Soc. Trans. 1897, 71, 509) gave some further results of an examination of the products of the limited action of diastase on potato starch paste at 70°. They obtained the following dextrins:

Maltodextrin-α $C_{24}H_{22}O_{11}$ (identical with that of Brown and Morris) having optical and reducing powers of $[\alpha]_D+180°$; R 32·81.

Maltodextrin-β $C_{24}H_{42}O_{21}$ (identical with a body isolated by Prior in 1896 (Bayer, Brauer, 1896, 157), which he termed achroodextrin III.) having the constants $[\alpha]_D+171{\cdot}6°$; R 43.

From the fraction designated *iso*maltose by Lintner an unfermentable substance was obtained, having the constants $[\alpha]_D+156°$; R 62·5, which probably consists principally of a substance having the formula $C_{12}H_{22}O_{11}$.

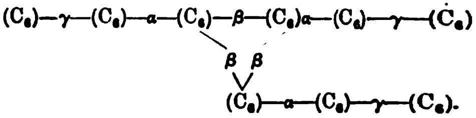
In 1898–1899 Brown and Millar (Chem. Soc. Trans. 1899, 75, 286–337) tried to isolate the intermediate products of saccharification by conversion into nitric acid esters. Owing to oxidation, however, this was unsuccessful; but by moderate oxidising agents dextrinic acids were obtained. Starting with the maltodextrin of Brown and Morris they first obtained an acid which they termed 'maltodextrinic acid A.' This can be hydrolised in two successive steps, by diastase and acids respectively, into first an acid which they term maltodextrinic acid-β, together with maltose, and, secondly, into a pentose acid and glucose. In further experiments they obtained a dextrin with optical and reducing properties corresponding to $[\alpha]_D 195°–195{\cdot}7°$; R 5·7–5·9, which they claim is a stable dextrin, proving this statement by the products of oxidation. On the data furnished by their researches they base their theory that the dextrin molecule may be empirically regarded as made up of 39 $C_6H_{10}O_5$ groups in combination with a terminal $C_6H_{12}O_6$ group; or in other words, a condensation of fatty glucose molecules with the elimination of $39H_2O$, the constitutional formula being—



$$O_{39}\left\{\begin{array}{l}C_6H_{11}O_5\\(C_6H_{10}O_4H)_{38}\\C_6H_{11}O_5\end{array}\right.$$

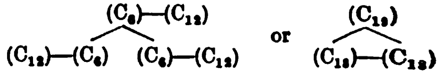
In 1900 and 1902 V. Syniewski (Annalen, 1900, 309, 282; 1902, 324, 212) brought forward a new theory on the breaking down of the starch molecule by hydrolysis. He points out that starch can be hydrolised in two ways, either so as to yield substances which do not reduce alkaline copper solutions (carbinol hydrolysis), or those which do reduce alkaline copper solutions (carbonyl hydrolysis). The simplest product of the carbinol hydrolysis of starch is a substance amylogen $C_{54}H_{90}O_{45}$, which is obtained by the action of sodium peroxide on potato starch. He finds that by heating starch paste at 140° in an autoclave carbinol hydrolysis occurs and proceeds as far as amylodextrin $C_{216}H_{372}O_{186}$. By treating this amylodextrin with malt extract previously heated at 78° for 18 minutes the solution contained exclusively a product identical with the maltodextrin of Brown and Morris, the achroodextrin II. of Lintner and Düll, and the maltodextrin-α of Ling and Baker, and which he denotes limit dextrin II. Elementary analysis and determination of the molecular weight established the formula $C_{36}H_{62}O_{31}$, having constants $[\alpha]_D 179{\cdot}36°$; R 30. Further hydrolysis of this product with malt extract to a point where the reducing power of the dissolved bodies was R 60 gave a product consisting mainly of a compound $C_{24}H_{42}O_{21}$, which was identical with Prior's achroodextrin III., and Ling and Baker's maltodextrin-β, which he called γ-maltodextrin, having constants $[\alpha]_D 172{\cdot}17°$; R 42·7. Both limit dextrin II. and γ-maltodextrin on complete hydrolysis with malt extract yield a mixture of maltose and *iso*maltose or, as the author terms it, dextrinose $C_{12}H_{22}O_{11}$, with constants $[\alpha]_D 141{\cdot}4°$; R 84·5.

Syniewski considers the theories of Lintner and Düll and of Brown and Morris on the mechanism of starch hydrolysis to be untenable, and elaborates a theory of his own. He regards the starch molecule as made up of amylogen residues, and he assumes that the nine glucose groups which make up the amylogen residue $C_{54}H_{90}O_{45}$ in the starch molecule are connected together by nine carbonyl bonds of three different kinds which he denotes as α-, β-, and γ-bonds. The amylogen residue may be thus represented—



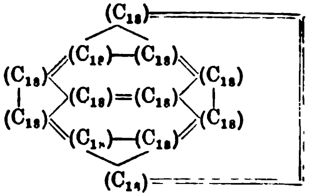
$$\begin{array}{l}(C_6)-\gamma-(C_6)-\alpha-(C_6)-\beta-(C_6)\alpha-(C_6)-\gamma-(\dot{C}_6)\\ \qquad\qquad\qquad\qquad\qquad\beta\ \ \beta\\ \qquad\qquad\qquad\qquad\qquad(C_6)-\alpha-(C_6)-\gamma-(C_6).\end{array}$$

The three monocarbonyl bonds which unite three maltose residues with the residue of limit dextrin I. are α- bonds. The three monocarbonyl bonds which are between the three glucose groups of the limit dextrin I. residue are β-bonds, and those bonds which unite the glucose groups of the maltose residues are γ- bonds. The amylogen residue may also be represented as follows:—



$$\begin{array}{ccc}\begin{array}{c}(C_6)-(C_{12})\\(C_{12})-(C_6)\quad(C_6)-(C_{12})\end{array} & \text{or} & \begin{array}{c}(C_{18})\\(C_{18})-(C_{18})\end{array}\end{array}$$

The composition of starch is represented by the formula $[(C_{54}H_{96}O_{48})_n—3H_2O)$, whilst that of amylodextrin is represented by the formula $n[C_{54}H_{90}O_{45}+1\frac{1}{2}H_2O)$. By the action of malt extract heated to 78° amylodextrin may be completely converted into limit dextrin II. $C_{36}H_{62}O_{31}$. From this it follows that n must be a whole number. Limit dextrin II. is formed from two different amylogen residues, and this conclusion is arrived at from the assumption that the β- carbonyl bonds are disrupted in its formation. From certain geometrical considerations the value of n in the potato starch molecule is considered to be 4, its empirical formula being $C_{216}H_{368}O_{180}$, which is thus graphically represented—



According to this formula each amylogen residue in the starch molecule is united by six carbinol anhydride bonds, three of these being between limit dextrin I. residue and three between maltose residues. The former are denoted *d*- bonds, the latter *m*- bonds. The single lines between the C_{18}- groups forming a dextrin ring are *β*- carbinol bonds; the double lines uniting two C_{18}- groups are carbinol bonds, one being a *d*- bond and the other an *m*- bond. It is conceivable that the molecular constitutions of other starches are analogous but contain a different number of amylogen residues, thus 2, 8, or 20. The author goes on to explain the several steps in the process of hydrolysis of the starch molecule, for which the reader is referred to the original papers or extracts of same in Jour. Inst. Brew. 1900, 6, 110; and 1902, 8, 732–737.

There is no doubt that much of the obscurity and confusion which has arisen in the interpretation of results up to this period has its origin in the fact that starch has been too generally regarded as a chemically uniform substance. From about this time onward most of the work on starch has been directed to the investigation of the nature and structure of the starch granule, and also to a closer study of the transforming enzyme *diastase*.

Pottevin (Annales de l'Instit. Pasteur, 1899, 665, 728, and 796) was among the first to work on these lines. He found two distinct phases in the saccharification of starch paste, one of extraordinary rapidity, and the other increasingly sluggish, and from among the possible causes of retardation he dismisses the weakening of the enzyme and the inhibitive effect of the soluble products, forming the conclusion that since the slackening refers to the production of dextrins as well as maltose, the lack of uniformity must exist in the starch itself.

In 1902 Ling and Davis (J. Inst. Brewing, 1902, 8, 475) showed that the unrestrained action of diastase at the temperature at which its activity is at its optimum, namely 55°, carried the transformation of starch paste to a point at which the constants of the substances in solution were substantially those of maltose. They formed the opinion that the so-called No. 8 equation of Brown and Heron is not really a resting stage in the reaction, but only marks a slowing down, the reaction continuing at a reduced rate until the end. When the diastase is heated in solution above 60° its action weakened and an alteration is produced in the enzyme molecule, this alteration being assumed by the production of *d*- glucose when it acts on starch paste. The amount of *d*- glucose formed depends on the temperature at which the diastase in solution is heated before adding to the starch paste, the maximum amount being obtained when the solution has been previously heated at 68°–70° for about 20 minutes. The amount of *d*- glucose formed in any case does not exceed about 12 p.c. of the total hydrolytic products.

In 1903 Brown and Millar showed that the so-called stable dextrin, one of the hydrolysation products of starch by diastase, is converted by the further action of diastase into about equal parts of *d*- glucose and maltose.

This was confirmed by Ling and Baker.

In 1904, following on these results, came the new theories brought forward by Maquenne and Roux on the structure of the starch granule, and the discovery by Fernbach and Wolff of the enzyme termed amylocoagulose. These workers formed the opinion that when starch is acted on by diastase the maltose is produced from that portion of the starch granule they termed amylose, and that the residual unsaccharifiable dextrin comes from the amylopectin. A comparison of the action of malt extract at 50° on starch paste and a solution of pure amylose, gave results as follows:—

	Percentage of maltose on original starch substances	
	Starch paste	Amylose
5 minutes .	66·7 p.c.	94·4 p.c.
1 hour . .	79·0 ,,	99·7 ,,
2 hours . .	81·1 ,,	100·1 ,,
3 ,, . .	82·0 ,,	101·4 ,,
28 ,, . .	91·8 ,,	104·2 ,,

The apparent halt in the reaction in the case of starch paste when about 80 p.c. of maltose is formed is explained on the assumption that the hydrolysis of the amylose is then complete.

In 1906 Roux (Compt. rend. 1906, 142, 95), after further experiments with starch pastes of other starches, prepared at 100°, came to the conclusion that they were similar to potato starch in being composed of amylose and amylopectin. He found that they all tended to give the same dextrin and maltose proportions when acted upon with diastase.

In the same year, Roux, in conjunction with Maquenne (Compt. rend. 1906, 142, 124), found that when the alkalinity of starch paste was made exactly neutral to methyl orange with decinormal sulphuric acid, and the malt extract neutralised to the extent of one-third or two-fifths, saccharification proceeded more rapidly, and the yield of maltose showed a large increase.

Fernbach pointed out that malt extract is acid to phenol pthalein and alkaline to methyl orange, as if it contained a mixture of primary and secondary alkali phosphates, the optimum reaction for saccharification being neutrality to methyl orange.

In conjunction with Wolff, Fernbach showed that natural starches were similar in this respect to malt extract, and they found that if starch paste and malt extract be rendered exactly neutral to methyl orange, practically the whole of the starch is converted into maltose by the malt extract.

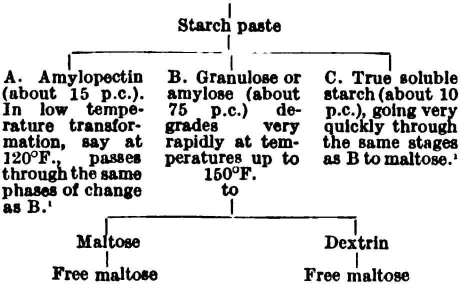
They came to the conclusion that the transformation of starch by diastase, if allowed sufficient time, will attain the theoretical limit of maltose production, and that the slackening observed in the later stages is due to the dilution of hydrolysable matter, and not to failure of the diastase. Solutions of the residual dextrins separated from an advanced transformation were found to be still susceptible to diastatic action.

Maquenne and Roux (Compt. rend. 1906) practically uphold these observations regarding saccharification, but consider that the reaction has two distinct phases, the first one of extreme rapidity, corresponding to the conversion of 70–80 p.c. of the starch into maltose, the second, a very slow one extending over several days.

In 1907 Van Laer (Bull. Soc. chim. 1907, 21, 8) discussed the later work on starch transformation, and accepted Maquenne and Roux's amylose and amylopectin hypothesis, but did not agree that the earlier work had been controverted, but rather had been extended. In starch conversions carried on at temperatures below 60°, the amylose may be regarded as being converted very rapidly into maltose with the producton of dextrins, the stable dextrin remaining being derived from the amylopectin. At temperatures above 60° dextrins are produced from the amylose of quite a different type, which are easily saccharifiable by malt diastase and correspond with the maltodextrin of Brown and Morris.

We must conclude, therefore, that from starch transformation with malt extract carried on at high temperatures we obtain mixtures of both kinds of dextrins, the complexity of which the older investigators ascribed to the modification of the action of diastase by heat, but which the more recent investigators attribute to the heterogeneous nature of the starch granule itself.

In 1911 Matthews and Lott (J. Inst. Brewing, 1911, 17, 219–266), as the result of a long series of experiments, practically endorse the views expressed by Maquenne in 1908 (*see* p. 152) on the structure of the starch granule, but find that experiments with potato starch do not exactly represent what happens with barley and malt starch when acted upon with diastase, but the relationship as to kind of products holds. Discussing dextrin they question whether really stable dextrin exists. Any so-called stable dextrin has its origin in the amylopectin, the part of the starch which requires liquefaction before transformation, any delay or injury to this action resulting in the production of very difficultly degradable dextrin. The weight of evidence appears to be entirely against the maltodextrin theory, but the proportions of combined maltose and dextrin in bodies of this character found in starch transformations mark them as ordinary products of change and representative of an intermediate state. The theory is that there is a stage in starch transformation where the whole of the readily transformable matter is present as a body degradable by successive stages to maltose. The change is represented as follows :—



Granular starch

Starch paste

A. Amylopectin (about 15 p.c.). In low temperature transformation, say at 120°F., passes through the same phases of change as B.[1]

B. Granulose or amylose (about 75 p.c.) degrades very rapidly at temperatures up to 150°F. to

C. True soluble starch (about 10 p.c.), going very quickly through the same stages as B to maltose.[1]

Maltose

Free maltose

Dextrin

Free maltose

Perhaps it is as well to call attention here to the fact that most of the work mentioned above has been carried out with carefully purified potato starch, but it has been ascertained that similar experiments made with widely differing starches—such as maize, rice, wheat, arrowroot, sago, barley, and various other starches—practically yield the same analytical results when acted upon in the form of paste by diastase, but it has been found that the same starches differ materially from one another when the unbroken granules are acted upon in the cold, as will be seen from the following table by Lintner (Brauer und Malzkalendar, 1890, 83)[1] :—

Table X.—*Action of Diastase on Ungelatinised Starch.*

Starch from	Percentage dissolved by 4 hours' contact at the undermentioned temperature				Gelatinisation temps.
	122°F.	131°F.	140°F.	149°F.	
					°F.

All the known digestive ferments belong to the class of soluble or unorganised ferments, and of these only two appear to have any very marked action upon starch—the diastases of the saliva and of the pancreatic juice. The action of these diastases upon raw starch and upon starch paste is very similar to that exercised by the diastase of malt, with the exception that in addition to dextrin and maltose, dextrose is also formed, through the hydrolysis of the maltose by these ferments, the action on raw starches varying according to the kind of starch acted upon (*see* Roberts, Digestive Ferments ; Church, Food Grains of India ; Bell, Chemistry of Foods ; Brown and Heron, Proc. Roy. Soc. 1880, 393 ; Chittenden and Cummins, Chem. News, 51, 256 ; Chittenden and Smith, *ibid.* 53, 109).

16. *Action of bacteria.* According to Fitz (Ber. 10, 276 ; 11, 42), starch yields by fermentation with a *Schizomycetes* (*Bacillus butylicus*, *Bacillus subtilis*) 35 p.c. of butyric acid and 9 p.c. of acetic acid, together with a small quantity of succinic acid. Inulin appears to yield the same products.

By the action of certain organisms, starch is rendered capable of being converted into dextrin and maltose, and eventually into alcohol. In this way the Indians of South America make an alcoholic liquor called *chicha* by the fermentation of the starch of maize. The grain is first allowed to soak for from 4 to 6 hours to soften it and afterwards fermented. The fermentation is due in the first instance to the presence of a minute organism, situated on the epidermis of the grain ; this secretes a diastase, which either produces or aids further fermentation (Marcano, Compt. rend. 95, 856).

Gayon and Dubourg (*ibid.* 103, 885) mention a species of mucor which has the power of converting dextrin and starch into sugar, and then fermenting the sugar.

---

[1] There is some evidence that a little dextrose may sometimes be formed.

[1] *V.* also Die Stärkenenbildenen Fermente f. Baranetzky 1878, and Brown and Morris, Chem. Soc. Trans. 57, 510.

Bacillus suavolens converts starch gradually into dextrin and glucose, with formation of alcohol, aldehyde, formic, acetic, and butyric acids, &c. (Sclavo and Gosio, Arch. ital. Biol. 14).

Villiers (Compt. rend. 112, 435 and 536) finds that the addition of a pure cultivation of *Bacillus amylobacter* to a 5 p.c. starch paste causes complete liquefaction in 24 hours, and on allowing the fermentation to continue some time the liquid no longer gives a blue colouration with iodine, the products of the change being almost exclusively dextrins, no maltose or dextrose being found to be present, from which he concludes that the organism converts starch directly into dextrin without the intervention of any diastase secreted by the ferment.

Perdrix (Ann. Inst. Pasteur, 1891, No. 5) has separated from Paris water a bacillus, *B. amylozymicus*, which ferments starch with production of dextrin, glucose, carbon dioxide, ethyl and amyl alcohols, acetic and butyric acids. A somewhat similar change is effected by the bacillus of malignant œdema (Kerry and Fraenkel, Monatsh. 12, 350).

MANUFACTURE OF STARCH.

17. *General considerations.* In growing various starch-producing plants for manufacturing purposes, the following facts must be taken into account: 1. The average percentage of starch contained in the root, tuber, or grain; 2, the yield per acre; and 3, the amount of starch yielded per acre. Thus, although the potato at best contains only 20 p.c. of starch; wheat, on the other hand, contains 55 p.c.; nevertheless the total amount of starch per acre is in favour of the potato, in the proportion of 2 to 1, since one acre of ground on the average produces 12,994 lbs. of potatos, containing 2598 lbs. of starch, as against 1860 lbs. of wheat, containing 1023 lbs. of starch.

Again, different varieties of the same species of plant will show very marked differences in the quantity of starch which they yield. For instance, the potato, as ordinarily consumed as food in this country, contains only about 13 p.c. of starch, but in Germany, where the potato is cultivated for starch production, by means of careful selection and suitable manuring the percentage of starch has been raised to as much as 20 p.c., and in some instances as great a yield as 24 p.c. has been obtained. The yield of starch is also affected by the age of the raw material, conditions of harvesting, and exposure to heat or cold during storage.

It has been found that over-ripe potatos contain less starch than others, the loss being from 3·18 to 9·88 p.c. on 100 of starch (Kramer, Bied. Zentr. 1881, 717).

A sample of barley, which had been exposed to bad weather for a fortnight, and had sprouted, was found to have lost an appreciable amount of starch, that in normal barley being 64·1, whilst that in the sprouted grain was only 57·9 p.c.

Diseased potatos contain considerably less starch than sound ones, owing to its conversion into sugar by the fungus which attacks them, those tubers which are grown with the aid of highly-nitrogenous manures being more susceptible to the disease than those which are grown under ordinary conditions (Gilbert, Agr. Students' Gazette, 4, pt. 2). Exposure to extreme cold tends to diminish the amount of starch in potatos, the generally-accepted idea being that by the freezing a portion of the starch is converted into sugar.

On the other hand, although the materials may be all that is desired, the yield of starch may be low, from causes due to carelessness in the processes of manufacture, such as insufficient washing or defective machinery, &c.

The raw materials almost exclusively employed in Europe and North America for the preparation of starch therefrom are wheat, potatos, maize, and rice. Wheat was very generally used at one time, but has now been almost entirely replaced by the other substances. Potatos are very largely employed on the Continent, rice principally in England, and maize almost universally in America.

The manufacture of starch may be classed under three heads.

1. For manufacturing purposes generally, such as the sizing of paper and of cotton goods, the dressing of cloth, the thickening of mordants and colours in calico-printing, the preparation of British gums, of white glucose syrups, &c.

2. For laundry purposes.

3. For edible purposes, either by itself, as in the preparation of cornflours, arrowroot, tapioca, &c., or in conjunction with other substances in the preparation of sauces, macaroni, semolinas, &c.

Starch was extracted from wheat and barley by the ancient Egyptians, Greeks, and Romans. It was called ἄμυλον by the Greeks, from the circumstance of its not having to be prepared by the action of grinding in mills like other farinaceous substances, whence the Latin *amylum*. Very little, however, appears to have been known about its history or composition until the beginning of the 18th century.

18. *Manufacture of starch from wheat.* The different methods of preparing starch from wheat are:

I. By fermentation, known as the old or sour process.

II. Without fermentation, or Martin's process.

I. Fermentation process. For the old method the wheat is used either whole or ground, but most frequently whole.

Where the whole corn is employed, the wheat is steeped in soft water for some days, until it becomes swollen and so soft as to be easily crushed between the fingers; the water being changed frequently, so as to ensure, at the same time, a thorough washing of the grain. The swollen corn is now transferred to bags, and placed in a wooden chest or flat tub, where it is exposed to strong pressure. By this means the grains are crushed, and the water, which is rendered milky by the starch, is drawn off by means of a tap; fresh water is poured in, and the pressure repeated until all or nearly all of the starch is extracted. Instead of putting the swollen grain in bags, it may be passed from a hopper between two wooden cylinders revolvin in opposite directions, or between one or two cylinders revolving upon a horizontal stone having a rim, to a cistern; by this means the swollen corn is readily crushed and the starchy liquor in the cistern separated by elutriation with successive quantities of water.

The milky liquor containing the starch is next run into cisterns, where it is allowed to remain for a period of from 10 to 30 days, according to the temperature of the surrounding atmosphere, during which time it undergoes fermentation, in order to accelerate which some of the sour liquor from a previous fermentation is added.

By this means the starch granules become completely freed from the glutinous envelopes containing them in the grain, the gluten becomes more or less decomposed and softened, and partially dissolved in the acids formed during the process, and completely loses its sticky elastic properties.

During the earlier stages of the fermentation the ready-formed sugars of the grain, as well as dextrin resulting from the action of the diastase on any broken starch granules, become converted into alcohol, which later on is changed into acetic acid; after a few days lactic, butyric, and other fermentations are set up, and allowed to proceed until the process is considered sufficiently far advanced to allow of the starch granules being easily separated in a state of comparative purity. As a rule, actual putrefaction, as shown by the evolution of stinking gases, should be avoided as much as possible, and the fermenting mass should always have an agreeable vinous smell. During the process it is necessary to agitate the mass throughout once or twice a day, in order to equalise the fermentation as much as possible.

As soon as the fermentation is considered to have progressed far enough the supernatant liquor is drawn off and fresh water run in, the whole well stirred up, allowed to settle, and the surface liquor drawn off. This washing is repeated as long as any perceptible colour is imparted to the water; after the last deposition and decantation, the starch will be found to have settled down in layers of varying purity, the topmost one containing the most gluten and albumen. These different layers are now taken up with a wooden shovel, and transferred to separate cisterns, where they are agitated with water and then passed through fine sieves. After the starch has again settled down, the clean water is drawn off, any impurity that may be on the top separated, and set aside to be washed up with the next batch; the underlying portion agitated again with fresh water, and purified by settling and decantation, this being repeated as often as may be deemed necessary.

It is then shovelled into wooden boxes about 4 feet long, 12 inches broad, and 6 inches deep, perforated throughout and lined with thin canvas; this is termed 'boxing.' When it has drained and dried into a compact mass, it is turned out by inverting the box upon a clean table where it is cut up into pieces 4 or 5 inches square; these are then set upon half-burned bricks, which by nature of their porosity absorb the moisture from the starch, so that the under surface of the blocks may not become hard and horny.

When sufficiently dried upon these bricks, the blocks of starch are put into a stove and left there until tolerably dry; they are then removed to a table, where all the sides are carefully scraped with a knife, next packed up in the paper in which they are sold, returned to the stove, and subjected to a gentle heat for some days, previous to being sent into the market.

II. Martin's process. In this process flour is employed in preference to the whole or crushed grain. It is kneaded into a stiff dough with water, exactly as for bread-making, and allowed to remain in that state until every part becomes thoroughly saturated with moisture. This requires 25 minutes in summer and about an hour in winter. For the separation of the starch from the gluten an apparatus is employed, consisting of two troughs which are similar to each other, and which may be of any convenient length. Within each of these troughs there is a rectangular frame, which is caused to move to and fro within the trough by a crank axis and connecting rod, the crank of one trough being set opposite to that of the other.

Each of the frames carries the bearings of four or other convenient number of grooved rollers. At the bottom of each of the troughs there are openings at intervals covered with wire gauze; at the ends of each trough are applied spring buffing apparatus. Below the troughs is an inclined sieve of fine wire gauze, and below it an inclined shoot, down which the fluid which passes the sieve flows, and from it into any suitable receiving vessel, where the starch is allowed to settle; above each trough there is a perforated pipe, through which the numerous jets of water flow on to the dough introduced into the trough, and which serves to wash away the starch from the gluten.

The dough which is to have the starch separated from the gluten is formed into small balls, and placed in the troughs between the rollers. The frame carrying the rollers is caused to reciprocate, a constant spray of water being allowed to flow over the dough at the same time, by which means the starch is washed out and separated from the gluten; the milky liquor flows through the openings in the bottom of the trough on to the inclined sieve, and thence by means of the shoot to a suitable receiving vessel. Should any particles of gluten pass through the openings, they pass along the inclined sieve, and are received in a vessel. After the dough has been subjected for a sufficient length of time to the action of the rollers, it consists for the most part of gluten, and is placed between the ends of the frames and the buffing apparatus, where it is beaten for several minutes, and can then be used for any purpose to which it is applicable.

The purification of the starch obtained in this way may be effected in the usual manner, by successive washings and decantations as in the fermentation process, or by the inclined plane method described below under potato starch. Subsequently, Martin introduced the following process for the purification of the crude starch, whereby a better product is obtained than is possible by mere washing with water. This consists in treating the impure starch with a weak solution of sodium hydroxide, sp.gr. 1·013, in sufficient quantity to turn red litmus paper blue, after the deposit has been well roused up. The mass is then allowed to stand for two hours, during which time the gluten swells up, and becomes partly dissolved. A considerable quantity of water is then added, and the whole thrown on to a No. 200 sieve, which retains the swollen gluten and allows the starch to pass through; the starch is then run on to the inclined plane as before. Almost the whole of the starch is by this means obtained as a first product, whilst with simple washing about 25 p.c. is produced in an impure, unmarketable form.

On the average, there is obtained from a sack of flour about 110 lbs. of moist gluten and about 220 lbs. of dry starch.

19. ***Manufacture of starch from potatos.*** At one time the manufacture of starch from potatos was carried on to a certain extent in Great Britain as well as in Ireland, the first published specification relating to starch being taken out as far back as the year 1717 by Newton, Nowell, Clark, and Joynes, for 'a way or method to make starch of and from the roots called by the name of potatoes,' but its development has been considerably checked by the potato disease, and is now entirely replaced by starch from rice.

In France and Germany, however, where much more attention has been directed to the growth of the potato as a starch-producer, the manufacture of fecula or starch from this source has attained very considerable dimensions and large quantities of potato starch are imported yearly from those countries.

On the Continent the manufacture of potato starch, for an account of which the writer is much indebted to Payen's Chimie Industrielle, includes the following operations—steeping, washing, separation of stones, rasping, straining, settling, removal of the starch, purification, second straining, washing, draining, and drying in the air or in a centrifugal machine, drying in an oven, packing.

Steeping. Potatos which are grown in tough clay or loam are covered with adherent earth, which clings so tenaciously to them as not to be removed by simple washing; they are therefore allowed to soak for several hours in a large vat containing water.

Washing. In France this operation is carried on as follows:—An apparatus called the washing drum (Fig. 1) is used, consisting of a hollow revolving cylinder *b*, formed of wood or iron bands, ½–1½ inches wide, and laid longitudinally from one end to the other, the distance between each being about ¾ inch, so as to allow of the escape of the dirt, sand, and stones, whilst the tubers are retained. The cylinder, which is slightly inclined, is immersed to half its diameter in water in the trough *c*, wherein it revolves at the rate of about fifteen revolutions per minute, and by which means the potatos are kept in continual motion, rubbing against and being rubbed by the sides of the cylinder. From the sides of the trough spring the boards *g*, slanting to the upper part of the cylinder, so as to prevent splashing of the water. The cylinder is worked by a band from the main shaft, passing over the wheel *f*. The potatos are fed into the hopper at *a*, and are thrown out at the opposite end, where, falling down the inclined plane *d*, they are conducted to the stone catcher (Fig. 2). This apparatus consists of a semi-cylindrical sloping trough, filled with water to the level A. In the trough is a shaft D, furnished with arms placed spirally (Figs. 3 and 4), and which by means of the cogwheel E is rotated by the driving wheel F. The potatos being fed in at A, are rubbed upon one another by the arms and repeatedly dipped in the water, so that the remainder of the dirt and all stones and sand is washed off, and, the heavier particles sinking to

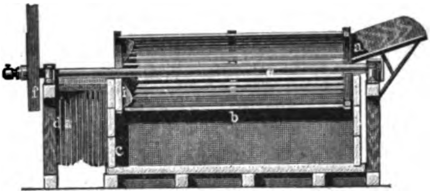

FIG. 1.

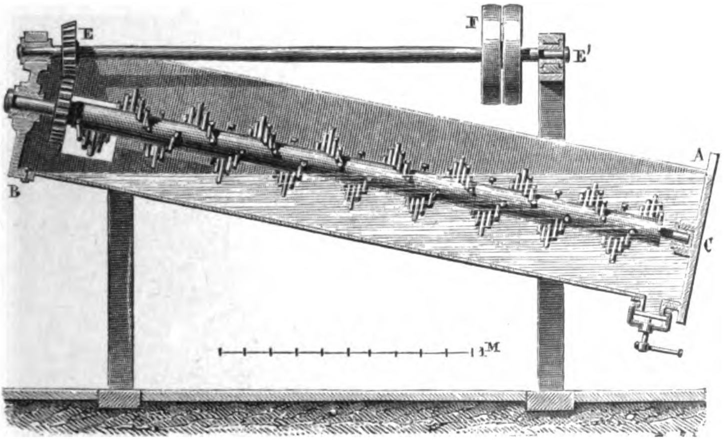

FIG. 2.

the bottom, are removed from time to time through the opening C. The potatos are carried forward by the action of the spiral until they reach the upper end of the trough, over which they fall into the hopper of the rasping machine.

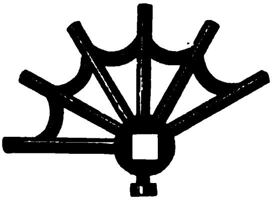

FIG. 3.

FIG. 4.

In the German factories the above operations are carried on at one and the same time, the trough in which the washing drum is placed being divided into two unequal parts, the larger one *d* for the washing drum, and the other *e* for the stone catcher; as shown in Figs. 5 and 6, the potatos are introduced into the smaller division *e*, and are drawn forward and kept in incessant motion by six or eight large iron arms *gg*, arranged spirally on a prolongation of the shaft of the washing drum *ab*. The stones, sand, &c., are drawn off at intervals through the openings *i* and *h*. The potatos thus reach the washing drum previously washed and freed from stones, from which they pass through *kk* to the rasping machine.

By means of this the tubers are reduced to a pulp, and the cells containing the starch are ruptured; and the more completely this is done the greater the amount of starch obtained, since it is only the starch from the cells which are actually ruptured that can be extracted, whilst all that remains in closed cells represents so much loss to the manufacturer. For this purpose Champonnois' rasper is generally considered the best, and is shown in Figs. 7 and 8. It consists of a hollow cylinder furnished with saw blades on its inner surface, against which the potatos are made to rub. The case A of the cylinder is seen in Fig. 8, with the rasper inside. This is so arranged that from one to four saw blades lie between thin steel bands, at an interval of from $\frac{1}{30}$–$\frac{1}{25}$ of an inch apart, and between each group is a space through which the pulp as it is formed can pass. This arrangement is shown in Figs. 9 and 10.

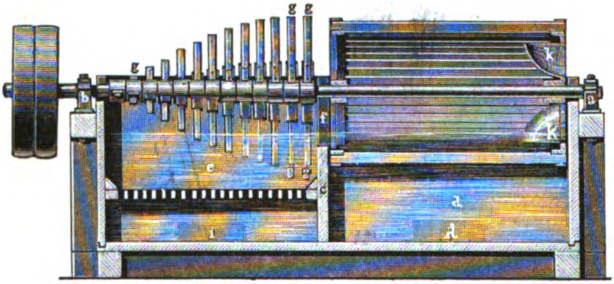

FIG. 5.

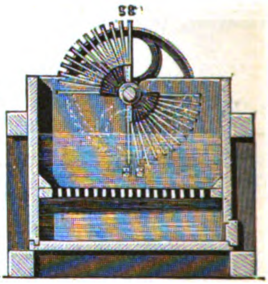

FIG. 6.

FIG. 7.

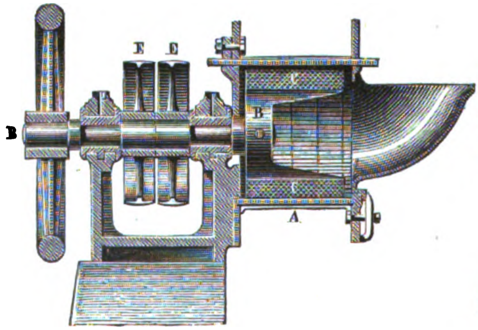

FIG. 8.

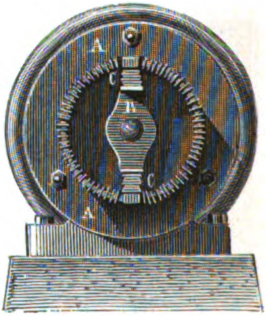

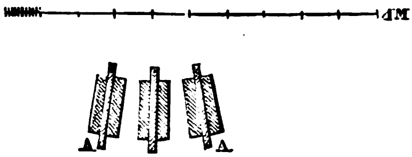

FIG. 9.

FIG. 10.

In the axis of the rasping cylinder is a shaft BB, making 800 to 1,000 revolutions per minute, by means of a band from the main shaft applied to the driving-wheels EB, and regulated by a fly-wheel. At the other end of the shaft, within the drum, is a strong fork-shaped scoop. The potatos, falling through a side opening, are seized by the scoop, and pressed forcibly against the saw blades CC in the cylinder. Water, being admitted into the interior, is driven by centrifugal force against the sides of the cylinder, and makes its way through the interstices, carrying with it the potato pulp, which passes away through a pipe underneath. The teeth of the saw blades are very short, projecting one-fifth of an inch from the drum. They require reversing twice a day, and after two days' use need to be re-filed. As much as thirteen tons of potatos can be rasped by this machine in ten working hours, whilst the yield of starch from a given quantity of potatos is considerably increased.

The pulp thus obtained is a mixture of starch and fibre. In order to separate one from the other the pulp is washed with water upon brass-wire sieves of different degrees of fineness, which allow the starch granules to pass through with the liquid and retain the coarser portions of the fibre. Several forms of apparatus have been devised for this purpose, the principal objects aimed at being uninterrupted working, as complete exhaustion as possible of the pulp within the smallest space, and economy of wash water. Fig. 11 shows a longitudinal section of Huck and Stoltz's machine. This consists of three cylinders A, B, C, of different diameters. The case of the first is formed of a wire sieve, 25 meshes to the inch. The pulp from the rasper is run in through the funnel *a*. Within this cylinder is another, *bb*, formed of perforated metal plate into which water flows through the pipe *a''*, and is distributed uniformly upon the potato pulp in A by means of the perforations in *bb* from A. After parting with the greater part of its starch the pulp is gradually brought forward into the second cylinder B, which is covered with sheet copper. The pulp is here worked about with a T-shaped iron fastened to the shaft DD′, which is rotated by the driving wheel G in an opposite direction to the cylinder; from here it is carried forward to the third cylinder, which is covered with wire tissue, 35 meshes to the inch, where it meets with a fresh spray of water coming through the perforated pipe *dd* from *a'''*. Whilst in the cylinders A and C the pulp undergoes a continual working with brushes, which, like the agitator in B, are connected with the shaft DD′. These three cylinders revolve at the rate of 22 revolutions per minute; whilst the agitator in B makes 35 in the same time. The starchy liquid flowing from A and C is collected in the trough K, and runs from thence into the sieve cylinder HH′, which is covered with wire gauze, 50 meshes to the inch. Here any fibrous pulp which may have passed through the other sieves is retained; whilst the water containing the separated starch is run off along the trough L into the settling vats. The coarse pulp as it is pushed out of the cylinders falls into the receivers MM′ underneath. In order to prevent the clogging of the sieves, a fine stream of water is thrown upon them during working from pipes running parallel with their axis.

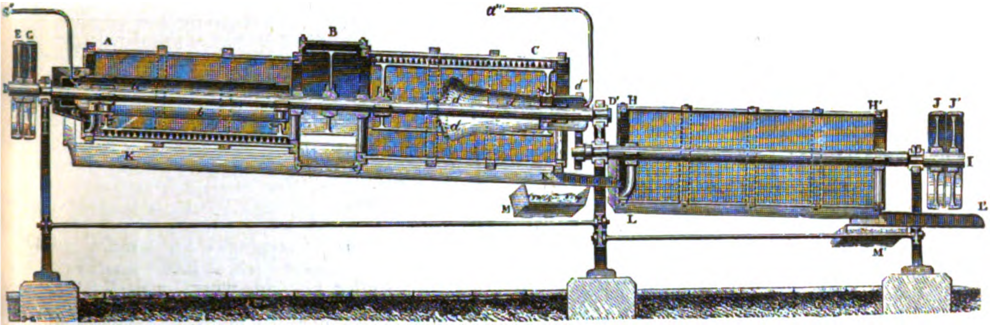

FIG. 11.

A modification of the above apparatus, by means of which considerably less water is required, and which is suitable for localities where water is more or less scarce, is shown in Fig. 12.

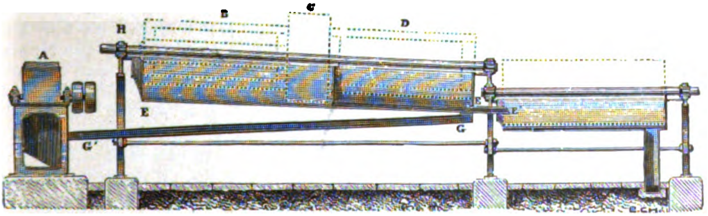

FIG. 12.

The pulp coming from the rasper A is raised by means of a centrifugal pump into the first cylinder B, where it gives up by far the greater part of its starch. The strained liquor from this cylinder is not joined with that from the other cylinders, but runs straight away into the purification vessel. The liquor from the mixing cylinder C and the other sieve cylinder D, containing comparatively but little starch, is carried by the pipe GG′ back to the rasper, where it is used instead of clean water for the thinning of the pulp.

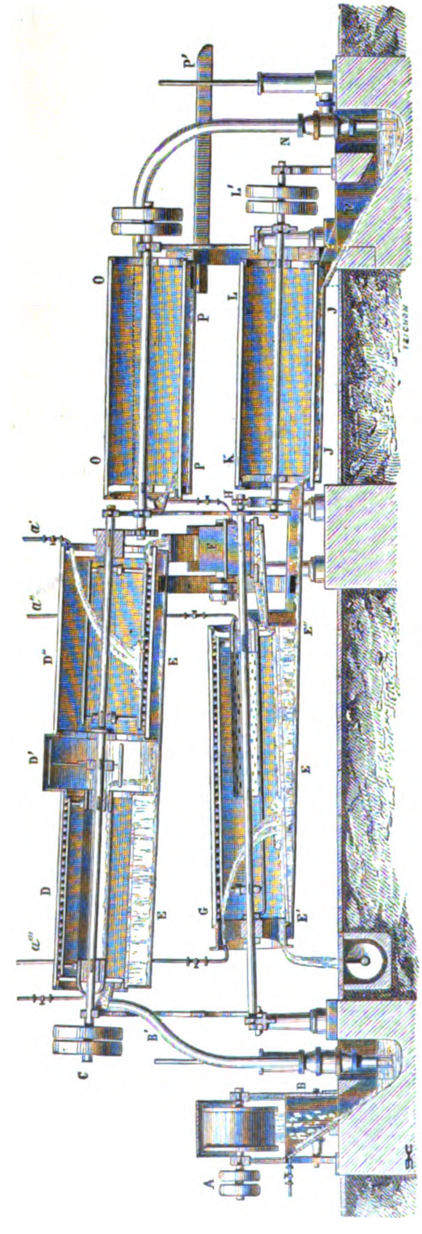

FIG. 13.

In some factories, by means of a modification of the apparatus just described, a second working of the pulp is effected, and a larger yield of starch thereby obtained. This is shown in Fig. 13. The pulp, thinned with water, falls from the rasper A into a small cistern, from which it is raised by the pump B, through the pipe B′, into the sieve and mixing cylinders D, D′, D″, and in the latter washed by a stream of water a'. The pulp rejected from D″ falls into the hopper of a second rasper, where it is rubbed between two cylinders F rotating in opposite directions; from thence it flows into the sieve G, where it meets with more water from a''', and, being washed, falls into a trough, along which it is pushed by an Archimedean screw.

The starchy liquid from D falls into the trough E, that from G into E′, and both united fall into the first purifier KL, thence into the trough J, into the cistern M, from whence it is raised by the pump to the second purifier O, where the last portions of fibre remain, whence by means of the trough P the liquor containing the nearly pure starch passes to the purification apparatus. In the smaller factories this is generally accomplished by means of settling vats.

In addition to rasping, a great many manufacturers are accustomed of late years to grind the pulp after rasping, whereby a slightly increased yield of starch is obtained. The following figures, calculated on the starch worked, show a comparison between the yield obtained when a rasping machine only is employed, and when, in addition thereto, grinding is carried on as well.

Obtained in form of green starch	Without grinding	With grinding
Experiment A. . .	81·8	87·4
Experiment B. . .	76·3	85·5

Various forms of machines for carrying on the rasping and grating processes simultaneously have been constructed during the last few years.

The starchy liquor as it comes from the sieves generally contains some sand, which was not separated during the washing of the potatos, and was too fine to be retained by the sieves. It is therefore run into a large vat and vigorously stirred so as to bring all the starch into suspension, and, before it has had time to settle, is siphoned off into another large vat, where it is allowed to stand for four hours, during which time the starch settles on the bottom. The sand, by reason of its greater specific gravity, sinks rapidly to the bottom, and remains in the first vat. The lower part of the sediment deposited in the second vat consists of pure starch, covered by a greyish layer, consisting of fine fibres that have passed through the sieves. The supernatant liquor having been run off, this impure mass is scraped off as clean as possible with an iron scraper. This impure starch is agitated with fresh water, passed through a very fine sieve, and allowed to rest for some time, until a further amount of white starch falls out, when the same operation is repeated.

The purified starch is again agitated with water, passed through a silk or wire sieve, 90 meshes to the inch, and again allowed to settle, the liquor decanted off, the surface of the starch scraped, and finally, if the mass be pure enough and of sufficient consistence, divided into lumps and placed to dry.

Sometimes the starch, deprived of its supernatant brownish deposit, is purified by being placed in a slightly sloping flat-sided trough about 22 feet long and 3 feet wide. Below this is a second trough, inclined in the opposite direction; and below this a third, inclined like the first. A spray of water from a very fine rose falls upon the starch, which is placed just beneath it at the top end of trough No. 1, and at the same time is kept constantly stirred. The water gradually washes everything forward with it, and while slowly flowing along the troughs the starch is gradually deposited; whilst the lighter fibrous matter remains in suspension, and passes with very little starch into vats underneath. The starch obtained in this way is added to that purified in the first settling vat, and is then ready for draining.

In large factories the settling vats have been entirely superseded by the inclined plane; this consists of a series of three wooden troughs, Fig. 14, 3½ feet wide and about 30 yards long, each having a fall of 1 to 1½ in 1,000. The third plane or trough rests on the ground and empties into the vat G. The second and first are affixed to wooden supports as shown. The starchy liquor, as it comes from the cylinder sieves, enters the first inclined plane at A, flows along in the direction AB, and thence along CD to F, the flow being regulated at will by means of the screw valves at B and D. The greater part of the starch is deposited in the first plane, from which it is removed once a day. The starch from the second plane, on which considerably less is deposited, is removed twice a week; and that from the third once a week. The liquor, containing very little starch, flows into vat G, or generally into a series of vats, whereby any starch that may still remain in the wash water is collected.

The starch thus deposited on these inclined planes is sufficiently pure for most purposes to be sent at once to market; but, as it is still contaminated to a slight extent with potato sap, it is advisable to wash it once or more in the usual settling vat in order to purify it completely.

Drying. The starch is taken from the planes or settling vats in the form of a very thick mud or sludge, from which the greater portion of the water may be removed by centrifugal action, by drying in the air or in ovens.

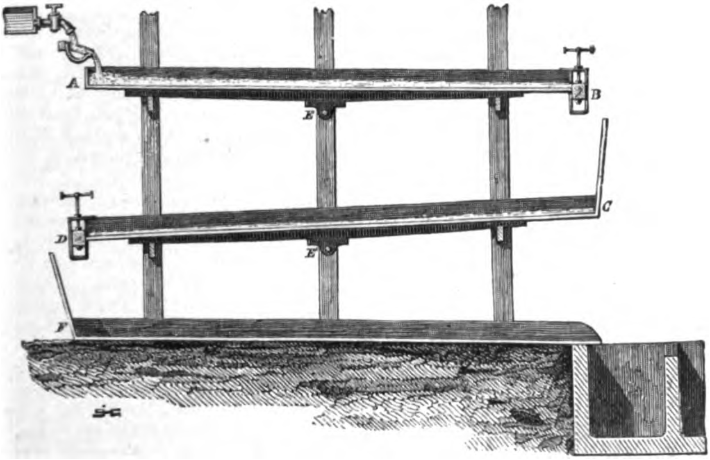

FIG. 14.

In the drying of starch by centrifugal action the same form of apparatus is used as in the manufacture of sugar, but as the starch mud is so thick as to render it incapable of being properly distributed on the sides of the machine, a quantity of water is mixed up with it to bring it into a sufficiently thin paste that will flow into the apparatus whilst it is in motion. It is then flung against the circumference of the machine, the water flies off, and the starch lies as a compact mass round the sides of the cylinder. Advantage has been taken of centrifugal action for the purification, as well as for the drying of starch at the same time, by Fesca, of Berlin. When the impure starch liquor is introduced into the machine, the densest and heaviest portion—and consequently the purest starch—is driven first against the sides of the cylinder. The fibrous portion remains longer suspended, and is deposited as a layer upon the surface of the pure starch, from which it is easily removed.

For many purposes—such as the manufacture of dextrin and glucose, &c.—the starch, as it comes from the centrifugal machine, and containing from 35 to 40 p.c. of water, needs no further desiccation, and is known in commerce as green starch.

In factories where a centrifugal machine is not used, the water is removed as much as possible from the starch before proceeding with the drying. Accordingly, as soon as the starch is considered sufficiently purified, it is dug out of the settling vats and transferred to perforated boxes, lined with clean linen, and set aside for some time to drain, during which time it acquires sufficient hardness to enable it to retain the shape of the box, and as soon as ever this takes place the box is inverted upon a dry porous slab, generally of plaster-of-Paris, which abstracts a further amount of moisture, so that it arrives at the state of green starch. It is now sufficiently solid to be removed to the drying room, on either side of which a series of shelves, formed of bars of wood placed at a distance of about one inch apart, are ranged in tiers one above the other, through which a current of air is made to pass freely by means of louvre boards or venetian ventilators. On these shelves the blocks of starch are placed, and allowed to remain for six or eight weeks, until sufficiently dried. One great drawback to this method is the exposure of the starch to any dust that may be floating about in dry weather, as well as the possibility of the moist starch becoming frozen in cold weather. The latter may be obviated by introducing heated air into the drying-room, and the dust precluded by shutting up all the windows—in fact, by practically converting the room into an oven. The starch dried in this manner is known as 'hurdle starch.'

The best quality, termed superior, which is used for the manufacture of starch sugar and dextrin, is singularly white, glossy and pure, and consists of large grains, being the first to deposit in the settling tanks. The deposits become lower in quality in succession. The gloss of starch depends on the size of the grain, the larger the grains the better the gloss, and the determination of the diameter of the grains by means of the microscope forms a good test for this starch.

A superior article consists of grains having a diameter 35·5μ, ordinary prima 32·5μ, prima seconds 21·0μ and inferior kinds 17 to 12·5μ. Considerable importance is also attached to the amount of impurity present, such as coal dust, potato skin, soot, sand, iron particles from wheels, algæ from water, particles of wood, &c. The amount is ascertained by smoothing a sample on white paper, and counting the particles in a square cm. Superior starch contains 15 to 30 particles, average samples 27–170, while inferior kinds contain as many as 800 upon 1 sq. cm.

20. *Manufacture of starch from rice.* Although no other starch-producing material is so rich in this substance as rice—containing, as it does, over 80 p.c. of starch—nevertheless, the cells and the starch granules contained in them are so intimately connected together by a small but very resisting quantity of gluten that their separation cannot be effected by a simple crushing and washing, as in the case of potatos, or by the old system of fermentation, as in the case of wheat and flour, and hence resort must always be had to chemical agents, alkalis or acids, to effect this object.

Since rice starch, on account of the smallness of its granules, possesses a greater firmness, and in practical operations gives a much higher lustre than wheat starch, it is much esteemed by laundresses, and preferred by them to any other, so that when the difficulties attending its successful preparation had been overcome, a great impetus was given to its manufacture in England, where it is at present carried on to a very large extent, and, being cheaper in this country than any other raw material, may be considered as a fairly remunerative business.

It need hardly be said that the value of any sample of rice for starch manufacture depends not only upon the amount and quality of the starch it contains, but on the percentage of gluten or protein matter as well, and on its degree of solubility in caustic soda solution.

The following analyses of rice from different countries show the relative amounts of these substances which are generally present in the matured grain :—

Analyses of rice.

The method of manufacture described by Jones (Eng. Pat. 1840, No. 8488)—and which is, with a few modifications, the one carried out at the present time in England—is as follows.

One hundred pounds of rice are placed in a tinned copper or stoneware vessel holding 50 gallons of a solution of sodium or potassium hydroxide, containing 200 grains of alkali per gallon of water; the mixture is well stirred and allowed to macerate for 24 hours, at the end of which time the liquor is siphoned off, and the rice well washed with twice as much cold water as there was of alkaline solution. The water is next poured off, and the grain placed upon sieves to drain, after which it is crushed or ground to flour with rollers or millstones. The flour is then passed through sieves by means of brushes, the coarser particles which do not pass through being returned to the mill to be reground and again sifted, until the whole is thus disposed of.

The flour thus obtained is again treated with alkali solution, one hundred pounds of the rice flour being added in small quantities at a time, to every hundred gallons of liquor. The whole is repeatedly stirred up during 24 hours, and then allowed to stand for about 70 hours to settle. The processes of this deposit takes place as follows: the first deposit consists of fibrous matters with little starch, followed by a deposit of the greater portion of the starch, the gluten and other matters remaining in solution in the alkaline liquor, which is siphoned off, and double as much water run on. The deposit is then well roused up with it, and the whole allowed to stand about an hour, during which time the matters other than starch subside, carrying with them a small portion of the starch, but leaving by far the greater bulk of it suspended in the liquor. This is drawn off, and passed through fine silk sieves. A further quantity of water is added to the deposit and agitated as before, and, after standing a short time again drawn off, and passed through sieves as before, this operation being repeated as often as necessary, until at length the whole of the starch is separated from the fibrous and other matters.

All these starchy liquors are then collected into one vessel and allowed to settle for about 70 hours, during which time the whole of the starch is deposited. The supernatant liquor is now drawn off, and the starch (blued if necessary) drained, dried, and finished in the usual way.

Several other patents for preparing starch from rice have been taken out by various manufacturers, the principal of which are the following :—

Berger's process (Eng. Pat. 9013, 1841).—By this method : 1. Starch is manufactured from rice by the application of an alkaline salt, *e.g.* sodium carbonate, whereby the gluten is dissolved or freed, so that the starch may be separated therefrom. The operations are in all respects analogous to those of Jones' process.

2. The rice is soaked in water and submitted to a process of fermentation ; or

3. The first and second processes are combined.

Colman's process (Eng. Pat. 2166, 1841).—1. Rice is mixed with the refuse from wheat or other grain in the proportion of fifteen pounds of the latter to every hundredweight of rice, and, the necessary quantity of water being added, the mass is allowed to ferment for 10 to 15 days, after which the starch is separated by washing and sifting as already described.

2. The rice is steeped in water for 4 days, then drained, and reduced to a pulp in a mill under a stream of water, collected in a reservoir, allowed to settle, and the water siphoned off.

The deposit is then agitated with a dilute solution of hydrochloric acid (about 2 p.c.) and allowed to stand for 5 days, being well stirred every 4 hours during that time, then allowed to settle for 18 hours, the clear liquor drawn off, and the operation repeated with a 0·5 p.c. acid solution. Finally, the deposit is washed with large quantities of water, passed through sieves, drained and dried in the usual way.

Rehe patented a process (Eng. Pat. 10359, 1884) according to which the rice is first submitted to a temperature of 160° to 180°F. before steeping, and afterwards macerated in soda lye (four pounds of soda to every hundredweight of rice), and the starch extracted in the usual manner later on.

Ransford introduced a process (Eng. Pat. 1853, 603), in which pressure is applied to the rice after it has undergone the steeping operation. The rice having been put into the steeping liquor, in a vessel capable of being closed down, is allowed to steep for some time. The vessel is then closed down tight and more liquor forced in by means of a pump, up to about 20 lbs. to the square inch ; this is continued for a short time, the liquor drawn off, and again pumped in. The liquor is then drawn off, and the rice further pressed so as to drive out as much gluten as possible, after which it is ground and treated in the usual way.

In Germany the manufacture of starch from rice has replaced wheaten starch to a large extent, and J. Berger, who appears to have given much attention to this subject, has published an interesting account of the process as carried out there at present (Chem Zeit. 14, 1440, 1571 ; 15, 843), an abstract of which is given below.

The raw material principally employed in Germany is obtained from rice-cleaning and polishing-mills, and consists of the broken grains. The percentage composition of various samples of this waste is given in the following table :—

—	East Indian rice			Russian rice	Egyptian rice	Persian rice
Water .	12·10	13·20	13·23	12·70	11·84	10·80
Starch .	76·25	73·90	77·44	75·81	78·30	73·20
Protein .	8·95	8·79	6·87	7·94	6·70	11·21
Fat .	0·42	0·71	0·35	0·40	—	0·75
Gum and sugar .	0·86	1·20	0·95	1·21	—	1·45
Fibre .	0·32	0·40	0·36	0·44	—	0·81
Ash .	1·10	1·80	0·80	1·45	1·16	1·78

Extraction. The operation for the extraction of starch is carried out in shallow tanks of 4–5 cm. capacity. The rice is piled on a perforated shelf fixed in the tank, and covered with soda lye of 0·5° to 1°Bé. The mixture is stirred a few times, and after about 18 hours the lye is run off and replaced by a fresh lot, which is allowed to remain for 12 hours, by which time the rice is, as a rule, sufficiently softened to be ground ; this is effected between millstones 1200–1400 mm. in diameter and 300–400 mm. thick, and making 120 to 140 revolutions per minute. Incomplete grinding must be avoided as much as possible, and therefore in most factories the rice is passed through two mills arranged side by side, so that the ground starch drops directly from the first into the second mill. During grinding, the rice is moistened with lye of the same strength as that used for softening, about 200 litres being required per 100 kilos. of rice. The starchy liquor flowing from the mill, and containing about 20 to 28 p.c. of solid matter, is carried up by suitable means to high-lying tanks, from whence it is distributed to the sieves and other apparatus.

Sieves. Rotating cylindrical sieves are almost invariably employed, and are constructed as follows : A shaft, 4–5 metres in length, is provided at intervals of 1 metre with three rods of equal length, arranged symmetrically at right angles to the shaft. The ends of these rods carry six wooden boards parallel to the shaft. The framework thus formed is covered with the finest silk gauze. The cylinder is so arranged that one end of it lies about 15 cm. higher than the other. The liquid to be strained is fed into the upper part of the apparatus. The starchy liquor, as it filters through, is collected in a wooden casing, which completely surrounds the cylinder, whilst the impurities remaining on the sieve pass along into a tank opposite the lower end of the cylinder. The shaft of the cylinder being hollow, and pierced with numerous holes, allows water to be forced through on to the sieves. By this means the walls of the cylinder are kept clean, and the passage of the impurities towards the lower end is facilitated. The starchy liquor passing through the sieves still contains much gluten, which may be separated in the manner described under *Potato starch*, either by means of settling tanks, or with the centrifugal machine.

Berger suggests many improvements in the above process. Great stress is laid upon the importance of the preliminary softening of the rice with a solution of caustic soda, as the precise action of caustic soda has been misunderstood by most rice-starch manufacturers, being generally regarded as a mere mechanical one instead of a distinctly chemical one, the caustic soda dissolving out the albuminous substance which cements the starch cells together, thus rendering them more amenable to the after-operations. This softening process should be carried out as quickly as possible, especially in warm weather, in order to prevent fermentation, the evil effects of which are to be seen in all the after-processes. It causes the mass to froth excessively in the grinding-mill, and renders centrifuging difficult, the starch not separating as it ought to do in a state of purity, but coming from the centrifugals in flabby lumps; and, for the same reason, it refuses to deposit in the settling tanks. The gluten assumes a slimy condition, and retains much starch. In order to obviate this, Berger recommends that the extraction and softening of the rice be effected by a continuous current of slightly stronger lye (1½°Bé.), as by this means the treatment is considerably shortened, and at the same time the action is rendered more energetic.

Another method proposed by Mack (Dingl. poly. J. 256, 35), and which has been successfully adopted in Germany, consists in blowing air under pressure through the mixture of rice and caustic soda in such quantities that the liquid assumes the appearance of boiling. For this purpose air enters through a series of small tubes into a tank provided with a false bottom, on which finely-ground rice is spread, the tank at the same time being filled with the caustic soda solution. After the operation is finished the liquor is run off, and the resulting rice starch allowed to drain. By this process the rice is said to soften quicker, and yields from 6 to 8 p.c. more of the finished product.

When the various processes are employed in the order given, the yield of starch of the first quality is about 60 p.c. (calculated as absolutely dry starch on the rice), whilst 7–10 p.c. are left in the various by-products, and may be recovered by repeated treatment.

The total yield in a properly conducted factory is about 85–90 p.c. of the starch contained in the rice.

Moulding the starch. Formerly this was almost exclusively done in wooden boxes with perforated bottoms covered with filtering cloth. The boxes are set up in rows, and the starch mixed with water or weak soda lye (0·1° to 0·3°Bé), being charged into the first box, overflows into the next, and so on. In order to make the water drain out more thoroughly, the boxes are repeatedly lifted from their supports and dropped again. After about 24 hours the blocks of starch, still containing 42–44 p.c. of water, are removed, and cut into rectangular pieces. Various forms of high-pressure filtering moulds are now employed, and with these the starch-milk used for filling must not exceed in sp.gr. 1·2–1·25, otherwise the finished product exhibits a rough fracture which detracts from its appearance.

Drying the starch. Blocks of starch, containing 40–45 p.c. of water, when dried, become covered with a yellow crust, owing to the separation of traces of dextrin, &c. This crust is about 10 mm. thick, and is cut off when the blocks are partially dry—*i.e.* contain 25–28 p.c. of water. The remaining starch may be now completely dried without any further development of yellow colour taking place. All attempts hitherto made to avoid this crust formation have failed. The crust constitutes about 20–30 p.c. of the total starch. The shavings are stirred up with water, centrifuged once, or filtered, and mixed with the subsequent batch of pure starch. Large masses of starch, when dried, fall into more or less irregular rod-like pieces, the size, shape, and smoothness of surface of which depend greatly on the rapidity of drying and the solidity of the blocks before drying, too rapid drying or too slow drying producing discoloured pieces which readily crumble during transit. The same thing happens when particles of fibre are present, the even fissures being prevented by their presence. Starch is generally coloured in order to hide its slightly yellow tint, ultramarine being usually employed for the purpose. The blocks after being planed and wrapped in paper, are kept for 2–3 days in the drying chamber at the ordinary temperature, after which the temperature is raised gradually, commencing at 25°, increasing to 28° during the next 3 days and then slowly to 32°–35° at which it is kept until dry, usually 8 to 14 days. Starch dried at too high a temperature during the earlier stages, loses its colour and brightness and may become quite yellow.

Fermentation should be prevented as much as possible, as it prevents the deposition of starch in the settling tanks by reason of the evolution of gas and the presence of gas when drying cause them to break irregularly. Sulphurous acid or some other like agent is usually employed to prevent fermentation.

The dried starch contains about 12 p.c. of water, but on exposure to air it absorbs moisture up to 15 p.c., which is the commercially recognised standard. If it be desired to obtain the starch in large lumps, the blocks, after scraping, are cut up into smaller pieces, which are then slowly dried in the air.

Waste products. These consist of gluten and impure starch. They may be mixed, and used for cattle-feeding; or, more or less separated and utilised, the starch for feeding, and the gluten for manurial, purposes.

21. *Manufacture of starch from maize.* This process is principally confined to the United States, and no industry in that country has grown so rapidly and concentrated itself into a small circle of factories within the last half century as the manufacture of starch from maize or Indian corn, which is there termed corn-starch. An interesting account of this industry is given by Dr. G. Archbold, in J. Soc. Chem. Ind. 1887, 80–84 and 1902, 4–9, of which the following is an abstract:—

The average composition of maize or Indian corn used in American factories is as follows, and is known as No. 4.

	p.c.
Oil	5·20
Carbohydrates (starch therein 54·8 p.c.)	71·22
Proteids	10·46
Ash	1·52
Water	11·60
	100·00

Process of manufacture. Many improvements have been introduced in late years, and all the older processes, with one exception, are no longer used. This exception, known as the 'Chemico-Mechanical' process, is a secret process, producing a starch which no other process appears to approach in purity. Advantage is taken of the fact that maize or Indian corn contains two albuminoids which envelop the starch, one of these is soluble in water and the other in weak caustic alkali solutions. The process consists primarily of extraction of these bodies from the corn so that the resulting starch, as it passes through the various cleansing and drying processes, is absolutely free from everything likely to set up fermentation and acidification, whereby the final product would be injuriously affected.

The process in most general use in the United States is that known as the sulphur dioxide process or that process combined with alkali in the later stages. The sulphur dioxide process throughout is used by glucose makers with advantage.

There is a later process, known as the attrition or dry process, which promises a new era in the starch industry, should it ever be brought to perfection, which it is very far from at present. It consists in grinding the maize in an attrition mill and separating the constituents by means of a blower, the starch then being purified as in other processes.

In the extraction of starch from maize by the sulphur dioxide process, the dry grain is conveyed from the granaries to large hopper-bottomed steeping vats, made of 2-inch pine about 14 ft. deep and 12 ft. diameter. Water, impregnated with about 1 p.c. of sulphur dioxide, is run in upon it and is kept in circulation by means of steam syphons and at the same time heated and maintained at temperatures varying from 120° to 140°F. Steeping is continued for 2 to 4 days, according as the corn is amenable to the softening and disintegrating process to follow.

The following figures show what takes place during steeping:

	lbs.
Original bushel of corn weighed .	56·0
Water contained in this . . .	6·5
Weight of steeped corn, subsequently dried at 100° *in vacuo* . . .	49·44

This shows a loss due to the washing away of oil, albumenoid and ash of 0·06 lb. or 1 oz. per bushel of corn. The water absorbed by each bushel of corn is 29·75 lbs. or about 3 gallons.

The steep waters may be run to waste or evaporated for the recovery of the soluble material therein for the manufacture of cattle food. In this wet and softened condition the grain is conveyed to the crushing room, where it is run through Foos mills or their equivalent, by which means it is cracked, decorticated and partially ground, giving rise to a diffluent mass. This is diluted with water so that the most finely ground portions form a liquor (separator liquor) and is passed through the Degerminator —a large long V-shaped tank fitted with a screw conveyor in the bottom and skimming paddles at the top. The oil-bearing germ floats and is skimmed off while the endosperm, starchy and glutinous matter, cortical tissues, bran and fibrous matter pass on. The oil bearing germ is conveyed away, washed free from adherent starch, dried, ground, 'cooked' with live steam, and its oil expressed in hydraulic presses. The resulting products are:

Corn oil, used in manufacture of soap;

Oil cake or *maize germ cake*, used as cattle food.

The cortical and endospermal portions, the most finely ground of which are termed separator liquor, are screened by passing them over a vibrating copper sieve. The coarse material separated is caught in an elevator and conveyed to the grinding room where it is ground with the necessary quantity of water in two or three burr stone mills built for grinding wet corn, and then pumped to feed vats fitted with stirring gear and combined with the previously separated 'separator liquor.'

This mixture is delivered from these tanks on to a series of shakers. These are wooden frames about 9 ft. by 4 ft., fitted with No. 10 bolting cloth of the best material in three or four sections which receive a vibratory motion by means of an eccentric shaft, the shakers themselves being set upon hickory sprains to give a soft but rapid motion. When run through these shakers the milky fluid has sp.gr. of 3°Bé on an average, and contains in one gallon about 5·42 oz. of pure starch and 1½ oz. of dry feed.

The separated unground portion is conducted back to the mills for a second grinding and then goes a second time over the shakers.

The branny portions of the grain or 'wet feed' left on the shakers is conveyed to a stirring tank mixed with water, passed over a second series of shakers, where it is washed as free from starch as possible, and conveyed to presses where it is practically freed from water, and emanates therefrom as 'press feed,' or is dried in an appropriate apparatus and sold as corn bran. Its composition is as follows:

Moisture	8·93
Proteids	10·50
Fat	2·75
Carbohydrates	65·04
Fibre (insoluble) . . .	12·30
Ash	0·48
	100·00

The liquors from the shakers and mill, now known as 'mill liquor' or 'crude starch liquor,' are sometimes passed over another series of sieves or shakers to remove the more or less gritty, glutinous and fibrous residues, or they flow immediately over runs, trays, tables or gutters as they are variously termed. These runs are made of wood and are in 16 sections, 120 ft. long and 6 to 8 in. deep. Each section is divided into 3 canals, 18 in. wide, by means of partitions, and is inclined at an inclination of ⅜ in. in every 12 ft.

The starch liquor is allowed to flow on each division of the tables at the rate of 1 gall. per 35 secs. at a density of 3½°Bé. Here the suspended impure starch is deposited almost completely, the liquor containing the glutinous and other residues flowing off at the ends at the rate of 1 gall. per 20 secs., having a sp.gr. of ½°Bé., the deposition of starch having caused the lowering of the density to this degree.

These run tailings are conducted into continuous settling tanks, where the solids are allowed to subside while the clear supernatant liquid is syphoned off and run into sieves. The so concentrated liquor is sold as a liquid feed under the name of 'slop' or 'swill,' or may be passed through filter presses and the solid material sold as gluten meal. The 'green starch,' which has been deposited on the runs, containing about 50 p.c. of moisture, is shovelled off and stirred up with water in the 'breakers.' These are wooden vats several feet high, the diameter of which is equal to the height, and are provided with agitators. The starch is here mixed with water to produce a mixture having a density of 7°Bé, and according to the use for which it is destined may or may not receive at this stage a chemical or alkali treatment with caustic soda before going on to the runs a second time.

If it is to receive alkali treatment the agitators are set in motion and a solution of caustic soda at 3°Bé very cautiously added until the milky liquid has changed to a greenish-yellow colour. The action of the alkali neutralises any acidity and precipitates a small proportion of the dissolved albuminoids, and the excess of alkali dissolves or emulsifies the oil, dissolves the gluten and coagulates and discolours the mechanically divided fine feed and insoluble gluten (that which acids alone dissolve). From the breakers or alkali tanks, it is pumped to the regulators, usually four wooden vats fitted with agitators, where it is reduced to 3° or 3½°Bé., and thence flows over the table or runs once more.

The deposited starch is transferred once more to the breakers, where it is mixed with water and run direct to the boxes, or first reduced to a gravity of 11° to 12°Bé and allowed to run on to a second series of shakers, where it is separated from fine coagulated matter, and passes through at about 8°Bé. This liquid is then run into settling vats, 10 ft. diameter by 10 ft. deep, in which at various heights up the sides are openings fitted with valves. The starch is allowed to settle in these vats and the impure water is run through the valves in the sides. Fresh water is now added and the liquor made up to a gravity of 23° to 24°Bé. The thickened purified starch liquor from the 'breakers' or settling vats now runs into a series of boxes, made of pine 7 in. × 7 in. × 5 ft. 7½ in. long, the sides being slightly inclined and having a perforated bottom to admit of drainage. These boxes are placed on a table and allowed to drain overnight when the moisture content is reduced to 55 p.c. It is then dumped from the boxes and the oblong blocks cut in pieces of about 12½ lbs. weight, placed on an absorbent medium or floor, generally made of porous brick covered with a layer of plaster of Paris cement, and heated underneath by means of a series of steam pipes. Here the starch remains for some hours until the moisture it contains is reduced to about 45 p.c. It is then ready for the crushing process. The blocks of starch are placed side by side on a rack or shelves in a kiln, and allowed to remain therein exposed to a heat of 120°–130°F. until a yellowish-brown crust forms on the outside, varying in thickness from ⅛ to ¼ in. They are then taken out and the crust removed, when the interior appears perfectly white. In this state it is wrapped in paper, and again returned to the kiln, and now exposed to a temperature of 156°–176°F. for a period varying from 3 to 15 days or sometimes even longer. During this time the blocks of starch separate up into a series of irregularly shaped rods resembling prisms, more or less, and are technically termed 'crystals.' A high temperature and short period in contact therewith gives small pipe 'crystals,' whilst with a low temperature and longer time the starch is obtained in larger chunks and more irregular.

The browned starch which has been removed from the blocks is returned to the washers, alkali added and again run over the tables and shakers, boxed, tiled and dried as with the former starch.

The methods of drying have been considerably improved within recent years, whereby the time taken is considerably reduced and the quality of the starch improved.

The purified starch liquor is run into specially constructed boxes lined with muslin and arranged on a table provided with a vacuum chamber, the moisture being extracted from the starch by means of a vacuum pump. By this method the crushing and scraping processes become unnecessary. The starch from the boxes is cut into 7-in. cubes and placed in drying kilns arranged with a current of hot air and an exhaust for moist air, the time for drying being reduced by this means from weeks or days to hours.

There are two types of starch on the market known respectively as (1) 'thick boiling' starches either 'chemicalled,' *i.e.* prepared by treatment with alkali, or 'unchemicalled,' in which no alkali has been used, the starch instead being put over the runs a second time and dried more or less slowly. These unchemicalled starches are used for baking powder or as a size in textile industries; (2) 'thin boiling' starches prepared by two processes termed the drying-in process and the in-suspension process.

In the 'drying-in process,' unchemicalled starch is suspended in water to about 22°Bé, and a certain quantity of hydrochloric acid added to the mills. It is then boxed and drained and the starch containing 42–43 p.c. of moisture is broken up and dried. During this process, the small quantity of hydrochloric acid converts some of the starch into the soluble form, the starch thereby producing a paste with considerably less viscosity.

In the 'in-suspension' process the starch, suspended in water at about 22°Bé, is heated at a temperature well below the gelatinising point with a small quantity of sulphuric or hydrochloric acid, the liquid being constantly stirred. It is then boxed and dried in the usual way.

These thin boiling starches, used principally in the laundry and confectionery trades, produce a paste on boiling with water of much less viscosity than the ordinary or thick boiling product, the degree of viscosity being regulated according to their application. Starches prepared from maize in this way are capable of yielding as good results in the laundry as starches from rice or wheat or any blend of such starches.

22. *Manufacture of starches for edible purposes.* Alimentary substances may naturally be divided into three well-marked groups—carbohydrates, proteids, and fats; and of these fully two-thirds, or perhaps more, of the food of mankind belongs to the carbohydrate group, of which starch is by far the most important member.

In the raw state, according to Roberts (Digestive Ferments, p. 17), starch is to man an almost indigestible substance, but when previously subjected to the operation of cooking it is digested with great facility. Diastase has, at best, only a comparatively feeble action on the unbroken starch granule, even at the temperature of the body. By the aid of heat and moisture in the process of cooking the starch granule is much more effectively broken up, and in the gelatinised state is very rapidly attacked and digested by the diastatic juices of the body.

In addition to the large quantities of starch consumed in the natural form—as rice, potatos, bread, &c.—numerous forms of prepared starches are met with in commerce as articles of food. These differ in a most essential degree from wheat and other cereal flours in that they consist almost entirely of absolutely pure starch granules, which very readily gelatinise and become easily assimilated.

In this country large quantities of edible starch are manufactured from maize and rice, whilst in France potatos are largely employed for the same purpose. The colonies furnish a very large proportion of edible starches, the principal being arrowroot from the West Indies, Natal, India, Fiji, and Queensland.

23. *Cornflour.* Although the manufacture of starch from maize has been practised in this country for the last fifty years, the product therefrom—known under various names, such as Indian cornflour, oswego, maizena—has been used chiefly for edible purposes, whilst most of the starch used for other household as well as manufacturing purposes has been that made from wheat and rice.

This industry is centred in Paisley, Scotland, having been first introduced by Polson (Eng. Pat. 1854, 1068). The process of manufacture is now, however, practically identical with that employed in America, the raw material being maize or Indian corn imported from various, and often widely different sources.

Large quantities of rice starch are treated in a somewhat similar way, and sent out for dietetic purposes, under the name of British cornflour and other fancy names.

24. *Arrowroot starch* or arrowroot is derived from plants of the genus *Maranta*, the most important member of which is *Maranta arundinacea* (Linn.), a native of the West Indies, and which furnishes most of the genuine West Indian arrowroot. Three other species of *Maranta* are also cultivated for the production of starch: *M. nobilis*, *M. Allouia* (Aubl.), which grow in the West Indies, and *M. ramosissima* (Wall.), which is a native of the East Indies.

The arrowroot plant is herbaceous, from 4 to 6 ft. high, and has broad, pointed leaves. The tuberous roots or rhizomes are pointed, covered with scales, and sometimes a foot in length and about the thickness of a finger.

The starch is stored in the rhizomes of the plant, and requires to be extracted and purified to render it fit for market.

The following details of manufacture are taken from a paper by J. W. Macdonald, on 'The Manufacture of Arrowroot Starch in St. Vincent' (J. Soc. Chem. Ind. 6, 334).

The first part of the manufacturing process is to soak the roots in water, to soften the covering and the adhering earth. They are then stripped of the covering and washed, and thrown into a second or rinsing tank. When thoroughly clean they are taken to the pulping machine. The skin is said to contain a resinous matter, which gives a yellow tinge and unpleasant flavour to the starch if the latter is not well washed. In former times the roots were skinned with German-silver knives before being pulped. This is said to have produced whiter starch; but as it was so laborious and expensive, it was discontinued. The skinned roots were pulped by subjecting them to great pressure by passing them through an upper, and then a lower and much closer, pair of brass rollers, to break the starch cells. The method of pulping now generally adopted is to feed the clean unskinned roots against a fine saw grater very similar to a potato grater. It is a solid cylinder of hard wood, about 23 in. diameter and 7 in. wide. Slits are made by a saw from end to end of the wood at half-inch intervals. Saw blades having 6 to 10 teeth to the inch are then fitted into the slits, and the whole immersed in water to swell the wood and fix the saws. The grater is now fitted into its place very close to a wooden feeding bed. As it revolves several hundred times per minute, it tears the roots into shreds. A great deal, however, depends on the fineness of the teeth and the velocity of the drum.

On account of the very fibrous nature of the pulp, there is considerable difficulty in the sieving or separating of the starch from it. The fibres readily gather into lumps and inclose the starch, so that hand-sieving, although very tedious, has to be resorted to. The pulp is first run into a box or sieve, the bottom of which is a sheet of copper or tin punched with holes one-fifth of an inch diameter. While water flows on, the contents are kept thoroughly agitated by hand until all the starch has been washed out. While one strainerful is being washed, another is being filled, so that there should be no delay. However careful one is, there is a loss of starch in the fibre, owing to the presence of small bits of roots which have escaped pulping.

In one factory a stationary half-cylinder is employed. Its under side is pierced with small holes; but there is a slide under this to open or close at will. Inside there are rakes attached to two shafts, which move in opposite directions and cause the rakes to oscillate very rapidly between each other, thereby keeping the fibre always open. The starch water is let out, more water run in, and the operation repeated until all the starch is extracted, after which the fibre is taken out. The great objection to any mechanical washer is the tendency of the fibre to accumulate on the agitators and break them. To get over this difficulty it has been proposed to chop up or slice the roots into small, short pieces, and either rasp them or pass them through metal rollers or millstones, so that the thin disintegrated pulp may flow over mechanical sieves. Although causing a loss of starch, the present method of rasping avoids an undue pulverising of the soft yellow fibre, and so gives a very white starch without much trouble.

From the fibre-strainers the starch water flows consecutively through a series of brass wire sieves of 40, 80, and 100 meshes to the inch; each of these retain small fleshy bits of unpulped root. From the last sieve the water runs into the settling cisterns, which are preferably lined with white glazed tiles to avoid accumulation of slime.

A portion of fibre collected on the finer sieves is used for feeding the animals on the estate; the remainder, and all the coarse fibre, is used as manure. For this purpose it is left in heaps until it decomposes, after which it is distributed on the fields along with pen manure; sometimes ashes and guano are used. The waste water from washing the starch contains a considerable amount of vegetable matter, and gives good results where it is run on the fields; but the extensive application is not practicable. After the starch has settled in the cisterns the water is run off, and more added; the whole is stirred up again, and allowed to settle. This generally suffices to dissolve out soluble matters. At night all the cisterns are drained, and the starch is dug out and taken to a mixing-box, where it is mixed with a small amount of water, then run through another fine sieve into the separating pans. These are small round galvanised cisterns, with smooth perpendicular sides. When filled, the starch-milk is stirred round with a small oar until it is in violent circulation. The oar is withdrawn, and the cisterns left until morning. The stirring has the effect of separating the starch from any remaining impurities. These, being of less specific gravity, settle last, and therefore on the top of the starch. Next morning the water is drained off, and the light, impure starch scraped off the surface. If the earlier parts of the process are carelessly done, this separation may have to be repeated before the starch is quite pure. The impure surface starch contains a large proportion of starch entangled in very fine particles of fibre and broken cell walls. Although this can be dried and exported as an inferior starch, it is generally given to the labourers as a perquisite. It is used in various forms as flour. Poultry and pigs are also fed with it. Weak caustic soda extracts a colouring matter from it, but also precipitates a yellow substance, making it very difficult to separate the starch from it in a pure state.

The pure starch in the separators is now taken out in blocks, and placed on trays for about 12 hours to dry and harden. It is then broken into smaller pieces and taken to the drying house, where it is air-dried, the building being open on all sides for free circulation. It is surrounded, however, with galvanised wire to keep out the small birds which hover about. Inside there is a series of wire shelves over large shallow wooden trays. The top shelf is made of very open wire, the next is closer, and so on, the lowest being the closest. The wet lumps of starch are placed side by side on the top shelf, where they remain until, by the action of the air, they crack up and fall through to the next shelf. In time the whole falls through the lowest shelf, and is in a fine granular state, ready for packing. It contains from 14 to 17 p.c. of water. In cold, wet weather the starch dries very slowly, taking sometimes as long as two weeks. During this time, if it has been imperfectly purified, the lumps get sour and become yellowish. Indeed, the whole process must be as rapid as possible. In the settling cisterns especially, if the starch is left in contact with the impure water too long, its whiteness is affected. The crop lasts from October to May. The name ‘arrowroot’ is probably derived from the Indian word Ara-ruta, or ‘mealy root’; but some say that this root has been confounded with the *Maranta Galanga* (Linn.), which was called the arrowroot on account of its bruised roots being employed as an antidote to the poison of the *Manihot utilissima* (Pohl), used for poisoning arrows.

Regarding the yield of arrowroot, an acre will produce 13,000 to 15,000 lbs. of roots, according to the season; in wet seasons the roots are heavy and moist, and give less starch. A fair average yield is 22 cwts. air-dried starch, with 14 p.c. water, per acre, or about 19 p.c. on good roots. There is no doubt this can be considerably increased by the use of improved pulping and sieving machinery.

The following analyses will give an idea of the constituents of the roots, as well as of the composition of the finished starch:—

	Roots	Starch
Starch	27·07	83·70
Fibre	2·82	0·04
Fat	0·26	0·07
Albumen	1·56	—
Sugar, gum, &c.	4·10	0·18
Ash	1·23	0·14
Water	62·96	15·87
	100·00	100·00

The ash consisted of calcium phosphate and alkaline sulphates and chlorides.

Arrowroot starch swells much more readily and with less heat than maize, rice, or wheat starch, and forms a stiffer jelly. It is, therefore, well adapted for sizing and laundry purposes. As an article of food it must be regarded as the purest, most digestible, and palatable of the starches.

Methods similar to the above are employed for the extraction of arrowroot starch in the East Indies, Natal, and Queensland.

25. *Cassava starch* or *Brazilian arrowroot*. The root which produces this starch is somewhat similar to that of the *Maranta*, and is known as Cassava or Manioc. It belongs to the genus *Manihot*, the most important of which is *Manihot utilissima* or *Jatropha Manihot*, a native of Brazil, but now cultivated in India, Guiana, West Indies, and various parts of Africa. In Brazil considerable attention has been given to the manufacture of starch from various tubers and roots; but cassava starch is

the principal kind which is manufactured there, and is known as Brazilian arrowroot. Its mode of preparation is very similar to that of East Indian arrowroot.

Tapioca is prepared by heating the cassava starch whilst still moist upon hot plates, keeping it well stirred with an iron rod all the time. A large number of the starch granules burst during the process of heating, and adhere together in small irregular masses, in which form it is imported into this country. Tapioca is partially soluble in cold water, and readily swells up in boiling water, forming a transparent jelly.

The natives of Brazil prepare cassava meal by reducing the tuberous roots to a pulp either by rasping or grinding, after having first washed and peeled them. This pulp is then placed in bags made of plaited reeds, and subjected to pressure, so as to express the juice. The residue —consisting of a mixture of starch, vegetable fibre, and albuminous matter—is partially dried in the sun and partially on hot plates over a slow fire, and kept continually stirred with a wooden spoon until it is dry, but not browned; it is then known as cassava meal, and used for making bread. The juice is allowed to stand for some time, when the starch contained in it subsides, and is washed with water, constituting a finer meal. The roots of the species known as bitter cassava contain an acrid poison, hydrocyanic acid, which, being volatile, is readily dissipated by heat, or may be washed away with water.

26. *Curcuma starch.* In the East Indies a starch is prepared from the tuberous root of *Curcuma angustifolia* (Roxb.), which is sometimes known as East India arrowroot, and said to be rather extensively manufactured in Travancore and other parts of North-west India.

27. *Arum starch.* A starch very much resembling cassava starch, and which was used as a substitute for arrowroot, and known in the market as Portland arrowroot, was obtained from the roots of the wild arum, or *Arum maculatum* (Linn.), this plant being formerly cultivated in the Island of Portland for this purpose.

28. *Tous-les-mois.* This starch, the granules of which are the largest known, is extracted from the rhizomes of the *Canna edulis* (Ker-Gawl), a native of the West Indies, principally at St. Kitts. That which is imported into this country is used partly in the manufacture of cocoa and partly in the preparation of food for infants.

29. *Sago.* This is the name given in commerce to a prepared starch obtained from the pith of several varieties of palms, which are indigenous to the Malayan archipelago, the Philippine Islands, and parts of India, wherever there is a soil suitable for their cultivation. This consists of marsh or bog land, composed of decayed vegetables, near the sea. The principal species are the following: *Metroxylon Sagus* (Roxb.), *Raphia pedunculata* (Beauv.), *Borassus flabellifer* (Linn.), and *Arenga saccharifera* (Labill.).

All these palms propagate themselves by lateral shoots as well as by seed, so that a sago plantation, when once formed, may be said to be perpetual. The growth is slow at first, but when once fairly started proceeds rapidly, until a height of some 20 to 30 feet is attained by the stem.

The sago tree, when cut down and the top severed from it, represents a cylinder about 20 in. in diameter, and from 15 to 20 ft. in length, consisting essentially of a hard woody tube, the interior of which is filled with starch granules intermixed with fibrous matter. From such a tree about 700 lbs. of starch would be extracted, so that three such trees would yield nearly double as much food material as one acre of wheat. Sago is, however, far from being either so palatable or nutritious as it is prolific, and even where it is more abundant is never preferred to rice.

By far the greater portion of sago imported into this country comes in the raw state as sago flour, and is used to a very large extent in the manufacture of glucose. Singapore is the headquarters for exportation of sago, both raw and manufactured being brought there from the islands to the eastward, principally from the north-west coast of Borneo and the north-east of Sumatra, with its adjacent isles from Siak to Indragari, as well as from many other places more distant.

To obtain the starch or flour, the trees, as soon as they have arrived at a suitable stage of growth, are cut down close to the roots, the stems sawn into pieces 7 or 8 ft. long, which are split open and the pith extracted. This is then pounded up in wooden mortars so as to reduce it to powder, agitated with water in a trough, run through sieves to free the starch from cellular tissue and fibrous matter, allowed to settle, and, after washing several times with water, is dried and sold as sago flour.

What is known as granulated or pearl sago is prepared from sago flour in the following manner:—The flour is made into a stiff paste with water, and rubbed through a metal sieve into a heated, very shallow, copper or iron pan, greased inside with vegetable fat. During the process of heating, the starch granules are kept constantly agitated, a portion of them swelling and becoming pasty serve to bind the remainder of the granules together. The resulting cohering particles obtained in this way are called pearl sago, of which two kinds are known in commerce, one consisting of small grains about the size of rape seed, and the other of grains about two or three times the size.

Granulated sago appears to have been introduced into Europe in the early part of the eighteenth century, but there is reason to believe that the starch from the sago palm has been used as an article of food by the natives of those countries in which it grows from a very remote period.

A sample of pearl sago gave on analysis:

Starch	84·64
Water	15·22
Mineral matter	0·14
Total	100·00

In later times, in Germany and France, sago has been made from potato starch, and introduced into commerce as 'Indian sago,' the best specimens of these imitations surpassing real sago in appearance and whiteness; so that the question arises, Is there any essential difference between the European imitation and the real sago of the tropics? Opinions as to goodness of flavour differ, and in reference to the nutritive values of the two there have been no scientific investigations. *A priori*, it is not impossible that the nutrient value of the real is greater than that of the artificial, since the former contains more granulose. However, the difference between the relative values of the two is not nearly so great as the difference in price, which stands almost as 1 : 2.

Sago has the property of swelling up in hot fluids without losing its coherence; the granules do not fall to pieces, but appear as transparent and gelatinous, but not sticky, spheroids.

30. *Inulin.* In the tubers of the dahlia, Jerusalem artichoke, and other plants of a similar character, there occurs an amylaceous substance which bears a very close resemblance to starch, having identically the same ultimate composition, and which, indeed, for all practical purposes may be regarded as another form of starch. To this substance the name of *inulin* has been given. It is a white hygroscopic powder or sphaero crystals, insoluble in absolute alcohol and sparingly soluble in dilute alcohol. It has the power of reducing ammoniacal silver nitrate.

Kiliani (Annalen, 205, 145) prepares inulin as follows. Roots of *Dahlia variabilis* (Desf.) are well washed, and, after being rasped, are boiled with water in the presence of sodium carbonate. The liquid obtained is cooled by means of a freezing mixture, allowed to stand some time, and the precipitate which settles out dissolved in hot water, filtered while hot, and again exposed to a freezing mixture. This process is repeated three or four times, after which the inulin is obtained as a perfectly white substance. It is then treated with alcohol, whereby any lævulose that may be present is removed, and the inulin finally dried over sulphuric acid *in vacuo*.

Inulin is not acted upon by diastase, but is converted into lævulose when heated with dilute acids.

31. *Lichen starch.* In Iceland moss there occurs a form of starch easily soluble in water, from which it is thrown down as a flocculent precipitate by alcohol, and which gives the characteristic blue colouration with iodine. It rotates polarised light strongly to the right, and is readily converted by diastase into dextrin and maltose. Lichen starch, therefore, appears to be a soluble, unorganised modification of ordinary starch.

32. *Glycogen.* In the livers of most animals there is produced a white amorphous substance which forms an opalescent solution with water, from which it is precipitated by alcohol, and is transformed into dextrin and maltose by the action of diastase, and to which the name of glycogen has been given. It has a formula $C_6H_{10}O_5$, specific rotatory power $[\alpha]_D + 197°$, and gives a wine-red colouration with iodine. It may be regarded in every sense as an exact counterpart of soluble starch, and is considered to be reserve starch material elaborated from the sugars and other carbohydrates consumed as food.

33. *Detection of starch.* The presence of starch existing in the solid state in any substance is most readily detected by microscopic examination, supplemented, where necessary, by the addition of iodine solution to the slide, when the characteristic blue colouration is at once observed if any starch granules are present. In this way the presence of starch in chlorophyll granules may be readily detected by Sachs' method (Chem. Zentr. 1884, 945). The fresh green leaves are plunged into boiling water for 10 minutes; certain soluble substances are thereby extracted, whilst the starch and colouring matter of the chlorophyll grains remain intact. A short immersion in 96 p.c. alcohol now removes the green colouring matter and certain bodies soluble in alcohol, leaving the starch behind in the colourless tissue, the decoloration proceeding more rapidly in sunlight or warm alcohol than in the dark and cold. After this treatment the leaves are placed in a strong solution of iodine, made by dissolving iodine in alcohol, and then diluting with distilled water until the liquid has a dark-brown colour. They are allowed to remain in this liquid for about an hour, or until they no longer acquire colour. If no starch is present the leaves are simply stained yellow; if they are stained slightly black, very little starch is present. If a large quantity of starch exists in the cells, the tissue appears blue-black or black, with a metallic lustre, the venation appearing as a pale network in the dark ground. By this means the absence of starch from etiolated leaves, from the white portions of variegated foliage, and from those portions of the leaf which have been covered by paper or tinfoil, may be readily demonstrated.

When a sample of a substance supposed to contain starch is to be examined under the microscope, it is first reduced to a fine powder, if not already in that state; a small quantity of it is then mixed with some water in a watch-glass by means of a glass rod, and a drop of the mixture placed on the slide, a cover glass put on, any superfluous moisture round the edges of the cover-glass carefully removed with blotting-paper, and the slide next placed under the microscope; the stage should be illuminated with rather oblique light, a ½ or ¼ inch objective, with a B eye-piece, being the most suitable magnifying power to employ.

The following points should be observed: the size and form of the granules, the position and character of the hilum, the nature of the striæ or concentric rings, and the appearance presented by the granules under polarised light. In the latter case, it is advisable to mount the sample in glycerin instead of in water; a red-green selenite plate may also be advantageously employed. It is only by careful microscopical examination that one particular form of starch can be differentiated from another, and it is comparatively easy when only one kind of starch is present; but when mixtures of different starches occur in the same sample, the detection of each particular one becomes a matter of some difficulty.

The following method, as given by Bell (Chemistry of Foods, 2, 151), appears to be practicable for most of the commonly occurring varieties:—

To insure the homogeneousness of the

sample, it is first rubbed in a mortar, and passed several times through a sieve. A small quantity, say 0·5 of a grain, is then weighed out and placed upon a glass slide, where it is worked into a thin paste with about two drops of water. A thin covering-glass, measuring about 1½ inch by 1 inch, is then placed over the paste, and moved about the slide until the paste is equally distributed and all under the covering-glass. With a ¼-inch objective and B-eyepiece the number of granules of foreign starch is counted in nine 'fields,' as fairly as possible representing the entire slide. The process is repeated until a correct idea of the composition of the sample is obtained.

Standard mixtures approximately representing the sample are then made up and treated in exactly the same way, and, from a comparison of the results, the percentage of foreign starch is computed.

When the percentage of foreign starch is large it is advantageous, in order to facilitate the counting of the granules, to insert in the eye-piece a slide accurately divided into squares.

In cases where the granules of added starch are so small and numerous that it is impossible to count them, as with rice starch, a similar process of preparing the slides is followed, and as correct an estimate of the foreign starch is made as is possible by a comparison of the appearance of the sample with that of the standard mixtures.

It is often advisable to use a dilute solution of iodine instead of water in preparing the slides for examination, as the resulting colouration of the starch granules renders them more distinctly visible.

Sometimes it is desirable to remove the colouring matter from the solid substance, and if cold water fails to effect this, alcohol and other solvents should be tried. Successive treatments of the substance with cold water and alcohol, however, will usually render the starch observable microscopically without having recourse to other solvents.

As an aid to their microscopical examination and recognition, Allen (Commercial Organic Analysis, 335; revised edition 1909, 411), following Muter, arranges the starches into five classes, having the following general characteristics :—

I. **The Potato Group** includes such oval or ovate starches as give a play of colour when examined by polarised light and selenite plate, and having the hilum and concentric rings clearly visible.

II. **The Leguminous Starches** comprise such round or oval starches as give little or no colour with polarised light, have concentric rings all but invisible, although becoming apparent, in many cases, on treating the starch with chromic acid, while the hilum is well marked, and cracked or stellate.[1]

III. **The Wheat Group** comprises those round or oval starches having both hilum and concentric rings invisible in the majority of granules. It includes starches from wheat and some other cereals, and a variety of starches from medicinal plants, such as jalap, rhubarb, senega, &c.[1]

IV. **The Sago Group** comprises those starches of which all the granules are truncated at one end. It includes some starches used for food, together with those from belladonna, colchicum, scammony, podophyllum, canella, aconite, cassia, and cinnamon.

V. **The Rice Group** contains the starches, all the granules of which are polygonal in form. It includes the starches from oats, buckwheat, rice, pepper, and ipecacuanha.

34. *Microscopical appearance of different varieties of starch.* The microscopical appearance of the different varieties of starch granules is shown in the following illustrations, which are taken from Dr. Bell's Chemistry of Foods, Pt. II.

Class I.—(*a*) *Canna*, or *Tous les mois* (Fig. 15). The granules of this starch are the largest known, are ovate in form, rounded at one end, and more or less pointed at the other, near which is situated the circular hilum. The rings are well marked, but not complete.

(*b*) *Potato* (Fig. 16). Granules vary much in form, the smaller ones being more or less spherical, whilst the larger are ovate or oyster-shaped. The hilum, which may be circular or stellate, is generally near the smaller end. In the larger granules the concentric rings are very distinct and complete.

(*c*) *Maranta* or *arrowroot*. According to Bell, *Bermuda arrowroot* (Fig. 17) may be taken as the most perfect type of a maranta starch. In no other kind of arrowroot do the granules so generally exhibit an irregularly oval form, with the peculiar, small, nipple-like projection near one end, where also is situated the hilum, which is either circular or linear. The rings are concentric and numerous, always visible, but not strongly marked.

(*d*) *Natal arrowroot* (Fig. 18), as compared with Bermuda, may be taken as an example of the divergence which occurs in the form, size, and general appearance of the starch granules yielded by different varieties of maranta. The hilum is generally linear. The rings are very distinct under water.

Class II.—*Bean*, *Pea*, and *Lentil* (Figs. 19, 20). These starches are very similar in appearance, and not distinguishable from one another in mixtures. The granules are oblong, kidney-shaped, and irregularly formed, most of them having a longitudinal cavity running along each granule lengthwise, and from which, in many instances, furrows diverge to the right and left, imparting to their surfaces a fractured appearance.

Class III.—*Wheat* (Fig. 21). The granules, which are nearly circular, present a flattened appearance under the microscope, and are generally of two sizes—large and small. Hilum central; rings concentric and very faintly marked.

Barley (Fig. 22). The granules are very similar to those of wheat, but rather more irregular in shape.

Rye (Fig. 23). The granules of this starch

---

[1] All these starches present very close resemblances, and are generally indistinguishable from each other when in admixture.

[1] The cereal starches may be divided into two well-defined groups, wheat, barley, and rye starches being circular, or nearly so, while the starches of rice, maize, buckwheat, and oat are polygonal.

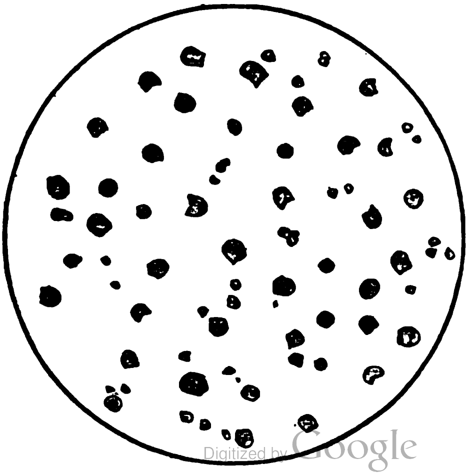

Fig. 26

are larger than those of wheat or barley, are more circular in form, and present a flattened appearance and fractured surface. The hilum in the majority of the granules is stellate.

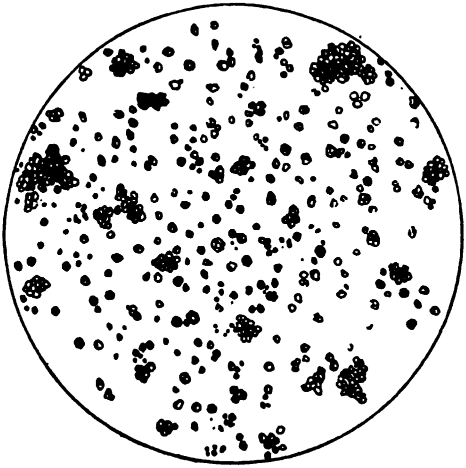

Fig. 27.

Class IV.—*Sago* (Fig. 24). The granules are elongated, rounded at one end and truncated at the other. Hilum circular, stellate, or linear, near convex end. The rings are concentric, numerous, and but faintly visible.

Cassava (Fig. 25). The granules are similar to those of sago, but not so elongated, presenting more the appearance of a kettledrum. The hilum, which is well defined, is situated near the centre.

Arum (Fig. 26). Somewhat like cassava, but much smaller.

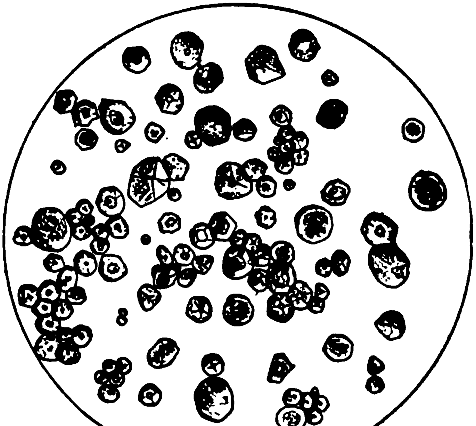

Fig. 28.

Class V.—*Rice* (Fig. 27). The granules of this starch are the smallest of all the commercial starches, and are pentagonal or hexagonal in form. Hilum extremely minute, but distinct with a very high power.

Maize (Fig. 28). The granules are polygonal, but approaching to circular, and are intermediate in size and general appearance between the starch granules of wheat and oats. The hilum is central and stellate.

Oat (Fig. 29). The granules are triangular to hexagonal in form. Both rings and hilum are invisible except under very high powers.

For illustrations of various other forms of starch granules, see under 'Starch' in Payen's Chimie Industrielle.

35. *Estimation of starch.* Various methods have been proposed and described for the determination of starch in different substances, both as raw materials and products of manufacture. As the conditions under which starch occurs in such substances vary so much, it naturally follows that one and the same method cannot be applied for its estimation in all cases, but the same general principle applies to all—viz. the extraction of the starch, either in a state of purity or after its decomposition into dextrin and maltose, or into dextrin, maltose, and dextrose, then estimating the amount of these starch products by one of the methods given under *Sugar analysis*, art. Sugar.

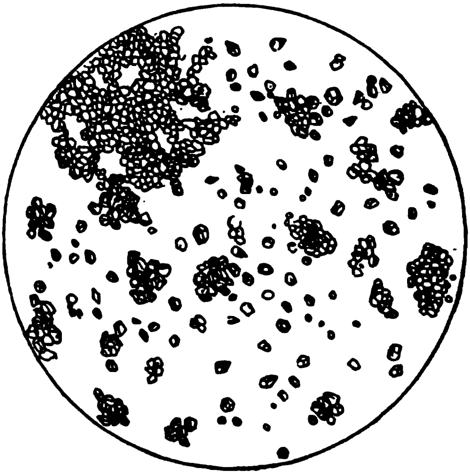

Fig. 29.

Several methods have been proposed for the direct estimation of starch—such as precipitation with solution of iodine, barium hydroxide—but none of these methods can be said to have yielded, up to the present, sufficiently trustworthy results, and the method of indirect estimation must be regarded as the only one approaching to accuracy. According to this, the starch in the substance under examination is brought into a state of solution, either as soluble starch, or as dextrin and cupric reducing sugars, by heating the substance for a certain time with glycerin, acid or diastase solution, and after filtration either carrying the process of decomposition further, or estimating the starch products first formed.

The most general process employed for the estimation of starch consists in the conversion of starch into dextrose by boiling with dilute acid (2 p.c. or more) for some hours, either with or without pressure, and estimating the dextrose by means of Fehling's solution. This process, even when most carefully conducted, is incapable of yielding anything like accurate results, these invariably coming out too low; on the one hand from the incomplete conversion to dextrose, on the other through overconversion, giving rise to condensation products having a much less or no cupric-reducing power.

A method giving fairly good results is obtained by boiling the starch with dilute acid for about half an hour to one hour, or until iodine solution shows the disappearance of starch, and then estimating the products of decomposition.

Twenty-five grms. of the substance are placed in a beaker, and heated on the water-bath with about 200 c.c. water containing 2 c.c. of strong hydrochloric acid, stirring occasionally, for about one hour. The solution is then cooled down to the normal temperature, transferred to a 250 c.c. flask, the beaker washed out two or three times with water, and the washings added to the liquid in the flask until it is made up to the containing mark at 15·5°. The whole is then well shaken and filtered, and the sp.gr. taken. The same quantity of acid as was taken for the conversion is introduced into a 250 c.c. flask, and diluted with water to the containing mark, the sp.gr. of this deducted from the sp.gr. of the starch conversion gives the sp.gr. due to the starch products, the resulting dextrin, maltose, and dextrose being estimated in the usual way.[1]

The method adopted by the A.O.A.C.[2] is as follows: 3 grms. of the material are extracted with 50 c.c. of cold water for an hour with frequent stirring. The residue is collected on a filter and washed with water sufficient to bring the filtrate up to 250 c.c. If the solution is difficult to filter, 2 c.c. of alumina cream are added. The soluble carbohydrates are determined in the filtrate both before and after inversion.

The insoluble residue is heated for 2¼ hours with 200 c.c. of water and 20 c.c. hydrochloric acid (sp.gr. 1·125) in a flask with a reflux condenser, the mixture cooled, nearly neutralised with sodium carbonate or sodium hydroxide, made up to 250 c.c., filtered and the dextrose determined in an aliquot portion of the filtrate, a correction being made for the soluble carbohydrate originally present. The weight of dextrose, multiplied by 0·9, gives the weight of starch.

For the estimation of starch in all the cereals, raw as well as malted, the method recommended by O'Sullivan (Chem. Soc. Trans. 45, 1) is undoubtedly the most trustworthy, and is carried out in the following manner:—

A fair sample of the grain is taken, and of this 5·1 grms. are weighed roughly, and ground fine in a coffee-mill, kept clean for the purpose. Of the finely-ground flour, 5 grms. or thereabouts, accurately weighed, are introduced into a wide-necked flask, capable of holding 100 to 120 c.c. The flour is just saturated with alcohol, sp.gr. 0·82, and then 20 to 25 c.c. ether added. The flask is corked and put aside for a few hours, the deposit being shaken occasionally. The clear ethereal solution is decanted through a filter, and the residue washed by decantation with three or four fresh quantities of ether, the washings being passed through the filter. To the residue 80 to 90 c.c. alcohol, sp.gr. 0·90, are added, and the mixture kept at 35°–38° for a few hours, with occasional shaking. The alcoholic solution, when clear, is decanted through the filter used in filtering the ether solution, and the residue washed a few times by decantation with alcohol, of the strength and at the temperature indicated. The residue in the flask, and any little that may have been decanted on the filter, is then washed with water into a beaker capable of holding half a litre, and the beaker nearly filled with water. In about 24 hours the supernatant liquid becomes clear, when it can be gradually decanted through a filter. The solution filters bright, but in the case of barley and oats exceedingly slowly at times; the malted grains, as well as wheat, rye, maize, and rice, yield solutions requiring no excessive time to filter. The residue is repeatedly washed with water at 35°–38°, but even this treatment does not completely free barley and oats from *a*-amylan, which dissolves with the greatest difficulty at this temperature. The residue is then transferred to a 100 c.c. beaker, and the portion adhering to the filter washed by opening the filter paper on a glass plate, and removing every particle by means of a camel's-hair brush, cut short, and a fine-spouted washbottle. When the transference is completed, the beaker, which should not now contain more than 40 to 45 c.c. of liquid, is boiled for a few minutes in the water-bath, care being taken to stir well when the starch is gelatinising, to prevent 'balling' or unequal gelatinisation. After this the beaker, still in the bath, is cooled to 62°–63°, and 0·025 to 0·35 grm. diastase, dissolved in a few c.c. of water, added. A trace of the solution ceases in a short time to give a blue colour with iodine, the starch being completely decomposed and dissolved. Yet it is well to continue the digestion at 62°–63° for an hour, as the solution, as a rule, filters better. At the end of that time the contents of the beaker are boiled for 8 or 10 minutes, thrown on to a filter, and the filtrate received in a 100 c.c. measuring flask. The residue is carefully washed with successive small quantities of boiling water. When the flask is nearly full its contents are cooled to 15·5°, and made up to 100 c.c. with water at that temperature. If care be not taken to use small portions of water at a time during the washing, the filtrate may exceed 100 c.c. before the residue is perfectly free from soluble matter; in this case the solution must be evaporated to less than 100 c.c., and then made up to that bulk after cooling to 15·5°.

Treatment with ether frees the grain from fat, &c., alcohol of 0·90 sp.gr. removes the sugars, the proteids other than casein, &c., and water at 35°–38° is intended to dissolve the amylans, &c., whilst the diastase is made to act on the residue at the temperature and under the conditions under which it dissolves starch. The 100 c.c. solution contains therefore, the products

---

[1] This method always gives results which are too high, due to a small portion of cellulose becoming converted during the digestion with acid, but as this also happens in the manufacturing process a fair idea may be obtained of the quantity of commercial glucose obtainable.

[2] Association of Official Agricultural Chemists, U.S.A.

of the transformation or decomposition of the substance.

The A.O.A.C. modifies O'Sullivan's method as follows: Extract 3 grms. of the finely powdered substance on a hardened filter with five successive portions of 10 c.c. of ether, wash with 150 c.c. of 10 p.c. alcohol and then with a little strong alcohol. Place the residue in a beaker with 50 c.c. of water, immerse the beaker in a boiling water bath and stir the contents constantly for 15 mins. or until all of the starch is gelatinised; cool to 55°, add from 20 to 40 c.c. of malt extract and maintain at this temperature until a microscopic examination of the residue with iodine reveals no starch. Cool, make up directly to 250 c.c. and filter. Place 200 c.c. of the filtrate in a flask with 20 c.c. of 25 p.c. hydrochloric acid (sp.gr. 1·125), connect with a reflux condenser and heat in a boiling water bath for 2½ hours; nearly neutralise while hot with sodium carbonate and make up to 500 c.c. Mix the solution well, pour through a dry filter and determine the dextrose in an aliquot portion. Convert the dextrose into starch by the factor 0·90.

Prepare the malt extract by digesting 10 grms. of fresh finely ground malt 2 or 3 hours at ordinary temperature with 200 c.c. of water and filtering bright. Ascertain the amount of dextrose in a given quantity of the filtrate after boiling with acid, &c., as in the starch determination, and make the proper correction.

The methods of estimating starch in cereals have been fully investigated in the Guinness Research Laboratory (Trans. Guinness Research Lab. 1903, 1, 79) under the direction of H. T. Brown, and they recommend a modification of O'Sullivan's method, in which they have reduced the time required for the estimation to 5 hours. The details given are as follows: 5 grms. of the very finely ground grain are weighed out into a paper thimble and placed in the extraction apparatus, the moisture being determined on another portion of the ground material. The extractor recommended is essentially Soxhlet's form, but the wide vapour tube is connected with the top of the condenser tube so that the course of the condensed vapour is always downwards. The vessel for boiling the solvent is a thin round-bottomed Erlenmeyer flask, made of copper. The condenser has a second tube which affords additional condensing surface and also serves to keep the system under normal pressure. Eighty c.c. of alcohol of sp.gr. 0·920 are introduced into the copper flask, and the working of the apparatus adjusted so that the barley in the thimble is washed with alcohol of sp.gr. 0·900 for 3 hours (malt requires about 9 hours' washing, owing to the higher content of reducing sugars), when the whole of the reducing substances and alcohol-soluble nitrogen compounds are removed.

The contents of the thimble are now transferred to a beaker containing about 100 c.c. of water, and the whole thoroughly boiled. After cooling to 57°, 10 c.c. of an active malt-extract are added and the conversion is allowed to proceed for 60 mins. The solution is then boiled, filtered into a 200 c.c. flask, the residue well washed, and the volume adjusted after cooling. The cupric oxide reduction of the solution is determined and the maltose calculated, after correction for the reduction due to the malt extract.

In calculating the starch, the authors take advantage of the fact that when starch is hydrolised by active diastase under suitable conditions, there is a well-defined resting stage which closely approximates to the 'No. 8 equation' of Brown and Heron (*l.c.*, p. 161), and which shows 100 parts of starch yielding 84·4 p.c. of maltose. The starch equivalent of the maltose determined in the solution is thus ascertained, on the assumption, if the conditions of the theoretical equation have been complied with, that 84·4 parts of maltose correspond to 100 parts of starch.

They summarise the chief precautions to be taken in carrying out this process as follows:

It is necessary to grind the sample as fine as possible.

The extraction of the reducing substances with alcohol must not be less than 3 hours for barley and 7 hours for malt.

The converting power of the malt extract must always be determined with all possible accuracy and under the usual conditions. A malt should be chosen which has been dried on the kiln at 50°–52°, and has a diastatic power of 80 Lintner.

Another method, originally proposed by Dubrunfaut and modified by Lintner, Ewers and others, which is largely made use of, consists in the conversion of the starch in the cereal into the soluble form by treating with strong acid in the cold and estimation from the optical activity of the solution. This method, which gives very good results, has the advantage of being less troublesome than the previous methods and of requiring a much shorter time to accomplish. The method proposed by C. J. Lintner is as follows: 5 grms. of the cereal previously reduced to the finest possible state of division are triturated in a mortar with 20 c.c. of water until no lumps remain; 40 c.c. of hydrochloric acid of sp.gr. 1·15 are then added, with continued trituration, in portions of about 5 c.c. at a time, and the mixture allowed to stand for about 10 mins. The liquid is then washed into a 200 c.c. calibrated flask by means of hydrochloric acid of sp.gr. 1·1; 10 c.c. of a 4 p.c. solution of phosphotungstic acid are added to precipitate the proteins, and the volume made up to 200 c.c. with the diluted acid. After mixing, the contents of the flask are transferred to a wide-necked, stoppered bottle, thoroughly shaken and filtered. The clear filtrate is examined by the polarimeter in a 200 m.m. tube.

The concentration of the soluble starch is calculated on the basis of $[\alpha]_{\mathrm{D}}=200{\cdot}3^\circ$ for barley starch dissolved in hydrochloric acid at 20°. Provided the liquid be not allowed to remain longer than 2 hours before polarising, no decrease in the rotatory power need be feared. The method gives results 4 to 6 p.c. lower than the acid conversion process owing to the pentosans, &c., being counted in the latter process.

Wenglein (Z. ges. Brauw. 1908, 31, 53) proposes the substitution of sulphuric acid of sp.gr. 1·70 for hydrochloric acid in Lintner's process, and washes with acid of sp.gr. 1·30. The method of procedure is otherwise the same, but the solutions can be kept 8 hours unchanged before polarisation. For starch in sulphuric acid, the $[\alpha]_D = 191 \cdot 7°$.

The above methods neglect the optical activity due to constituents other than starch in the material under examination. Where these other constituents are present in appreciable quantities, correct results will not be obtained, and Ewer proposes a method in which allowance is made for this error, which is as follows:

25 c.c. of glacial acetic acid are run into a 200 c.c. flask without wetting the neck. Five grms. of the finely ground material are then added and the flask closed and vigorously shaken until the mixture is uniform. The stopper and neck of the flask are then washed down with a further 20 c.c. of glacial acetic acid and the flask placed in a boiling water bath for 10 minutes; 10 c.c. of dilute hydrochloric acid (1 in 10) are added, and the flask is left in the water bath for exactly six minutes, being shaken round every minute. Hot water is then added to make the volume up to 180 c.c. and the mixture is heated for a further 18 minutes in the boiling water bath. The solution is finally cooled, clarified by the addition of 2·5 c.c. of potassium ferrocyanide, made up to the mark with water, filtered and polarised. If the filtrate cannot be obtained clear, a few crystals of zinc sulphate can be added to assist clarification.

A blank experiment is then made to correct for the optically active bodies other than starch; this is conducted as follows: 5 grms. of the finely ground material are transferred to a 100 c.c. flask with 70 c.c. of water at about 50°, and the whole thoroughly mixed by vigorous shaking. This is digested at the ordinary temperature for one hour, then 25 c.c. of glacial acetic acid are added and the digestion continued at the same temperature for half an hour, during which the temperature is adjusted to 15·5°, the ferrocyanide added as before, and the liquid made up to the 100 c.c. mark, mixed, filtered and polarised.

For manufacturing purposes, the mere determination of the total amount of starch in a sample of grain is of little value, as no distinction is made between the insoluble and soluble starch, the latter being useless if the grain is to be used for making starch. Also the amount of gluten seriously affects the quantity of starch obtainable from the grain, for which allowance must be made in valuing the sample. According to Schreib (Zeitsch. f. Chem. 1888, 24), each part of gluten in rice causes the loss of an equal quantity of starch in the course of manufacture; consequently, a sample of rice containing 78 p.c. of starch and 4 p.c. of gluten would be more valuable than a sample containing 80 p.c. of starch and 8 p.c. of gluten, as 74 p.c. of starch could be obtained from the former, and only 72 p.c. from the latter (the yield being found by deducting the percentage of gluten from the total starch in the sample). In the case of wheat the gluten is a valuable byproduct, but in rice it is so difficult to separate from the starch—and when separated can only be sold for cattle-feeding or manurial purposes—that the less gluten the rice contains the more valuable it is. Schreib prefers, in making an analysis of 'broken rice,' to estimate the gluten, ash, and moisture, and determine the starch by difference, after making a fixed allowance for the other non-starchy constituents of the grain—that is, fat, sugar, gum, and cellulose. The whole analysis by this method can be finished in 4 hours, or considerably less time than is required for a direct estimation of the starch by the methods already given.

The starch in potatos is estimated in a rough and ready manner by ascertaining the specific gravity of the tuber. Five kilograms of potatos freed from dirt are taken and weighed in water. The weight in water divided into the original weight in air gives the specific gravity. The specific gravity ranges from 1·08 to 1·15, the heaviest potatos containing most starch and most dry matter. Tables have been drawn up by Behrend, Märcker and Morgen for ascertaining the percentage of starch from the specific gravity of the potato tuber, which give results accurate within 2 p.c.

Several varieties of starch are largely used in the adulteration of cocoa and chocolate, sago being frequently employed for this purpose; but, owing to the variable amount of starch in cocoa beans, a chemical analysis of the supposed adulterated article cannot be regarded as decisive, unless the percentage of starch found amounts to more than 10 p.c. In such cases it is advisable to resort to microscopical examination, and for this purpose the chocolate is best deprived of its fat and sugar before being placed under the microscope. The following method of examination is recommended by Hartwich (Chem. Zeit. 12, 375). The number of starch granules (which may be stained with iodine solution if advisable) in each field is counted, and a mean taken; a pure chocolate is then mixed with a corresponding amount of the supposed foreign starch, and examined in the same manner. In this way the quantity of starch added as an adulterant may be estimated with sufficient accuracy.

For estimation of starch in fodder, Leclerc (J. Pharm. Chim. [v.] 21, 641) gives the following method: 5 grms. of straw, hay, &c., are placed in a 250 c.c. flask, 10 c.c. of water added, and shaken about until every particle of the substance under examination is thoroughly moistened. 180 c.c. of a neutral zinc chloride solution, sp.gr. 1·450, are next added, and the whole heated in a salt-water bath at 108° for 1½ hours. The flask is then taken out and cooled down, and the volume made up with zinc chloride solution to 253 c.c. at normal temperature and filtered. From 25 c.c. to 100 c.c. of the filtrate is poured into a beaker containing 2 c.c. to 8 c.c. of hydrochloric acid and a sufficient quantity of 95 p.c. alcohol added to precipitate the whole of the dextrin and starch. After 24 hours the precipitate is collected on a tared filter and washed with 90 p.c. alcohol containing 0·5 p.c. hydrochloric acid until free from zinc chloride. The acid is then washed out with alcohol alone, and the precipitate weighed, then burnt, and the weight of the ash, of which there is usually a little, being carried down by the alcohol with the starch, deducted.

Starch is of very general occurrence in paper, and may be very easily detected by moistening the latter with a dilute solution of iodine, the intensity of the violet to blue colouration often forming the only means employed to ascertain the quantity of starch present. For the quantitative estimation of it Würster (Dingl. poly. J. 229, 538) proceeds as follows. The quantity of water present is first estimated, then the resin, by boiling out with alcohol, drying the paper, and weighing. The starch is next dissolved out by boiling the paper for some time with a mixture of equal parts of water and alcohol, to which a few drops of hydrochloric acid are added, and drying and weighing the residual paper; but, since the acid causes a certain loss in mineral constituents, the ash must be determined in the paper before and after extraction, and the difference deducted from the result. The following p.c. results were obtained on analysis by this method :—

Paper	Water	Resin	Starch	Ash	Fibre and cellulose by difference
Fine post, thin . .	7·2	2·9	3·5	1·8	84·6
Fine post, medium .	7·6	5·4	3·1	1·9	82·0
Fine post, strong .	7·2	3·4	3·7	7·8	77·9
Common writing paper	5·8	3·9	9·1	33·4	47·8

The starch met with in commerce and used for laundry and manufacturing purposes is almost exclusively derived from rice, maize, and potatos, and generally contains very little or no impurities. These, when they do occur, consist of vegetable fibre, gluten, or albuminoid matter, remains of pulp water, and other mineral matters. Fibre gets into the finished starch owing to imperfect arrangement of the sieves. Remains of pulp water in starch are owing to bad washing, whilst the presence of sand and other mineral matter may be due to the mixing of that portion of the starch which settles in the washing tanks next to the axis of the stirring apparatus, with the bulk of the starch—or to addition as an adulterant.

The quantity of mineral matter in starch should not exceed 0·5 p.c. When it is more than this, mineral matter, frequently barium or calcium sulphate, has been added; or the starch has been carelessly washed and not properly purified—in this case the other impurities will also be high.

As has already been stated, the proportion of moisture in ordinary air-dried starch averages about 18 p.c. It may be determined by drying the starch *in vacuo* over sulphuric acid, and finishing off in a current of dry air at 100°, the temperature being very gradually raised to this point. If the starch is at all acid, this must be neutralised by moistening it with a few drops of very dilute ammonia.

J. H. Hoffman (Woch. für Brauerei, 1903, 31) proposes a method in which the starchy matter is heated to drive out the water, which is collected and measured. Fifty grms. of starch are immersed in 400 c.c. of oil of turpentine and 10 c.c. of toluene in a vessel and heated, first at 50°, then to 140°, and finally to 155°, for 5 minutes in each case. The water formed is collected and measured, a correction of 0·2 c.c. added and the whole multiplied by 2 to give the percentage of water in the starch.

For the estimation of water in potato starch, Saare (Chem. Zeit. 52, 934) has worked out a method which combines rapidity of execution with sufficient accuracy for technical purposes. 100 grms. of the starch are rinsed into a tared 250 c.c. flask, which is then filled up to the mark with water at 17·5° and weighed; the weight of the empty flask is now deducted from this, and the percentage of water corresponding to the difference found from the following table :—

Weight found	Water p.c.	Weight found	Water p.c.
289·40	0	277·20	31
289·00	1	276·80	32
288·60	2	276·40	33
288·20	3	276·00	34
287·80	4	275·60	35
287·40	5	275·20	36
287·05	6	274·80	37
286·65	7	274·40	38
286·25	8	274·05	39
285·85	9	273·65	40
285·45	10	273·25	41
285·05	11	272·85	42
284·65	12	272·45	43
284·25	13	272·05	44
283·90	14	271·70	45
283·50	15	271·30	46
283·10	16	270·90	47
282·70	17	270·50	48
282·30	18	270·10	49
281·90	19	269·70	50
281·50	20	269·30	51
281·10	21	268·90	52
280·75	22	268·50	53
280·35	23	268·10	54
279·95	24	267·75	55
279·55	25	267·35	56
279·15	26	266·95	57
278·75	27	266·55	58
278·35	28	266·15	59
278·00	29	265·75	60
277·60	30		

The results obtained are correct to 0·5 p.c. The method may also be applied to the estimation of the water in 'green' starch, and may be used for testing the progress of the drying process in the drying chambers.

The following rule may be employed in the place of the above table.

From the weight of starch and water contained in the bottle subtract 250 and divide the difference by 0·3987, when the quotient will be the percentage of starch in the sample.

It may be more generally expressed :—

$$\frac{\text{contents of bottle in grms.}\ \textit{minus}\ \text{capacity of bottle in c.c.}}{0{\cdot}3897}=\text{grms. of anhydrous starch in weight of sample taken.}$$

J. H. and H. H.

STARCH GUM *v.* DEXTRIN.

STEAM. When water, by the agency of heat—or otherwise,—has so far changed its state as to become a compressible fluid, it is known as *steam*.

To produce steam for the purpose of performing work by its agency, water must be submitted to the action of heat until that temperature is reached at which the change from liquid to vapour is realised. This temperature, which is generally known as the 'boiling-point,' is variable, and dependent on external conditions; namely, the pressure on the surface of the liquid. At any particular pressure there is one temperature, and one only, at which steam and water can exist in equilibrium with one another.

In effecting this change of state a quantity of heat is absorbed without any rise of temperature. This is known as 'the latent heat of vaporisation,' or, more commonly, in the case of water, as 'the latent heat of steam.'

At 100° and 760 mm. pressure the quantity of heat absorbed in changing 1 grm. of water to 1 grm. of steam is 536·5 therms. As the pressure is increased, so the boiling-point rises, and the latent heat absorbed in the change diminishes. Values of the boiling-point and latent heat corresponding to temperatures are given in the 'steam table' quoted.

The following formulæ, showing the relations between temperature, pressure, and latent heat may be given, without going into the reasoning on which they are based, which is somewhat outside the scope of this article.

(α) Regnault's formula—

$$L_t = 606{\cdot}5 - 0{\cdot}695t$$

where L_t = latent heat at temperature t.

(β) The latent heat equation—

$$dT = \frac{T(v_2 - v_1)dp}{L \cdot J}$$

where L = latent heat; J = Joule's equivalent; v_2 = volume of 1 grm. of steam at temperature T; v_1 = volume of 1 grm. of water at temperature T; T = absolute temperature; dp = small increase in pressure (dynes); dT = corresponding change in temperature.

The pressure and boiling-point of a liquid cannot be raised indefinitely. If a quantity of water is heated in a sealed tube of strong glass, it is found that upon reaching a certain temperature the 'meniscus'—or surface differentiating the liquid from the vapour—disappears, and the contents of the tube become homogeneous. For water this temperature is 362°. Above this temperature steam *cannot* be converted into water, no matter how high the pressure to which it is subjected. This is known as the *critical temperature.*

The existence of such a temperature can be proved from theoretical considerations, and by the use of Van der Waal's equation—based upon the kinetic theory of gases—its value can be ascertained. Such proof, however, need not be considered here.

Entropy. The entropy is that function of the conditions of a body, such that, if it change from a value A to a value B, reversibly—

$$(B - A) = \int_A^B \frac{dH}{\theta}$$

Let a gram of water undergo a small increase of temperature dT at temperature T. Then heat absorbed $= \sigma \cdot dT$ (where σ = specific heat).

With water $\sigma = 1$. Therefore heat absorbed $= dT$.

The temperature at which this heat is absorbed is T. Therefore increase in entropy $= \frac{dT}{T}$.

And change in entropy when the liquid is heated from T_2 to T_1

$$= \int_{T_2}^{T_1} \frac{dT}{T} = \log \frac{T_1}{T_2}$$

If $T_2 = 273°$ abs. and entropy at this temperature is taken as zero, then entropy $= \log \frac{T_1}{273}$.

At the boiling-point of water under atmospheric pressure the entropy of 1 grm. of *water* $= \log \frac{373}{273}$.

Let this be converted into steam at the same temperature, the increase in entropy $= \frac{536{\cdot}5}{373}$.

Therefore the entropy of 1 grm. of *steam* at $100° = \log \frac{373}{273} + \frac{536{\cdot}5}{373}$.

The 'θ–ϕ' diagram. The relations between entropy and temperature as water is converted into steam may be represented in diagrammatic form. It is usual to take the values of the entropy as abscissæ and the values of the temperature as ordinates. The temperature is represented by the symbol 'θ' and the entropy by 'ϕ.'

In this way two curves may be plotted. One the entropy curve for water and the other the entropy curve for steam. The *area,* included between such entropy-temperature curves representing a complete cycle, gives a measure of the *heat* put into the system and that taken out. Wherefore the entropy-temperature diagram is very useful as a means of obtaining absolute values of heat efficiencies.

The increase of entropy in the case of *superheated* steam is given by the formula—

$$\text{Increase in entropy} = \sigma \int_{T_2}^{T_1} \frac{dT}{T} = \sigma \log \frac{T_1}{T_2}$$

where σ = specific heat of superheated steam.

In all entropy-temperature diagrams, *adiabatic* changes are represented by vertical lines, since, during an adiabatic change the entropy is constant in value, *i.e.* the change is 'isentropic.' Isothermal changes are represented by horizontal lines.

Velocity of steam. The velocity acquired by steam upon adiabatic expansion from a nozzle has become a matter of much importance owing to the development of the steam turbine. The velocity is obtained as follows:—

$$\text{The velocity, } v = \sqrt{2g \cdot J \cdot W} = 223{\cdot}8\sqrt{W},$$

where g = acceleration of gravity, J = Joule's equivalent, and W=work done. And the work done (in ft.-lbs.)

$$=J\left\{(T_1-T_2)\left(1+\frac{L_1}{T_1}\right)-T_2\log\frac{T_1}{T_2}\right\}$$

for initially dry steam, or

$$=J\left\{(T_1-T_2)\left(1+\frac{x_1L_1}{T_1}\right)-T_2\log\frac{T_1}{T_2}\right\}$$

for wet steam, or

$$=J\left\{(T_1-T_2)\left(1+\frac{L_1}{T_1}\right)-T_2\log\frac{T_1}{T_2}+C_p(T_s-T_1)\right.$$
$$\left.-C_p(\log T_s-\log T_1)T_2\right\}$$

for superheated steam; where J=Joule's equivalent; T_1=initial saturation temperature of steam (absolute); T_s=initial superheat temperature of steam (absolute); T_2=final temperature of steam after expansion (absolute); L_1=latent heat at temperature T_1; x_1='dryness' of the steam; C_p=specific heat of superheated steam at constant pressure.

The quantity of heat required to convert 1 lb. of water into steam, from an open vessel, or at atmospheric pressure, is 1146·1 units − F°, as given in the third column of the table (p. 193) of the properties of saturated steam.

In a closed vessel, such as a steam boiler, the temperature at which steam is produced differs with different pressures (*see* Table, p. 193). The total quantity of heat required to convert 1 lb. of water into steam is very nearly the same at all pressures (*see* Table).

In Fig. 1 let A be the cylinder of a steam engine, and *b* the piston, and let the piston occupy the dotted position *c*. Now let steam at 40 lbs. pressure per square inch above the atmosphere, or 54·7 lbs. absolute (40+14·7), be admitted behind the piston, and let the admission be continued till the piston arrives at *d*; then let the steam supply be stopped. The piston can then make no further movement except by virtue of the expansive force of the steam. Assume the piston to have moved to the position *b*, or four times as far from the end of the cylinder as the point *d*, where the steam supply was stopped; the steam in the cylinder will then have been expanded to four times its former volume.

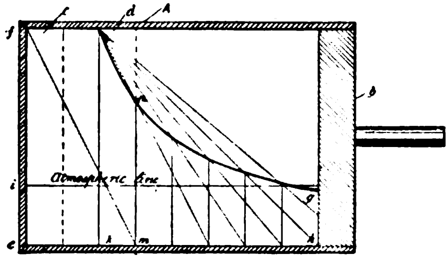

FIG. 1.

Now if we select a scale on which the height from *e* to *f* represents 54·7 lbs., and make *ei* equal to 14·7 lbs., we shall then be able to complete the figure *e, f, d, g, h, e*, the area of which represents the total force exerted by the steam on the piston, the ordinates of the curve representing on the scale the pressures at the different points occupied by the piston in its movement.

We have assumed the steam to have now expanded to four times its former volume; its pressure will then be $\frac{54\cdot7}{4}=13\cdot67$ lbs.

To find the pressure at any point between *d* and *g*, draw the line *kd*, parallel to *ef* and perpendicular to *eh*; then take any point *m*, making *mn* parallel to *kd*; join *fm*, and draw *dn* parallel to *fm*. The point *n* is a point in the curve of pressures, and *mn* represents on the scale the pressure of the steam when the piston was at that point. All other points in the curve *dng* can be determined in the same way.

The average pressure of the steam diagram, *e, f, d, g, h, e* may be calculated thus:

Let R=the ratio of expansion; H, the hyperbolic log. of the number expressing that ratio; P, the initial pressure of the steam; *p*, the mean pressure—then

$$p=\mathrm{P}\frac{1+\mathrm{H}}{\mathrm{R}}.$$

Taking the example before us

$$\mathrm{R}=4,\ \mathrm{H}=1\cdot386,\ \mathrm{P}=54\cdot7;$$

then $54\cdot7\frac{1+1\cdot386}{4}=32\cdot6$ lbs. mean pressure.

We have assumed that the pressure of steam has been fully utilised down to the line *e, h*, or line of no pressure or perfect vacuum. In practice this is not realised, and the bottom line of the actual steam diagram is generally 2 lbs. above that of a perfect vacuum; the real mean pressure would therefore be not 32·6 lbs., but 30·6 lbs. We have assumed the expansion to be isothermal. It is not so, and the practical effect of the conducting power of the cylinder is, that during the former part of the stroke of the piston, steam is being condensed in the cylinder, and during the latter part it is being re-evaporated.

Steam diagrams.

We get our knowledge of what actually takes place in a steam-engine cylinder from the indicator. This instrument is illustrated by Fig. 2. It consists of a drum *a* (on which is fastened a sheet of paper) made to oscillate backward and forward on its axis by means of a cord connection *b* to a moving part of the engine, having the motion of the piston on a reduced scale. At the side of the drum is placed a small cylinder *c* having a piston held down against the steam pressure by a spring of known tension. Let the piston be 1 square in. in area, and the tension of the spring 30 lbs. to the inch; then a pencil attached to the piston would indicate by its position the pressure of steam on the piston, at a scale of 30 lbs. per square inch.

The pencil is made to mark a horizontal line on the paper before the steam is turned on to the indicator piston; that line is termed the atmospheric line, as it indicates the pressure of the atmosphere. The indicator being attached to one end of a steam cylinder by means of a pipe, and the drum being made to turn by the engine, the pencil is caused to describe a figure on the paper of the drum like that on Fig. 3, in which the horizontal length represents the stroke of the engine on a reduced scale, and the vertical height the pressure of steam in the cylinder at all parts of the engine stroke. It is evident that the area of the figure represents the total force exerted behind the engine piston, and the average height of the diagram the average pressure of steam during that stroke. The average height—or, in other words, the average pressure—is obtained by the ordinary method of measuring irregular figures..

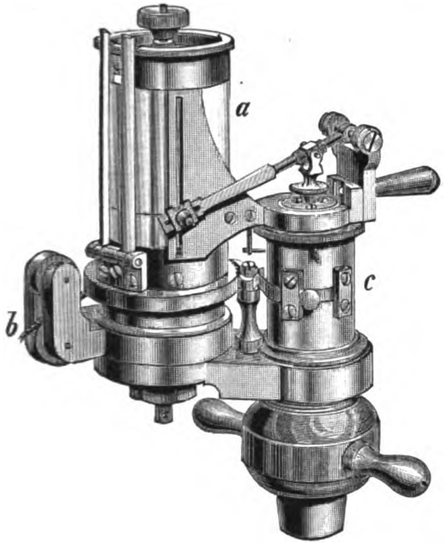

FIG. 2.

Fig. 3 represents an actual indicator diagram.

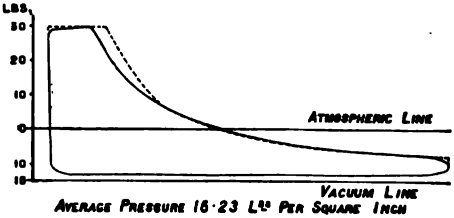

FIG. 3.

One horse-power equals 33,000 ft.-lbs. per minute. Steam engines are of various types. Single cylinder in which the steam is expanded in one cylinder only, compound engines with two, and triple expansion engines with three cylinders. The modern triple engine receives steam at 150–200 lbs. pressure per square inch, and expands it to about 6 lbs., the consumption of steam being from 12 to 10 lbs. per I.H.P. per hour, with a heat efficiency of from 15 to 20 p.c.

The best examples of steam boilers give a heat efficiency of from 60 to 80 p.c., and evaporate from 8 to 10 lbs. of water per lb. of good coal. The combined heat efficiency of engine and boiler is from 9 to 16 p.c. in the best examples of condensing engines.

PROPERTIES OF SATURATED STEAM.

H. D.

STEARIC ACID, STEARIN *v.* OILS, FIXED, AND FATS.

STEATITE. (*Speckstein*, Ger.). A compact form of the mineral talc (*q.v.*).

STEEL *v.* IRON.

---

[1] Atmospheric pressure.

STEPHANITE, 'black silver-ore,' or 'brittle silver-ore.' A silver sulphantimonite

$5Ag_2S{\cdot}Sb_2S_3$ or Ag_5SbS_5,

occasionally mined as an ore of silver (Ag, 68·5 p.c.). Crystals are orthorhombic with an iron-black colour and brilliant metallic lustre. Considerable quantities of the massive mineral have been obtained from the Comstock lode in Nevada. L. J. S.

STETHAL. *See Spermaceti*, art. WAXES.

STIBICONITE Sb_2O_4,H_2O *v.* ANTIMONY.

STIBNITE, *Antimony* or *Antimony-glance.* Native antimony sulphide (Sb_2S_3), of importance as an ore of antimony. It forms blade-like or acicular, orthorhombic crystals which possess a highly perfect cleavage in one plane direction parallel to their length. Radially-fibrous and lamellar masses, with the perfect cleavage conspicuous on their broken surfaces, are of common occurrence. Sp.gr. 4·6. The colour is steel-grey with a brilliant metallic lustre, but on exposure to light the surface becomes dulled. Although often regarded as a typically opaque mineral, very thin cleavage flakes of stibnite transmit a small amount of red light (refractive indices, $\alpha=3{\cdot}194$, $\beta=4{\cdot}046$, $\gamma=4{\cdot}303$ for wave-length 760), and they are still more transparent for heat rays (A. Hutchinson, Min. Mag. 1903, 13, 342; 1907, 14, 199). Light has a remarkable effect on the electrical conductivity of crystals of stibnite: the close proximity of a strong electric arc-light causes this to increase by over 200 p.c., and when the light is removed it quickly returns to its former value (F. M. Jaeger, Zeitsch. Kryst. Min. 1907, 44, 45).

The mineral is quite soft (H.=2), and the crystals are readily bent, with the production of characteristic zigzag forms. The bending is accompanied by a slipping, along a glide-plane, of one portion of the crystal over another portion. This gives rise to fine striations running transversely across the cleavage surfaces, which being almost always present (no doubt as a result of earth pressures) render stibnite a mineral easily recognisable at a glance.

Stibnite occurs in metalliferous veins, and is found in many localities. The finest specimens (magnificent groups of brilliant, prismatic crystals reaching a length of 20 ins.) come from the Ichinokawa antimony mine, near Saijo on the Japanese island of Shikoku. Good crystals, often penetrating crystals of barytes, are well known from Felsöbánya in Hungary. As an ore of antimony stibnite is mined in several countries, the principal ones, arranged in the order of their production, being: France (Auvergne), China (prov. Hunan), Italy, Mexico, Victoria, and Hungary.

Besides being smelted as an ore of antimony, stibnite is used to a limited extent for the preparation of pure hydrogen sulphide. In the East, powdered stibnite is employed for darkening the eyebrows, and it was also used by the ancients for the same purpose, hence the old name *platyophthalmon* for this mineral.

STICK LAC *v. Lac resin*, art. RESINS.

STILBENE, *toluylene*, sym-*diphenylethylene* $C_6H_5{\cdot}CH:CH{\cdot}C_6H_5$, is formed when benzylidene chloride is heated with sodium (Limpricht, Annalen, 1866, 139, 38); by heating benzoin with zinc-dust and acetic acid (Blank, *ibid.* 1888, 248, 7); by the slow distillation of phenyl fumarate (Anschütz, Ber. 1885, 18, 1948); by the action of light on the silver salt of phenylnitromethane (Angeli, Castellana and Ferero, Chem. Zentr. 1909, [ii.] 975); on treating phenylbenzyl carbinol with dilute sulphuric acid; by heating a mixture of benzaldehyde and phenylacetic acid in a sealed tube—all of which methods indicate the above constitution.

Preparation. Stilbene is obtained in fair yields by dropping toluene into a red-hot tube containing lead oxide (Lorenz, Ber. 1874, 7, 1096); by heating benzthioaldehyde with copper powder (Klinger, *ibid.* 1877, 10, 1878), or more simply by heating benzaldehyde alone with sulphur in sealed tubes to 180°. Better results are obtained by treating deoxybenzoin with sodium ethoxide (Sudborough, Chem. Soc. Trans. 1895, 67, 604); by acting upon benzaldehyde with phenyl magnesium iodide (Klages and Heilmann, Ber. 1904, 37, 453); by the action of 10 p.c. caustic soda on phenylnitromethane at a temperature of 160°, when a 90 p.c. yield is obtained (Wislicenus and Endies, *ibid.* 1903, 36, 1194).

Properties and *reactions.* Monoclinic tables, m.p. 124°, b.p. 306°, insoluble in water, easily soluble in hot alcohol, ether, benzene, &c. On passing through a heated tube it forms toluene and phenanthrene (Graebe, *ibid.* 1873, 6, 126); on reduction with hydriodic acid it yields dibenzyl; it is oxidised by chromic anhydride to benzoic acid; heated with sulphur it forms tetraphenylthiophene; by the action of sulphuric acid it forms a disulphonic acid (Limpricht and Schwanert, Annalen, 1868, 145, 335); it is converted by ozone into an ozonide (Harries, Ber. 1903, 36, 1933); on passing nitrogen peroxide into its benzene solution it forms stilbene nitrite (Gabriel, *ibid.* 1885, 18, 2438); with picric acid it forms an insoluble picrate; by the addition of bromine in carbon disulphide solution there are produced two stereoisomeric stilbene bromides (m.p. 237° and 110°) (Wislicenus and Seeler, *ibid.* 1895, 28, 2694).

iso-*Stilbene.* From the lower melting-point stilbene bromide obtained as above, a stereoisomeric modification of stilbene may be obtained by careful reduction. As this bromide has the trans- configuration *iso*stilbene must be the trans-isomeride. It is extremely unstable, and on distillation, or under the influence of sunlight, or in presence of traces of bromine or iodine it passes immediately into ordinary stilbene, which consequently possesses the cis- configuration (Wislicenus, Chem. Zentr. 1901, [i.] 463).

o-*Dinitrostilbene* from *o*-nitrobenzyl chloride and alcoholic potash, exists in two stereoisomeric forms (m.p. 126° and 196°); on reduction they yield the same *o*-diaminostilbene (Bischoff, Ber. 1888, 21, 2072).

p-*Dinitrostilbene*, prepared in the same way, has also been isolated in two forms (m.p. 210° and 280°), which form on reduction *p*-diaminostilbene (m.p. 227°) (Strakosch, Ber. 1873, 6, 328; Walden and Kernbaum, *ibid.* 1890, 23, 1959).

Tetranitrostilbene, from tetranitrobenzyl chloride and alkali (m.p. 264°) (Kraususky, J. Russ. Phys. Chem. Soc. 27, 339).

Nitrostilbene sulphonic acids (v. Bender, Ber. 1895, 28, 422; Fischer and Hepp, *ibid.* 1895, 28, 2281; Green and Wahl, *ibid.* 1897, 30, 3100).

Stilbene colouring matters. *p*-Nitrotoluene and its *o*-substituted derivatives under the influence of alkalis yield derivatives of stilbene, which are the parent substances of numerous dyes (*see* Azo- colouring matters).

STOCKHOLM TAR. A bituminous liquid obtained from the wood of *Pinus sylvestris* (Linn.) and other species of *Pinus* by destructive distillation.

The tar exported from Stockholm in earlier times, and to which the term Stockholm tar was applied, was brought from the northern part of Sweden and from Finland, where the tar was produced by peasants from dry wood stumps burned in 'tjärdàlar,' or specially made tar-burning ground. On arrival at the Stockholm tar court all barrels were 'wrecked' before being shipped abroad. The procedure of wrecking was as follows: After the barrel had been filled with tar it was left standing for some hours, when the water which had accumulated on the surface was drawn off and the barrel refilled with tar. The 'wreckers,' who were sworn servants of the Tjärhof, issued a certificate, which at that time was required for the export, stating that the barrels contained the regulation quantity and that the tar had been 'wrecked.' The old Stockholm tar was shipped in barrels of 125 litres. Several tar exporters in the north of Sweden still use barrels which have been examined by the State Comptrollers as to their capacity, and if found to hold the right measure the barrel is stamped with three crowns. Many importers attach great importance to this mark, and erroneously look upon it as a quality mark. A variety of tars differing very much from one another are imported from Sweden. So-called Stockholm tar is generally shipped in three qualities or grades, viz.: fine thin (no grains or crystals), middle fine or ordinary (either gluey or thin and fine-grained), thick (very close-grained). The name 'Umea tar' is applied to similar tar produced in the Umea district and shipped from the port of Umea. This tar is delivered in 'Swedish barrels' containing 27½ galls. and weighing 167 kilos. gross, and 133 kilos. net. 'Umea tar' is considered the best in the market. 'Skelleftea' and 'Lulea' tar are of a similar quality. These three tars are sometimes also shipped as 'Stockholm tar.' Swedish 'factory tar'—obtained from waste wood in charcoal kilns at the saw mills, and produced as a by-product in charcoal burning—must not be confounded with 'Stockholm' or 'Umea' tar. It is easily distinguished by its colour and smell. The genuine tar is yellow-brown or light-brown in colour, and with a turpentine smell, while the factory tar is of a dark-brown or black colour with a strong smoky smell. The tar manufactured by peasants and shipped from Finland (Wasa and Uleaborg) was formerly, and is sometimes now, called 'Stockholm tar,' but is generally shipped as 'Wasa tar.'

Until comparatively recent years there were only two kinds of wood-tar regularly exported to England, viz. Stockholm tar exported from the Gulf of Bothnia, and Archangel tar from Archangel. The latter was shipped in barrels containing about 112 litres. Then the so-called Russian tar exported from Riga, Libau, and Königsberg came on the market, and has largely taken the place of 'Stockholm tar,' owing to the scarcity and high price of the latter, and also because Russian tar is obtainable at all times of the year. Disputes between buyers and sellers as to the real meaning of 'Stockholm tar' have arisen since the appearance of the cheap factory tars on the market, and British importers have suggested that the term 'Stockholm tar' should be retained for the peasant-made article, as it has been used for centuries, and for the 'factory tar' 'Swedish kiln wood-tar.' The Swedish exporters advise that buyers of tar should purchase from samples and insist on a full description of the tar. They much prefer this to a guarantee to sell 'genuine Stockholm tar.' (D. McEwan, Brit. and Col. Drug. 1911, 59, 138; J. Soc. Chem. Ind. 1911, 30, 274).

STORAX *v.* Balsams.

STOVAINE. Trade name for the hydrochloride of dimethylamino-*tert* amyl benzoate

$$(CH_3)(C_2H_5)[CH_2{\cdot}N(CH_3)_2,HCl]C{\cdot}O{\cdot}COC_6H_5,$$

obtained by acting on dimethylaminoketone with ethyl magnesium bromide; ethyl dimethylaminopentanol is thus obtained, and on treating with benzoyl chloride gives stovaine. Used as an anæsthetic (*v.* Synthetic drugs).

STOWITE *v.* Explosives.

STRAMONIUM *v.* Datura.

STRASS *v.* Gems, imitation and counterfeit.

STRAWBERRY. The fruit of *Fragaria vesca* (Linn.). Many varieties are known.

König gives as the average composition—

	Water	Protein	Invert sugar	Cane sugar	Other N-free sub.	Acidity: malic acid	Fibre	Ash
European	87·0	0·6	5·1	1·1	2·8	1·1	1·6	0·7
American	89·7	1·0	4·8	0·6	0·4	1·4	1·5	0·6

According to American investigations (Bull. 28, U.S. Dept. of Agric. 1899) about three-fourths of the total N present exists as real proteids.

The acidity of strawberries is usually stated to be due to malic acid, but according to Paris (Chem. Zeit. 1902, 26, 248) it is chiefly due to citric acid. On the other hand, Stone (Agr. Science, 1889, 257) states that citric acid can only be present in small quantities, if at all. Stone found that the ratio of acid to sugar is, in wild strawberries 1 : 2, in American varieties 1 : 3·5, and in European varieties 1 : 9.

There appears to be no doubt that American-grown strawberries are richer in protein and acid, but much poorer in total solids, sugar, and cellulose than European ones.

Strawberries contain small quantities of salicylic acid, probably in the form of an ester (Portes and Desmoulières, J. Pharm. Chim. 1901, 14, 342; also Süss, Chem. Zentr. 1903, ii. 841; and Windisch, Zeitsch. Nahr. Genussm. 1903, 6, 447), the amount found being usually about 2 or 3 mgms. per litre of juice. The fatty oil of strawberries has a sp.gr. 0·9345 at 15°/4°, saponification number 193·7, acid number 6·41, Reichert-Meissl number 2·1, iodine number (Hübl) 180·3. It yields 88·2 p.c. of insoluble fatty acids, their iodine number being 192·3 (Aparin, J. Russ. Phys. Chem. Soc. 1904, 36, 581).

Strawberry root contains a tannin, *fragarianin*, of a pale-yellow colour, soluble in water and alcohol, yielding *fragarin* when boiled with dilute hydrochloric acid (Phipson, Chem. News, 37, 135).

The flavour of strawberries is imitated in confectionery by the use of a mixture of 2 parts ethyl acetate and 1 part of amyl acetate.

Strawberries are highly valued as a fruit, and in most cases are easily digested; in the case of a few susceptible persons, however, they produce an urticaria comparable to that produced by eating shell-fish. According to Mendel and Hooker (Amer. J. Physiol. 1902, 7, 380), intravenous injections of an aqueous extract of strawberries produced an increased flow from the thoracic duct, a fall of blood pressure, and a diminution in the coagulability of the blood.

For the effect of manuring upon the yield and especially the earliness of strawberries, *v.* Dyer and Shrivell (J. Roy. Hort. Soc. 1903, 27, 4), who found that moderate dressings of phosphates and sodium nitrate, applied with a light manuring with dung, slightly increased the yield of fruit, but had a distinct influence upon early ripening, whilst potash salts had an injurious effect, diminishing the yield and retarding maturity. H. I.

STREAM-TIN *v.* Cassiterite.

STROMEYERITE. *Argento-cuprous sulphide* or *Argentiferous copper glance* AgCuS or $Ag_2S{\cdot}Cu_2S$. A mineral crystallising in trimetric forms isomorphous with copper-glance. Sectile, dark steel-grey colour, shining streak; subconchoidal fracture. H. 2·5–3·0; sp.gr. 6·2–6·3 (*v.* Copper-glance).

STRONTIANITE. Native strontium carbonate ($SrCO_3$) crystallising in the orthorhombic system and isomorphous with aragonite and witherite (*q.v.*). The mineral takes its name from Strontian in Argyllshire, where it was known in the lead mines as early as 1764, and in material from this source the element strontium was discovered. Crystals are rare and usually acicular or spiky in form; more often the mineral is found as columnar or fibrous masses. The colour is usually white or pale-yellowish, but the columnar masses from Strontian show a characteristic and delicate shade of green; sp.gr. 3·7; H. 3½. Strontianite is a mineral known in comparatively few localities, and in quantities sufficient for mining only in the neighbourhood of Münster and Hamm in Westphalia, where it forms veins in calcareous marl. It is used for the preparation of strontium hydroxide, which is employed (in preference to the poisonous barium compound) in the refining of beet-sugar. It is also used for producing the red fire of fireworks, and in the manufacture of 'basic bricks.' L. J. S.

STRONTIUM. Sym. Sr. At.wt. 87·6.

Strontium derives its name from Strontian in Argyllshire, where strontianite, the carbonate of strontium, was first found. This mineral was suspected by Crawford in 1790 to contain a new earth, the existence of which was confirmed by Hope in 1792, and by Klaproth in 1793.

All primary rocks contain strontium in greater or less quantity. More strontium than barium has been taken up by water, owing to the readier solubility of the sulphate, which is found deposited along with gypsum on evaporation. The carbonate and sulphate of strontium are often found along with deposits of common salt (Dieulafait, Ann. Chim. Phys. [v.] 15, 540).

Strontium is chiefly found as the sulphate, *celestine* $SrSO_4$, and the carbonate, *strontianite* $SrCO_3$. It almost invariably accompanies calcium in traces in the various forms of aragonite and calcite. In *barytocelestine* it occurs along with barium as a mixed sulphate; barytes also generally contain traces of strontium. *Brewsterite* $Al_2O_3{\cdot}H_4(BaSr)O_3{\cdot}(SiO_2)_6,3H_2O$ is a silicate in which strontium occurs associated with barium. Strontium, in minute traces, is present in the mineral waters of Carlsbad, Kaiser-Franzenbrunnen, and many other places, and in sea-water.

Davy obtained, by a method identical with that described under barium, a metallic body which he supposed to be strontium, but which was probably only a rich amalgam. Matthiessen, by the electrolysis of the fused chloride, obtained a metallic-looking mass, and the method was used also by Borchers (Zeitsch. Elektrochem. 8, 759) with similar results. It seems, however, probable that some action similar to that described under Barium and Calcium takes place, and that a sub-chloride and not the metal is formed. The compound has the property of decomposing water. The best method of obtaining strontium is probably that of Guntz, described under Barium. An amalgam is obtained by Davy's method, and the greater part of the mercury may be removed by distillation in a vacuum. The impure strontium so obtained is then treated with hydrogen at a red heat, whereby the hydride is formed and the last traces of mercury removed. The hydride is then decomposed by exhausting the tube and finally raising the temperature to 1100°.

Guntz does not appear to have determined the physical constants of strontium, and it is doubtful whether those given by earlier experimenters are of value. Like barium, it is a white, malleable metal. It decomposes water in the cold and unites with the halogens, sulphur, and phosphorus.

Strontium hydride SrH_2 is obtained by heating the amalgam in a current of hydrogen. The mercury distils off, leaving a white solid, which decomposes water, yielding hydrogen and the hydroxide.

Strontium monoxide, or *strontia* SrO, is obtained when the nitrate is heated to redness, or when the carbonate is ignited, either alone or in contact with carbonaceous matter, such as coal or charcoal. Leplay (Dingl. poly. J. 256, 169), having observed that in the decomposition of strontium carbonate by means of superheated steam the hydroxide so formed loses water at temperatures near its melting-point, and is converted into a solid mass of oxide, devised a process for the production of strontium oxide upon the large scale. Moist strontium carbonate, moulded into suitable forms, is deprived of a portion of its moisture and heated in retorts placed over a decomposing furnace. Superheated steam is also blown into the retorts, and the liberated carbon dioxide led away. The oxide formed by ignition of the hydroxide is removed in waggons, fresh carbonate being introduced in order to make the process continuous. Specially constructed kilns using generator gas are now usually employed for preparing the oxide by burning the carbonate at a high temperature.

Strontium oxide is a greyish-white porous mass of sp.gr. 3·9, non-volatile, infusible and glowing with a dazzling white light in the oxy-hydrogen flame. It possesses an alkaline taste and reaction. Like lime, when moistened with water, it slakes, becoming hot and falling to powder. If the calculated quantity of water be added to form the crystalline hydroxide, the whole solidifies to a solid mass.

Strontium hydroxide $Sr(OH)_2$ is the product of the action of water upon the oxide. On dissolving the hydroxide in 5–6 parts of boiling water, filtering hot and allowing to cool in a closed vessel, small transparent quadratic crystals of $Sr(OH)_2,8H_2O$ are deposited; these deliquesce in the air and are rapidly converted into carbonate. Heated to 100°, water is expelled, leaving the hydroxide $Sr(HO)_2$. This hydroxide may also be obtained in the fused state by heating the crystals to low redness, when they solidify on cooling to a greyish-white crystalline mass. At a red heat all the water is expelled, anhydrous strontia remaining. The crystals of $Sr(OH)_2,8H_2O$ are soluble in 50 parts of cold and 2·4 parts of boiling water, forming strontia-water, which rapidly absorbs carbon dioxide from the atmosphere, becoming coated with a crust of carbonate.

According to Heyer (Ber. 19, 2684), when strontium hydroxide is heated to bright redness and the oxide so formed exposed to air saturated with aqueous vapour and afterwards to dry air, a crystalline powder of the composition $Sr(OH)_2,H_2O$ is obtained. Another hydrate $Sr(HO)_2,2H_2O$ also exists according to Müller-Erzbach (Ber. 20, 1628).

Strontium hydroxide is used largely in the preparation and refining of beet-root sugar, and in the extraction of crystallisable sugar from molasses. Its use depends upon the property of the oxide and hydroxide of strontium to combine with sugar to form saccharates easily decomposable by carbon dioxide. Lime was formerly used, but strontia is preferable, the precipitated saccharate of strontia being more granular than that of lime. Scheibler shows that to obtain a good yield 3 molecules of $Sr(OH)_2$ should be employed; if 4 molecules are used 98·4 p.c. of the sugar is precipitated. For 1 kilog. of molasses ½ a kilog. of $Sr(OH)_2$ in 1½ kilogs. boiling water is a good proportion. The mixture is stirred, then, after standing nearly a day, the saccharate crystallises out; it is afterwards pressed and washed with cold strontium hydroxide solution. Under increased pressure and temperature a tribasic saccharate is obtained, but if this while hot is introduced into hot water it is decomposed, $Sr(OH)_2$ crystallising out, and the ordinary saccharate

$$C_{12}H_{22}O_{11}\cdot SrO,5H_2O$$

remaining in solution. On the large scale this clear solution is heated to over 100° when the saccharate is precipitated, impurities remaining in solution. The saccharate is afterwards decomposed by carbon dioxide.

Many processes have been devised for the manufacture of strontium hydroxide, of which the following are the most important:—

In Niewerth's process (Dingl. poly. J. 251, 191), celestine ($SrSO_4$) is mixed with equal quantities of coal and brown iron ore and roasted. On lixiviation of the product with water, strontium hydroxide and ferrous sulphide are produced.

Claus (Dingl. poly. J. 253, 82) proposes to obtain it from the chloride by addition of an equivalent of barium hydroxide to the hot solution; $Sr(OH)_2$ crystallises out and barium chloride is recovered by evaporation and crystallisation. Also by adding an equivalent of barium hydroxide to a hot solution of strontium sulphide. It is also found that if a solution of barium sulphide is added to a hot solution of strontium sulphide, strontium hydroxide crystallises out on cooling, barium hydrosulphide remaining in solution. A similar reaction occurs between sodium and strontium sulphides. On evaporating the solutions of barium or sodium hydrosulphide, mixing with coal-dust, igniting gently and lixiviating, solutions of barium and sodium sulphides are obtained which can be used again. Mother liquors containing strontium hydrosulphide when evaporated and ignited with coal-dust give strontium hydroxide on lixiviation with water. Claus also (J. Pharm. Chim. [v.] 11, 434) describes a process based on the decomposition of strontium monosulphide into hydroxide and hydrosulphide under influence of water, the hydroxide crystallising out.

Leplay's process (Dingl. poly. J. 254, 436) consists in treating strontianite ($SrCO_3$) with steam superheated to a temperature higher than the melting-point of the hydroxide. The carbonate is introduced into iron pots and there heated to low redness; the contents are then removed to retorts, into which the superheated steam is blown. The semi-fluid hydroxide flows into a suitable receiver, and is thence run off into moulds. It is best to prepare the carbonate by working it into a paste with 30–40 p.c. weak caustic lye, and converting into balls or hollow cylinders.

Knight (Eng. Pat. 16220, 1884) precipitates strontium sulphide with an equivalent of zinc chloride; after decantation from the precipitated zinc sulphide, the clear solution is decomposed with caustic soda, strontium hydroxide crystallising out on cooling.

Lee Pattinson (Eng. Pat. 16989, 1884) employs the following process: An equivalent of manganese dioxide is added to a solution of strontium sulphide and air of the temperature of 100°F. blown through. About 66 p.c. is converted into hydroxide and 33 p.c. into insoluble thiosulphate, 33 p.c. of the sulphur present being also deposited. The sulphur is extracted by naphtha, and the oxide of manganese used again. If air is blown through only until a precipitate begins to form, two-thirds of the strontium is found to be converted into hydroxide, and on crystallising almost pure hydroxide is obtained. The mother liquor containing trisulphide is converted to sulphide and used again.

Mactear (Eng. Pat. 5170, 1886) mixes strontium sulphate with slightly more than its equivalent of sodium sulphate and a quantity of carbonaceous matter. The finely-divided mixture is heated in a furnace until the sulphates become reduced to sulphides. The product is treated with hot water, when the two sulphid react, with the production of sodium hydrosulphide and strontium hydroxide, which latter is obtained by crystallisation. The mother liquor containing the former is evaporated, and the residue used again in reducing a fresh supply of celestine. The strontium hydrosulphide obtained as a by-product in the working of the Claus process may be utilised by mixing it with a solution of sodium sulphide Na_2S, when strontium hydroxide and sodium hydrosulphide are formed, the former of which may be crystallised out as usual.

According to Trachsel (J. Soc. Chem. Ind. 1886, 630) other processes for the manufacture of the hydroxide from strontianite and celestine are as follows. If the native carbonate is employed as the raw material, it is first converted into oxide in kilns, the burning requiring a higher temperature than that of lime; the resulting oxide is then dissolved in boiling water, the solution clarified and crystallised. If the sulphate is used, the process is more complicated. The powdered mineral may be boiled with a solution of sodium carbonate, and the resulting carbonate made into bricks with sawdust and calcined as above. Or a mixture of strontium sulphate and sodium carbonate may be furnaced, also yielding strontium carbonate and sodium sulphate. In a third process ammonium carbonate is used to convert the sulphate into carbonate, the conversion being accomplished in closed vessels provided with stirring apparatus.

Trachsel, in order to simplify the manufacture, has devised the following more direct process. It is based upon the fact that a solution of strontium sulphide treated with caustic soda becomes converted into strontium hydroxide, sodium sulphide or hydrosulphide being simultaneously formed

$$SrS+2NaOH=Sr(OH)_2+Na_2S$$
$$SrS+NaOH+H_2O=Sr(OH)_2+NaSH.$$

The second reaction is more advantageous, requiring only half the soda. The sodium sulphide and hydrosulphide are then converted into carbonate by a stream of carbon dioxide:

$$2NaSH+CO_2+H_2O=Na_2CO_3+2H_2S.$$

The sulphuretted hydrogen may be utilised by converting it into sulphur dioxide by passing it through a Claus kiln.

The sodium carbonate is next treated with caustic lime, obtaining thereby calcium carbonate and caustic soda, which can be used again, thus rendering the process continuous.

The sulphate fresh from the mine is passed through a crushing apparatus, mixed with 7 cwts. of coal to every 20 cwts. of sulphate, and the mixture calcined in a plus-pressure or revolving furnace, 3–4 hours being sufficient for the conversion into sulphide. It is then carried to the lixiviators, consisting of round or square vats of boiler-plate, each provided at 6 ins. from the bottom with a removable grating of iron bars, on which is spread a filter of sugar bags covered with fragments of brick or other suitable material to protect it from the red-hot furnace charge. In the centre of the grating an upright cast-iron pipe is fixed, passing through the grating but not quite touching the bottom of the vat, and bearing on the top a flat or umbrella-shaped plate, between which and the pipe an interstice is left for the escape of liquor which is forced up by the steam entering through a steam-pipe placed in the centre of the cast-iron pipe at the bottom of the vat, over which it projects several inches. In these vats the charges as they come from the furnace are covered with boiling water or weak liquor from a former operation, and the steam is turned on, which not only keeps the liquor boiling, but also circulates it energetically, forcing the liquor which has percolated through the false bottom upwards in the cast-iron pipe, when it falls back upon the charge. When the liquor has attained the strength of 24°Tw. it is allowed to settle, and then run off to crystallising tanks, where it is treated with a strong solution of caustic soda. The greater part of the strontium hydroxide falls down at once, a further quantity crystallising out on cooling. The mother liquor (chiefly NaSH) is drained away from the crystals and run into evaporating pans, where it is concentrated to 30°Tw. and again run into other crystallising tanks, where it deposits practically all its strontium hydroxide.

The crystals are dried and washed in hydro-extractors and twice re-crystallised, which renders them ready for packing. This double re-crystallisation causes serious loss, but by the following device one re-crystallisation is found sufficient. The impure hydroxide, after being once dried and washed is thrown into a muffle-furnace, where it is gently heated and stirred about. Part of the water of crystallisation is thus driven off, the iron sulphide is oxidised, and any strontium sulphide is changed to sulphite, sulphate, and thiosulphate, a little strontium carbonate being also formed. This carbonate is sufficient to precipitate all the iron when the furnace product is dissolved in boiling water. The solution is clarified and allowed to cool, and the crystals, after passing through the hydro-extractor, are ready for packing. By this means also the crystals can be produced in a shorter time, about six days being the average required.

Strontium dioxide SrO_2 is formed as a hydrate when a solution of strontium hydroxide is mixed with one of hydrogen peroxide, shining scales of the composition $SrO_2,8H_2O$ being deposited. When heated to 130°, or even in dry air at the ordinary temperature, it gives off water, and the peroxide is left in the form of a white powder. On heating this powder to redness, oxygen is evolved without fusion, strontium monoxide remaining.

Strontium chloride $SrCl_2$ is formed directly by the combustion of strontium in chlorine, or by heating anhydrous strontia in a stream of chlorine. According to Konigel-Weisberg (Ber. 12, 511) chlorine has no action on dry $Sr(OH)_2$, but it converts the hydrate $Sr(OH)_2,8H_2O$ into chloride and chlorate, a small quantity of hypochlorite being also formed. Strontium chloride is generally obtained from strontianite or celestine. The former, dissolved in hot hydrochloric acid, deposits on cooling long hexagonal deliquescent needles of $SrCl_2,6H_2O$ of sp.gr. 1·603, isomorphous with the hydrate of calcium chloride. When heated the crystals lose their water, the white anhydrous salt being left, which fuses at a high temperature, forming a glassy mass of sp.gr. 2·96. According to Mulder, 100 parts of water dissolve 44·2 parts $SrCl_2$ at

0°, 83·1 parts at 60°, and 101·9 parts at 100°. It is also soluble in alcohol.

The anhydrous chloride absorbs dry ammonia, forming a white powder of the composition $SrCl_2·8NH_3$.

Wackenroder (Dingl. poly. J. 253, 440) proposes to prepare strontium chloride on the large scale by adding an equivalent of calcium chloride to strontium sulphide obtained by the reduction of celestine, and passing carbon dioxide into the mixture, when sulphuretted hydrogen is given off and the calcium precipitated as carbonate. The filtered solution is then evaporated to the crystallising-point of the strontium chloride.

Mactear (Eng. Pat. 1915, 1886) mixes celestine and calcium chloride with charcoal or other form of carbon and a little limestone or lime, and strongly heats the mixture in a furnace. the waste fire-gases being utilised to dry the calcium chloride. The product, consisting of strontium chloride and calcium sulphide or oxysulphide, yields on lixiviation solutions from which strontium chloride can be crystallised.

Strontium oxychloride. When strontium hydroxide is boiled in a concentrated solution of strontium chloride, the liquid, on cooling, deposits nacreous lamellæ of $SrCl_2·SrO,9H_2O$, easily decomposed by water and alcohol. *In vacuô* this oxychloride loses water, becoming $SrCl_2·SrO,H_2O$ (André, Compt. rend. 93, 58).

Strontium bromide $SrBr_2$ is obtained when strontium is burnt in bromine vapour, or when the carbonate is dissolved in hydrobromic acid. From the solution, on evaporating, long needles of the hydrate $SrBr_2,6H_2O$ are obtained. It is readily soluble in water and slightly soluble in alcohol.

Strontium iodide $SrI_2,7H_2O$ is prepared by evaporating a solution of hydriodic acid saturated with strontium hydroxide. It crystallises in six-sided plates, very soluble in water. Heated in a closed vessel it may be fused without parting with iodine, but in contact with air iodine fumes are evolved, strontium oxide being left.

Strontium fluoride SrF_2 is also similarly obtained by treating the oxide or carbonate with hydrofluoric acid, or by precipitating a soluble strontium salt with sodium fluoride. Strontium fluoride is a white powder insoluble in water.

Strontium carbide SrC_2 has been prepared in the pure crystalline condition by Moissan by reducing the oxide with carbon in the electric furnace, using 120 grms. of strontia to 30 grms. of sugar carbon. The reduction is effected at a lower temperature than the corresponding calcium carbide. It is a brownish crystalline mass, density 3·19, which decomposes water yielding acetylene and strontium hydroxide.

Strontium carbonate $SrCO_3$ occurs native as strontianite in rhombic crystals, isomorphous with those of aragonite and witherite. Strontium oxide absorbs CO_2, as does CaO, when strongly heated to a temperature about 1050°, becoming incandescent, the luminosity being greater than that of lime. But the normal carbonate is never formed in this way (Raoult, Compt. rend. 92, 1110). When a solution of a strontium salt is precipitated by an alkaline carbonate, strontium carbonate is obtained as a white powder of sp.gr. 3·62 It may be obtained crystallised in the form of strontianite by fusing a mixture of potassium chloride, sodium chloride and the amorphous carbonate, and allowing to cool (Bourgeois, Bull. Soc. chim. [ii.] 37, 447). When gently heated it becomes converted into strontia. A litre of water, according to Fresenius, dissolves 55 milligrams of strontium carbonate. It is still less soluble in aqueous ammonia or ammonium carbonate, but dissolves more readily in ammonium chloride and nitrate. Boiled with ammonium chloride solution it becomes converted into strontium chloride.

Several processes have been devised, in view of the use of strontia in sugar refining, for the production of strontium carbonate on the large scale. Urquhart and Rowell (Dingl. poly. J. 1884, 252) treat native sulphate (celestine) with sulphuric acid to remove iron and aluminium, then boil the product with mixed solutions of sodium sulphate and carbonate. The resulting mixture of strontium sulphate and carbonate is heated in a furnace with excess of Na_2CO_3, and the mass lixiviated, $SrCO_3$ being thus obtained, together with a liquor which is used for the treatment of fresh celestine.

Mebus and Decastro (Dingl. poly. J. 257, 198) digest finely-pulverised strontium sulphate with a solution of ammonium carbonate, the decomposition being effected in an apparatus fitted with agitating appliances.

A basic hydrated strontium carbonate is formed when the hydrate $Sr(OH)_2,H_2O$ is exposed to a current of carbon dioxide, and the product dried at 145° (Finkener, Ber. 19, 2958).

Strontium nitride Sr_3N_2 may be obtained by the action of nitrogen on the amalgam at a red heat. The mercury distils off, leaving a dark fused mass which decomposes water with the formation of ammonia and strontium hydroxide.

Strontium nitrate $Sr(NO_3)_2$ may be prepared by dissolving the carbonate in dilute nitric acid. On allowing the hot concentrated solution to evaporate, the anhydrous nitrate separates out in transparent crystals belonging to the regular system, generally in octahedrons modified by faces of the cube. Its sp.gr., according to Schröder, is 2·96. It possesses a cooling taste, and when thrown upon red-hot charcoal deflagrates, burning with a red flame. Owing to the fact that this salt lends itself most readily to the production of red fire, it is much used in pyrotechny.

On cooling a dilute solution of strontium nitrate a hydrate $Sr(NO_3)_2,4H_2O$ separates out in large monoclinic prisms, which rapidly effloresce in the air. Strontium nitrate is soluble in about twice its weight of water at 13°, and in an equal weight at 100° (Mulder). It is but slightly soluble in alcohol and almost insoluble in strong nitric acid.

Strontium phosphide Sr_3P_2 is prepared by reducing tristrontium phosphate with carbon in the electric furnace. It forms brownish-red crystals, density 2·68, and decomposes water yielding phosphoretted hydrogen and strontium hydroxide.

Di-strontium ortho-phosphate $Sr_2H_2P_2O_8$, or $SrHPO_4$, is obtained by precipitation of solutions of strontium salts with disodium phosphate as a white amorphous powder, insoluble in water but soluble in acids or ammonium salts. It is not decomposed by aqueous solutions of alkalis.

After being heated strongly to the fusing-point it exhibits phosphorescence.

According to Kühn, a mixture of di-strontium and mono-strontium phosphates is formed when the strontium salt is incompletely precipitated in the cold by the alkaline phosphate.

Potassium strontium phosphate $KSrPO_4$, and sodium strontium phosphate $NaSrPO_4$, are obtained by ignition of one molecule strontium pyrophosphate with a molecule of potassium or sodium carbonate and extraction with water. They are, however, somewhat readily decomposed by water, the residue being invariably found to contain neutral strontium phosphate. According to Joly (Compt. rend. 104, 905) a molecule of HNa_2PO_4 reacts with one of $SrCl_2$ in three stages. A gelatinous trimetallic phosphate is first formed, which then becomes crystalline, and is afterwards transformed into di-strontium phosphate, the solution becoming acid. The temperature remains stationary at first, while cubic crystals of $NaSrPO_4,9H_2O$ begin to form, almost insoluble in cold water. If the precipitate is allowed to remain in the liquid and phenolphthalein added, and then sodium hydroxide, a white gelatinous precipitate, rapidly crystallising, is formed. When the indicator changes, one equivalent of alkali has been added, and the whole of the strontium is precipitated as $NaSrPO_4,9H_2O$.

Strontium pyrophosphate $Sr_2P_2O_7$ is obtained by precipitation as an amorphous powder, rapidly becoming crystalline when the liquid is kept warm. It is insoluble in acetic but soluble in stronger acids. Heated to 100° the hydrate $Sr_2P_2O_7,H_2O$ is left, but above that temperature the water is driven off.

On adding strontium nitrate to a boiling solution of sodium pyrophosphate, a precipitate forms which is probably a mixture of strontium pyrophosphate with a double salt.

Di-strontium arsenate $SrHAsO_4$. When a solution of HNa_2AsO_4 is added to one of $SrCl_2$ a precipitate of $SrNaAsO_4,H_2O$ is thrown down; when the filtrate from this is evaporated, a white precipitate of the di-strontium salt is obtained (Salkowski). According to Joly (Compt. rend. 104, 905), when 1 molecule $SrCl_2$ solution is added to one of HNa_2AsO_4 no precipitate is formed, the solution remaining alkaline; but after some time, if the sides of the vessel are rubbed, a crystalline precipitate separates, and the liquid becomes acid. In 24 hours large cubic crystals of $NaSrAsO_4,9H_2O$ (isomorphous with corresponding phosphate) are deposited. On addition of one equivalent NaOH the precipitation is complete.

Strontium silicate. According to Kirwan, equal weights of strontia and silica fuse, with formation of an amber-coloured glass and a black and white enamel. Vauquelin found that with 3 parts of strontia a solid grey mass is formed, difficultly soluble in water, but readily in dilute acids. According to Kuhlmann, strontium carbonate, digested in solution of silica is converted into a hydrated strontium silicate.

Strontium monosulphide SrS is prepared by reduction of the sulphate with coal or other form of carbon. It is a white, granular, semi-fused and brittle mass. It is decomposed by treatment with a large quantity of boiling water, with formation of strontium hydroxide, which crystallises out on cooling, and strontium sulphydrate, which remains in solution:

$$2SrS+2H_2O=Sr(OH)_2+Sr(SH)_2.$$

If a less quantity of water be employed, nearly pure hydrosulphide is extracted, while the residue on treatment with more water gives a solution of almost pure hydroxide.

The strontium sulphide obtained by heating 100 parts $SrCO_3$, 30 parts sulphur, and 5 parts arsenious oxide shows a greenish-blue phosphorescence if the carbonate has been prepared from the chloride and ammonium carbonate, but a greenish-yellow if precipitated by sodium carbonate (Verneuil, Compt. rend. 103, 600). According to Becquerel (*ibid.* 104, 551) the colour of the phosphorescence varies with the temperature. At −20° it is violet-blue, at +40° pale blue, at 90° a greenish-yellow, and at 150° orange. The reverse series of colour-changes is noticed as the temperature falls.

Strontium tetrasulphide SrS_4. When the monosulphide and sulphur are digested in water in the proportion of 1 to 3 molecules, and the solution allowed to evaporate below 17°, a brown syrup is obtained which crystallises at 8° to a mass of the composition $SrS_4,6H_2O$. This substance is very hygroscopic, and soluble in alcohol as well as in water. On exposing the solutions to the air, strontium thiosulphate remains in solution, sulphur and a little $SrCO_3$ being deposited. On heating the syrup to 100°, or concentrating under the air-pump between 20° and 25°, a light-yellow solid of the composition $SrS_4,2H_2O$ separates. Heated above 100°, its own water of crystallisation decomposes it. It is insoluble in carbon disulphide.

When an alcoholic solution of SrS_4 is exposed to air, transparent ruby-red rhombic crystals are formed of the composition $SrO{\cdot}SrS_4,12H_2O$, which are decomposed by water. They are probably identical with Gay-Lussac's disulphide, which he obtained by allowing a solution of strontium sulphide to stand.

Strontium pentasulphide SrS_5 is obtained when the monosulphide is digested in water with 4 molecules of sulphur, but is only known in solution. On attempting to isolate by evaporation under the air-pump, a mixture of the tetrasulphide and sulphur is obtained (Schöne, Pogg. Ann. 117, 56).

Strontium hydrosulphide $Sr(SH)_2$ is readily obtained by saturating strontia water with sulphuretted hydrogen, or by passing sulphuretted hydrogen through water holding strontium sulphide in suspension. Also by dissolving the monosulphide in a small quantity of boiling water, by which it is decomposed into soluble sulphydrate and insoluble hydroxide. By evaporating the solution obtained by the first method, Berzelius obtained the hydrosulphide in large striated prisms, which on heating melt in their water of crystallisation, then give it off, together with sulphuretted hydrogen, and leave a residue of the monosulphide.

Strontium sulphite $SrSO_3$. Strontia commences to absorb sulphur dioxide at 230° with production of $SrSO_3$. Strontium sulphite is obtained by double decomposition as a white powder soluble in aqueous sulphurous acid, from which solution the sulphite is again deposited in crystalline grains. The crystals are flat, rectangular tables, which are gradually converted into sulphate on exposure to air.

Strontium sulphate $SrSO_4$ is found native as celestine in large rhombic crystals and fibrous masses. The name celestine was originally given to the mineral on account of the light-blue tint which it generally possesses. By fusing potassium sulphate with excess of strontium chloride Manross obtained well-developed artificial crystals of celestine. Sulphuric acid added to the solution of any strontium salt gives a precipitate of sulphate more or less crystalline. According to Haushofer (J. M. 1887, 1, Ref. 15), solutions containing 0·1 grm. $SrCl_2$ in 20–80 c.c. water treated with 1 c.c. concentrated hydrochloric acid, give with dilute sulphuric acid very perfect rhombic crystals. Precipitated strontium sulphate has a sp.gr. of 3·7, and fuses on being strongly heated. It is less soluble in hot than in cold water, but is more soluble in acids. According to Fresenius, 1 litre of water dissolves 0·145 grm. at ordinary temperature and 0·104 grm. at 100°. This aqueous solution at once gives a turbidity with solutions of barium salts. Strontium sulphate dissolves to a considerable extent in a solution of common salt and other saline solutions, but the presence of sulphates or dilute sulphuric acid diminishes the solubility. Unlike barium sulphate, strontium sulphate is completely converted into carbonate by boiling with solutions of alkaline carbonates.

Strontium sulphate is soluble in hot, strong sulphuric acid, crystals of celestine separating out on cooling. If it is heated with strong sulphuric acid to 100° and the solution digested with an excess of salt at a still higher temperature, the acid salt $SrH_2(SO_4)_2$ separates as a crystalline powder, which changes on exposure to moist air to the hydrated salt $SrH_2(SO_4)_2,H_2O$, forming shining tabular crystals. According to Varenne and Pauleau (Compt. rend. 93, 1016) 1 grm. of $SrSO_4$ precipitated from the chloride dissolves in 1256 grms. sulphuric acid.

Strontium chromate $SrCrO_4$ is formed as a lemon-yellow precipitate, composed of slender microscopic needles, when a strong solution of chloride or nitrate of strontium is mixed with one of neutral potassium chromate. After drying over sulphuric acid or at 100° the salt is anhydrous, and remains unaltered on heating. One part of the salt is soluble in 840 parts of water at 16°. It is readily soluble in hydrochloric, nitric, and chromic acids. It dissolves with difficulty in acetic acid, and is insoluble in alcohol. No precipitate is formed in presence of acetic acid if the solution contains for 1 molecule K_2CrO_4 1 molecule $Sr(NO_3)_2$ or $Sr(C_2H_3O_2)_2$ and 30 molecules water, or for 1 molecule $SrCl_2$, 25 molecules H_2O. The separation from barium by means of K_2CrO_4 is, therefore, not complete, some $SrCrO_4$ coming down along with the $BaCrO_4$ (Meschtchersky, J. Russ. Phys. Chem. Soc. 1882, 219).

Bourgeois (J. M. 1880, 1, Ref. 351) prepared $SrCrO_4$ by heating 2 molecules $SrCl_2$ with 1 molecule K_2CrO_4 and 1 molecule Na_2CO_3 to bright redness. The $SrCrO_4$ thus obtained forms beautiful yellow rhombic lamellæ, cleaving parallel to faces of a rhombic prism, and sparingly soluble in water.

Strontium dichromate $SrCr_2O_8,H_2O$ has been obtained by Preis and Rayman (Ber. 13, 340) by dissolving $SrCrO_4$ in concentrated chromic acid and drying the product at 100°. It consists of readily-soluble dark-red crystals. A second salt, containing $3H_2O$, was obtained in the form of red deliquescent crystals.

Detection and estimation of strontium. Strontium salts colour the flame a characteristic crimson. Examined by the spectroscope, the spectrum is found to consist of a large number of bright lines, of which the orange line $Sr\alpha$, the red lines $Sr\beta$ and $Sr\gamma$, and the blue line $Sr\delta$ are most characteristic. Even in presence of a large quantity of barium salts this reaction affords a ready means of distinguishing strontium.

In its reactions strontium very much resembles barium. It chiefly differs in forming more soluble salts. Thus the sulphate, chromate, and silico-fluoride are considerably more soluble. Hence dilute solutions are only precipitated after some time by sulphuric acid or soluble sulphates, and a solution of strontium sulphate gives an immediate precipitate with soluble barium salts.

The chromate is very much more soluble, a precipitate of stellar aggregates of needles only forming with strong solutions and in absence of much acetic acid. Strontium sulphate is formed after a time if the solution is dilute, but immediately if strong, on addition of a solution of calcium sulphate to one of a soluble strontium salt, and thus strontium may be distinguished from calcium.

Strontium may be estimated as carbonate by precipitation with ammonium carbonate and ammonia from a hot solution; the carbonate is not decomposed by ignition over an ordinary Bunsen burner. It may also be estimated as sulphate, the completion of the precipitation being effected by addition of alcohol. This method, of course, can only be used when the original strontium salt is soluble in alcohol.

Atomic weight of strontium. Richards, using the bromide, obtained as mean 87·616; $O=16$. Thorpe and Francis (Proc. Roy. Soc. 83 A. 277), using various methods, obtained as mean 87·649.

G. S. B.

STROPHANTHUS. *Kombé Arrow-poison.* The seed of *Strophanthus hispidus* (De Cand.) is used by the natives of Central Africa for the preparation of arrow-poison. A paste is made by crushing the seed with water, and with this the arrow-heads are smeared. Arrows tipped in this way appear to be used both in warfare and in the chase. In the latter case the animal falls quickly, when the flesh immediately around the wound is cut away and the remainder eaten without any injurious effect. Strophanthus arrow-poison is very widely used throughout the whole of Central Africa, specimens having been obtained and sent to Europe from time to time from nearly all parts of the east and west coasts. The plant is a woody climber of the natural order *Apocynaceæ*, which ascends the highest trees and hangs in festoons from one to another. The pods contain one to two hundred seeds, each seed weighing about half-a-grain, and having attached to it a beautiful comose appendage on an extremely brittle stalk. The seed was first examined by T. R. Fraser, of Edinburgh, in 1872, who drew attention to its important physiological action on the movements of the heart, and pointed out that both its physiological and toxic action depends upon the presence of an active constituent to which he gave the name 'strophanthin' (Pharm. J. [iii.] 3, 523; 19, 660).

There has been some doubt as to the precise botanical origin of the seed of commerce. That examined by Fraser came from the East coast, has a fawn colour, and when viewed in certain positions a greenish-grey appearance. West African seed is dark-brown in colour and smaller. The latter is without doubt derived from *S. hispidus*, and to distinguish the former, which alone is recognised by the Pharmacopœia, it is described as the product of *S. hispidus*, variety *Kombé* (Oliver) (Holmes, Pharm. J. [iii.] 21, 233; Brit. Pharm. Additions, 1890, 29). *V.* also Holmes (*ibid.* [iii.] 16, 778; 17, 903); Maisch (*ibid.* [iii.] 17, 972); Hanausek (*ibid.* [3] 17, 972); Blondel (J. Pharm. Chim. [v.] 17, 249, 297, 554); Christy (Pharm. J. [iii.] 20, 318).

In 1877 Hardy and Gallois isolated an active crystalline compound from strophanthus seed which was named 'strophantin,' and which had neither the characters of a glucoside nor those of an alkaloid. Fraser, however, finds the active constituent to be a glucoside, which readily breaks up under the influence of dilute acids into an easily-crystallisable neutral compound and a sugar. The glucoside is *strophanthin*, and the neutral compound produced by its decomposition *strophanthidin*, the latter probably identical with the 'strophantin' of Hardy and Gallois. Both these compounds are toxic and bitter, and have similar physiological action. The seed also contains a large proportion of *fixed oil*, and an acid forming an insoluble lead salt, *kombic acid*, and the alkaloids choline and trigonelline have been shown to be present in small amounts (Thoms, Ber. 31, 404).

A specimen of seed examined by Fraser lost at 100° 6·7 p.c. of water, and the residue yielded successively to light petroleum 31·8 p.c. of oil; to ether, 0·8 p.c. chiefly resin and chlorophyll; to rectified spirit, 8·9 p.c. of bitter extract; and to water, 9·3 p.c. mostly mucilage and albumen. When burnt, there remained 3·5 p.c. of ash; insoluble undetermined constituents, 38·9 p.c. *Strophanthin* is found in the alcoholic extract. To obtain it a concentrated solution of the extract in water is prepared, and precipitated by a solution of tannin. The precipitate is well washed and mixed with enough moist oxide of lead to combine with the quantity of tannin employed. This mixture is allowed to digest at a low temperature for several days, and when dry is extracted successively with rectified and proof spirit. If any tannin remains in the solution, the lead oxide process has to be repeated. Excess of lead is removed from the alcoholic solutions by a stream of carbon dioxide passed for 2 or 3 days. The solutions are then evaporated to dryness, the residue exhausted with rectified spirit, and the alcoholic solution precipitated by the addition of ether. The more or less crystalline precipitate of crude strophanthin thus obtained is purified by solution in alcohol and evaporation in a vacuum. The yield of strophanthin amounts to 65 p.c. of the alcoholic extract.

A second method is to extract the seeds, which have previously been freed from fat and oil, with cold 70 p.c. alcohol. The alcohol is removed by distillation and the residue extracted with water. Lead acetate is added to the aqueous extract as long as a precipitate is produced, and then ammonium sulphate in just sufficient quantity to precipitate the excess of lead which is removed. On further addition of a large excess of ammonium sulphate the strophanthin separates in a pasty mass, and may be purified by repeated precipitation by the addition of ether to the alcoholic solution (Thoms, Ber. 31, 271).

Strophanthin is usually obtained as an amorphous mass, although crystals can be produced. Its empirical formula is not known with certainty, but analysis gives figures agreeing approximately with $C_{16}H_{26}O_8$. It readily absorbs moisture, and is capable of forming several hydrates. After drying over sulphuric acid it melts with decomposition at 170° (Feist, Ber. 31, 534; 33, 2063, 2069). It is very soluble in water or aqueous alcohol; is less soluble in alcohol, acetone, or amyl alcohol; and is insoluble in ether, chloroform, light petroleum, and carbon disulphide. Mineral acids give characteristic colour-reactions with strophanthin. Sulphuric acid in the cold gives a bright-green colour, which on heating to 43°–49° changes to olive, dark-brown, violet, violet-blue, and finally to a violet-black. A 10 p.c. solution of sulphuric acid produces similar changes of colour. Nitric acid gives colour-reactions. Hydrochloric acid dissolves it, forming a pale-yellow solution, changing to brownish-yellow. A 10 p.c. solution of hydrochloric acid forms a colourless solution, which when heated to 46°–54° for 20 mins. changes to green and dark-blue, the latter colour remaining for several hours (Fraser). If a trace of strophanthin, dissolved in a drop of water, be mixed with ferric chloride and a drop of sulphuric acid added, a reddish-brown precipitate forms, which either at once or after standing some hours changes to emerald green (Helbing, J. Soc. Chem. Ind. 1891, 575).

On hydrolysis strophanthin yields strophanthidin and a carbohydrate. Strophanthidin has the composition $C_{27}H_{38}O_7,\frac{1}{2}H_2O$. It melts at 169°–170°, but when anhydrous at 235° The sugar, *methylstrophanthobioside*

$$C_{12}H_{21}O_9OMe,$$

obtained by the hydrolysis of strophanthin, forms a colourless crystalline powder melting at 207°. When hydrolysed it yields methyl alcohol, *d*-mannose, and *d*-rhamnose (Feist, *l.c.*, and Ber. 33, 2091; *cf.* Karstein, Chem. Zentr. 1902, ii. 1514).

Kombic acid has not been isolated in a definite condition. The *oil* extracted by light petroleum does not appear, when properly washed, to possess any physiological activity. It varies in colour from pale yellow to green and brown, and in sp.gr. from 0·975 to 0·927 (Fraser), and consists mainly of the glycerides of malic and palmitic acids (Mjoen, Arch. Pharm. 234, 283). *See* also Elborne (Pharm. J. [iii.] 17, 743; 18, 219); Helbing (*ibid.* [iii.] 17, 747, 924); Gerrard (*ibid.* [iii.] 17, 923); Merck (*ibid.* [iii.] 18, 72); Adrian a. Bardet (*ibid.* [iii.] 18, 539); Castillon (J. Pharm. Chim. [v.] 17, 334); Fischer (Pharm. Post. 20, 489).

The arrow-poison of the Somalis 'ouabaïo,' the botanical origin of which is not known with certainty, contains a compound, *ouabain*, which is nearly related to strophanthin or strophanthidin. This compound is now prepared from a variety of strophanthus seeds, known in the market by the unscientific name of 'strophanthus glabrus' (Holmes, Pharm. J. [iii.] 21, 234; Arnaud, Compt. rend. 106, 1011; 107, 1162; 126, 1208, 1280; Cathelineau, J. Pharm. Chim. [v.] 20, 436). *V.* Oubaïo, vol. iv. 26. A. S.

STROPHANTOBIOSE *v.* Carbohydrates.

STRYCHNINE *v.* Vegeto-alkaloids.

STYPHNIC ACID *v.* Phenol and its homologues.

STYRACINE, *cinnamyl cinnamate* $C_6H_5{\cdot}CH:CH{\cdot}CH_2{\cdot}O{\cdot}CO{\cdot}CH:CH{\cdot}C_6H_5$, occurs in storax. It crystallises in needles, m.p. 14°. On saponification it forms a salt of cinnamic acid and styrone (*v.* Balsams).

STYRACOL *v.* Synthetic drugs.

STYRENE, *styrolene, cinnamene, phenylethylene* $C_6H_5{\cdot}CH:CH_2$, occurs in liquid storax (*v.* Balsams), from which it may be obtained on distillation. It is formed by reducing phenylacetylene with zinc-dust and acetic acid (Aronstein and Hollemann, Ber. 1889, 22, 1184); by heating cinnamic acid with barium hydroxide (Gerhardt and Cahours, Annalen, 1841, 38, 96): by acting upon cinnamyl alcohol with sodium amalgam (Hatton and Hodgkinson, Chem. Soc. Trans. 1881, 39, 319); by heating dragon-blood resin either alone or in the presence of zinc-dust (Bötsch, Monatsh. 1880, I, 610); by heating phenylethyl bromide with alcoholic potash (Thorpe, Zeitsch. Chem. 1871, 130); by the action of aluminium chloride on a mixture of benzene and ethyl bromide (Anschütz, Annalen, 1886, 235, 331); by acting upon phenylmethylcarbinol with phosphoric acid (Klages and Allendorff, Ber. 1898, 31, 1298). Styrene is, however, most conveniently prepared by acting upon cinnamic acid with hydriodic acid and then heating the product with aqueous potash (Fittig and Binder, Annalen, 1879, 195, 137).

Properties and reactions.—Colourless aromatic liquid; sp.gr. 0·925 at 0°; b.p. 146°; insoluble in water, but soluble in all proportions in alcohol and ether. On keeping it changes gradually into metastyrene; with the halogens and halogen acids it readily forms addition compounds; on reduction it yields phenylethene and on oxidation benzoic acid; by the action of nitrogen trioxide it is converted into a nitrite (Sommer, Ber. 1895, 28, 1328).

Distyrene $(C_8H_8)_2$, m.p. 124°, is obtained by the distillation of calcium cinnamate (Engler and Leist, Annalen, 1833, 6, 256) or cinnamic acid alone (Miller, *ibid.* 1877, 189, 340), and also by the distillation of truxillic acid (Liebermann, Ber. 1889, 22, 2255). A liquid distyrene is said also to exist, being obtained when styrene is heated with concentrated hydrochloric acid (Erdmann, Annalen, 1883, 216, 187).

Metastyrene. Styrene on keeping, especially at high temperatures, changes, slowly in the dark, more quickly under the influence of light, into another polymer, which forms an amorphous glassy mass, metastyrene; on distillation it regenerates styrene.

α-**Chlorostyrene** $C_6H_5{\cdot}CCl:CH_2$ is obtained by heating styrene chloride with soda-lime (Blyth and Hofmann, Annalen, 1845, 53, 310); liquid b.p. 199°.

β-**Chlorostyrene** $C_6H_5{\cdot}CH:CHCl$ is formed when cinnamic acid is heated with sodium hypochlorite or with potassium chlorate and hydrochloric acid (Stenhouse, Annalen, 1845, 55, 1; 1846, 57, 79); also by heating phenylchlorlactic acid with water to 200° (Glaser, *ibid.* 1870, 154, 166); also by the action of zinc-dust on trichlomethylphenyl carbinol (Jocitsch, Chem. Zentr. 1899, i. 607).

αα'-**Dichlorostyrene** $C_6H_5{\cdot}CH:CCl_2$ is formed by the action of chloral on benzene in the presence of aluminium chloride (Biltz, Annalen, 1897, 296, 259).

αβ-**Dichlorostyrene** $C_6H_5{\cdot}CCl{:}CHCl$ is formed by the action of phosphorus pentachloride on acetophenone (Dyckerhoff, Ber. 1877, 10, 120).

Trichlorostyrene $C_6H_5{\cdot}CCl:CCl_2$ is obtained by the action of alcoholic potash on phenyltetrachlorethylene (Bilz, Annalen, 1897, 296, 270).

Bromostyrenes are obtained by similar methods (Glaser, *ibid.* 1870, 154, 168; Fittig, *ibid.* 1879, 195, 142; Fincke, *ibid.* 1883, 216, 290; Jocitsch, Chem. Zentr. 1899, [i.] 607; Favorsky, *ibid.* 1899, [i.] 778; Nef, Annalen, 1899, 308, 273).

Iodostyrenes (*v.* Peratoni, Gazz. Chim. ital. 22, [ii.] 69; Liebermann and Sachse, Ber. 1891, 24, 4155).

o-**Nitrostyrene** (m.p. 12°) from β*o*-nitrophenylpropionic acid and alkalis (Einhorn, Ber. 1883, 16, 2213).

m-**Nitrostyrene** (m.p. −5°) similarly obtained (Prausnitz, *ibid.* 1884, 17, 597).

p-**Nitrostyrene** (m.p. 29°) similarly obtained (Basler, Ber. 1883, 16, 3005).

α-**Nitrostyrene** (m.p. 58°) from styrene and nitric acid (Simon, Annalen, 1839, 31, 269); by heating benzaldehyde with nitromethane and zinc chloride (Priebs, *ibid.* 1884, 225, 321); by heating phenyl*iso*crotonic acid with fuming nitric acid (Erdmann, Ber. 1891, 24, 2773).

For other *nitrostyrenes, see* Priebs, Annalen, 1888, 245, 343; Friedländer and Mahly, *ibid.* 1885, 229, 224; Friedländer and Lazarus, *ibid.* 1885, 229, 233; Lipp, Ber. 1884, 17, 1070.

STYROGALLOL (*o-Dihydroxyanthracoumarin*) $C_{16}H_8O_5$ is prepared by heating 10 parts of cinnamic acid with 17 of gallic acid and 150 of sulphuric acid for 2–3 hours at 45°–55°. The yellowish-red mass, after cooling, is poured into a large excess of water, the pale green microscopic crystals so formed are filtered off and washed with boiling, slightly acidified water, and recrystallised from alcohol, glacial acetic acid, or aniline (D. R. P. 40375; Frdl. 1877–87, 569; Jacobson and Julius, Ber. 1887, 20, 2588; Kostanecki, *ibid.* 3137).

Styrogallol forms light yellow needles which do not melt at 350° and sublime at 360° almost without decomposition. It is sparingly soluble in alcohol, acetic acid or aniline, and almost insoluble in other solvents. It dissolves in alkalis with a green colour, which on warming becomes blue, violet, and finally red. It dissolves in strong sulphuric acid with a yellowish-red colour, and when oxidised with nitric acid it yields much phthalic acid.

Styrogallol is a dyestuff which gives on mordanted materials similar shades to nitroalizarin.

With acetic anhydride it yields a *di-* and a *tri-acetyl* derivative, and when the former is digested with boiling alcohol and potassium acetate for about 2 hours, it yields a crystalline purple-coloured *potassium salt* $C_{16}H_7O_5K$ (Perkin and Wilson, Chem. Soc. Trans. 1903, 139), which readily dissolves in water with a red colour. With fuming sulphuric acid styrogallol forms a *sulphonate*. When *p*-coumaric acid is condensed with gallic acid it forms *hydroxystyrogallol* or 2 : 3 : 6-trihydroxyanthracoumarin $C_{16}H_8O_6$, which resembles styrogallol, but the presence of an additional hydroxy group causes it to be less soluble and more intensely coloured. *Triacetoxystyrogallol* $C_{16}H_5O_6(OAc)_3$ melts at 250° in a vacuum (Slama, Chem. Zentr. 1899, ii. 967).

STYRONE, *cinnamyl alcohol*

$$C_6H_5{\cdot}CH : CH{\cdot}CH_2OH$$

occurs in storax. It crystallises in thin needles; m.p. 33°; b.p. 250°; it has a characteristic smell of hyacinths. On mild oxidation it yields cinnamaldehyde; with more vigorous oxidising agents cinnamic acid.

SUBCUTIN *v.* SYNTHETIC DRUGS.

SUBERIC ACID (Ger. *Korksaüre*)

$$CO_2H[CH_2]_6CO_2H.$$

Obtained by the oxidation of the following substances with nitric acid: cork (Markownikow, Ber. 1893, 3089; Étaix, Ann. Chim. Phys. [vii.] 9, 384); castor oil (Markownikow, Étaix, *l.c.*; Tilley, Annalen, 39, 166); oleic acid (Laurent, *ibid.* 28, 258; Bromeis, *ibid.* 35, 96); stearic acid (Bromeis, *ibid.* 35, 89); linseed oil (Sacc, *ibid.* 51, 226); cocoa-nut oil (Wirz, *ibid.* 104, 271); almond oil, spermaceti (Arppe, *ibid.* 120, 292; 124, 89); palmitic acid (Schröder, *ibid.* 143, 33); paraffin (Pouchet, J. 1874, 358); by treating pyrollidine with cyanogen bromide and phosphorus pentachloride (Braun, Chem. Zentr. 1909, ii. 1993); by treating the copper derivative of dipropargyl with iodine, followed by carbon dioxide and reducing the $\Delta^{\beta\epsilon}$-hexadiinene-$\alpha\zeta$-dicarboxylic acid thus formed with hydrogen and platinum black (Lespieau and Vavon, Compt. rend. 148, 1322; 149, 997); by the oxidation of azelaone with potassium permanganate (Derlon, Ber. 1898, 1962). It has been synthesised from trimethylene bromide, magnesium and carbon dioxide (Zelinsky and Gutt, *ibid.* 1907, 3049), and by the electrolysis of an aqueous solution of the potassium salt of the monoethyl ester of glutaric acid and subsequent hydrolysis of the diethyl ester thus formed (Brown and Walker, Annalen, 261, 119). To separate suberic acid from azelaic acid, which is also produced in many of the above reactions, use is made of the different solubilities of their magnesium salts (Gantter and Hell, Ber. 1881, 1552; Derlon, *ibid.* 31, 1959).

It crystallises in white scales, m.p. 139·5° (Massol, Bull. Soc. chim. [iii.] 17, 746); sparingly soluble in water and ether, insoluble in chloroform. By heating suberic acid with chalk, suberone (*cyclo*heptanone), carbon dioxide, water and a trace of benzene are formed (Markownikow, Ber. 1893, Ref. 813). The *anhydride* obtained by heating suberic acid with acetyl chloride, melts at 62°–63° (Anderlini, Gazz. chim. ital. 24, i, 474). The *amide* melts at 208°. Twenty-six isomerides of suberic acid have been prepared.

SUBERONE *v.* KETONES.

SUBLAMIN *v.* SYNTHETIC DRUGS.

SUBLIMATION. The passage of a stable substance, when heated, into the state of vapour may take place in one of three ways:—

1. The substance is liquid under ordinary conditions; it boils at a definite temperature, depending on the pressure.
2. The substance is solid; when heated it melts at a definite temperature, and when more strongly heated it boils like an ordinary liquid.
3. The substance is solid; when heated it does not melt, but passes directly from the solid state to that of vapour at a definite temperature depending on the pressure.

Similarly in the condensation of vapour we may have (1) liquefaction; (2) liquefaction and subsequent solidification; (3) direct passage from the gaseous to the solid state.

The term *distillation* is applied to vaporisation and subsequent condensation of the first kind, *sublimation* to the corresponding changes of the third order.

Vaporisation and condensation of the second kind should be included under the term *distillation*, since it is really liquid which is converted into vapour, and which, as a rule, is first formed in the process of condensation. The term sublimation is, however, not unfrequently employed in the case of substances whose melting-points are high or are not far removed from their boiling-points, and, indeed, if the application of the term were strictly limited to changes of the third class it would not be very frequently employed in practical chemistry.

As a matter of fact, the majority of substances may undergo either distillation or sublimation, according to the pressure under which the vaporisation and condensation take place. This may be best understood by means of the diagram (Fig. 1), in which temperatures are measured as ordinates and pressures as abscissæ.

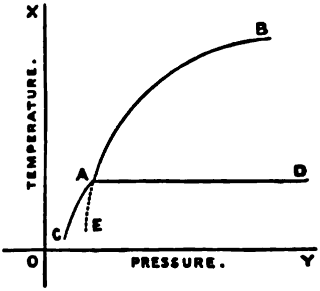

FIG. 1.

The curve AB represents the boiling-points of a substance, the curve CA its subliming-points, and the curve AD its melting-points under varying pressures. The boiling and subliming-points vary greatly with alteration of pressure, the melting-points to so slight an extent that the curve AD, drawn to true scale for any substance, could not be distinguished in such a diagram from a straight horizontal line.

All three curves intersect each other at A, called the *triple point*. The temperature at A, measured vertically from the horizontal axis OY, gives the melting-point of the substance under the pressure represented by the horizontal distance of A from the vertical axis OX; it is practically the same as the melting-point under atmospheric pressure—generally a small fraction of a degree lower.

If a solid substance is heated under pressures greater than the *triple-point pressure*, its temperature will rise until the melting-point is reached; then, after fusion, the temperature will again rise until the liquid reaches its boiling-point. The melting- and boiling-points under any given pressure are indicated by the intersection of a vertical line representing that pressure with the curves AD and AB.

If, however, the pressure is lower than the triple-point pressure, the substance cannot, under ordinary circumstances, exist in the liquid state at all, and when heated it sublimes without previous fusion at a temperature given by the intersection of the vertical line of constant pressure with the curve CA. (It is, however, possible to cool a liquid below its freezing-point without solidification taking place, and it may, indeed, be made to boil below its freezing-point. This is indicated by the dotted line AE, which is simply a continuation of the curve BA.)

The pressure at the triple point varies very greatly for different substances, but in the vast majority of cases it is far below the atmospheric pressure. Hence under ordinary conditions true sublimation rarely takes place.

The following table gives the melting-points, the boiling-points under normal pressure, and the triple-point pressures of a few substances; complete data have been obtained in only a limited number of cases:—

Substance	Melting-point—degs.	Boiling-point—degs.	Triple-point pressure
Water	0·0	100·0	4·6 mm.
Acetic acid	16·4	118·5	9·45 „
Benzene	5·6	80·2	35·9 „
Bromine	−7·1	58·7	44·5 „
Nitrogen	−214	−193·1	60·0 „
Iodine	114·3	184·3	91·0 „
Camphor	180·0	204·0	380·0 „
Mercuric chloride	288·0	303·0	554·0 „
Carbon hexachloride	188 (about)	188 (about)	1 atm.
Arsenious oxide	200 (about)	?	a little above 1 atm.
Aluminium chloride	180–185	?	a little above 1 atm.
Arsenic	500 (about)	450 (about)	above 1 atm.
Carbon dioxide	−57 (about)	−78·2	about 5·3 atm.

Some other compounds—such as mercurous chloride and indium trichloride—sublime without fusion, but exact data are wanting.

It will be seen from the table that the triple-point pressure of carbon dioxide is over five atmospheres, hence when the liquid is allowed to escape from a steel cylinder in which it has been stored under pressure, that which escapes vaporisation at once solidifies and cannot be melted in an open vessel, but passes directly into the gaseous state.

Arsenic and arsenious oxide also sublime when heated under atmospheric pressure, and carbon hexachloride sublimes if the pressure is very slightly lowered, but melts and distils if the pressure is slightly raised. Water again cannot exist as a stable liquid under a pressure lower than 4·6 mm. Below this pressure, ice, when heated, sublimes without melting.

The curve CA represents not only the subliming-points of a solid substance under varying pressures, but also the vapour pressures of the substance at varying temperatures (Ramsay and Young, Trans. Roy. Soc. 1884, i. 37), just as the curve AB represents both the boiling-points and the vapour pressures of the substance in the liquid state; hence the relation of the subliming-point of a solid to the pressure may be defined in precisely the same way as that of the boiling-point of a liquid.

The ordinary definition of the 'boiling-point' (a liquid boils when its vapour pressure is equal to the superincumbent atmospheric pressure) is, however, to some extent misleading. There is, in the first place, perhaps some ambiguity about the terms 'boiling-point' and a 'boiling' liquid. It is true that when a liquid is described as boiling, the impression conveyed is that the liquid is in a state of ebullition, but the 'boiling-point' is certainly not the temperature of ebullition. What is called the 'boiling-point' of a liquid is usually determined by placing a thermometer in the vapour over the liquid, care being taken that the thermometer bulb is always moistened by condensed liquid. It is, in fact, the condensing-point of the vapour that is directly measured.

On the other hand, in order that a bubble of vapour may form below the liquid, not only has the pressure of vapour or air over the liquid to be overcome, but also that of the column of liquid over the point where the bubble forms, and, lastly, the adhesion of the liquid to the solid surface (or possibly the cohesion of the liquid itself). In the case of a very clean smooth vessel, and a liquid very free from dissolved air, this last factor becomes very important, and the ebullition-point may be considerably higher than the 'boiling-point.' Under the most favourable conditions it is somewhat higher (Regnault, 'Relation des Expériences,' 1847, 525–529).

The boiling-point of a liquid is, in fact, not its ebullition-point—which does not depend solely on the pressure—but it is *the highest temperature attainable by the liquid under a given pressure when evaporating with a perfectly* *free surface, and when heat is received from outwards towards the surface.* It is only under these conditions, where ebullition is obviously impossible, that the boiling-point can be accurately determined by measuring the temperature of the liquid itself (Ramsay and Young, Chem. Soc. Trans. 47, 42).

In the case of sublimation this difficulty does not occur, for anything analogous to ebullition is impossible, and since the solid can only be in partial contact with the vessel containing it there is practically always a free surface for evaporation.

The ordinary definition of the 'boiling-point' of a liquid takes also no account of the fact that a law analogous to Dalton's law of partial pressures holds good for distillation and sublimation.

That this is the case is proved by the behaviour of two non-miscible liquids when distilled together (*v.* DISTILLATION). It is found that the boiling-point and the composition of the mixed vapour are independent of the relative quantities of the two liquids present, and that the 'boiling-point' is the same as that of either liquid when distilled alone under a pressure equal to its partial pressure in the mixed vapour. Hence, as the pressure of the vapour of the one liquid is without influence on the 'boiling-point' of the other, it might be inferred that the pressure of an indifferent gas, such as the air, would be without influence on the 'boiling-point' of a liquid or on the subliming-point of a solid. This is, in fact, the case, and it is really not the pressure of the atmospheric air, but that of the vapour itself in contact with the liquid or solid, that influences the 'boiling-' or subliming-point.

In ordinary cases of distillation or sublimation the vapour of the substance completely expels the air from the flask or retort; hence the substance is surrounded by its own vapour at the same pressure as that of the external atmosphere, and the 'boiling-' or subliming-point does depend—though indirectly—on the atmospheric pressure.

But if the substance be made to vaporise in the open air, or in such a manner that the rapid diffusion of the vapour prevents the complete expulsion of the air from the immediate neighbourhood of the substance, then the 'boiling-' or subliming-point does not depend on the atmospheric pressure.

Thus water, when distilled in the ordinary way under a pressure of 15 mm., boils at about 18°, but Schrötter observed in 1853 (Annalen, 88, 188) that when some water was placed on a shallow clock glass, supported by a short tripod on a second clock glass, in a bell-jar over sulphuric acid, the temperature fell to −3° when the pressure was reduced to 15 mm. More rapid diffusion and removal of vapour was effected by suspending in the bell-jar a thermometer the bulb of which was covered with a sponge soaked in water; in this case, under a pressure of 40 mm., at which the 'boiling-point' of water under ordinary conditions is 34°, the temperature fell to −10°.

The following experiments afford a still more striking proof of the correctness of the statement that the 'boiling-point' does not necessarily depend on the atmospheric pressure. A copper air-bath was heated to 205° and a thermometer, the bulb of which was covered with cotton wool and moistened with boiling water, was suspended in the bath through an opening at the top. The pressure of the atmosphere was 748 mm., and the water on the cotton wool was in a strongly-heated chamber, yet the temperature, instead of remaining at nearly 100°, fell to 66°, and remained constant at this point while the water rapidly evaporated. A second experiment was carried out under the same conditions, except that steam was introduced, so as to replace the air as completely as possible by aqueous vapour. The temperature of the bath was in this case 195°, and the steam was passed into it after the temperature of the water on the thermometer bulb had fallen to 69°; the result was an immediate rise of temperature, the highest point reached being 99°. A fall of temperature to 80° was again observed on allowing some of the steam to escape.

In these cases the 'boiling-point' certainly does not depend on the pressure of the surrounding atmosphere, and in all probability the observation that the temperature of a drop of water in the spheroidal state does not reach 100° (under normal atmospheric pressure) may be explained in the same way, the vapour round the drop of water being always diluted with a certain amount of air. Again, by passing a current of air through water or any other liquid boiling in an ordinary distillation bulb, the vapour above the liquid becomes diluted, and the result is an immediate fall in temperature, both of the liquid and of the vapour, although the liquid continues to distil rapidly, and this is the case even when heated air is introduced.

Thus by bringing about admixture of air with the vapour surrounding a vaporising substance the same effect is produced as by reducing the pressure in an ordinary distillation bulb, and in this way, in certain cases, the partial pressure of the vapour may be reduced below the triple-point pressure, so that the substance which in a bulb or test-tube would melt first and then boil, will under these circumstances sublime at a temperature below the melting-point. If the bulb of a thermometer, by repeated immersion in melted camphor, be completely covered by the solid substance, and if the thermometer be then suspended in a strongly-heated air-bath through which a moderate current of air is passing, the camphor will not melt, but will sublime at a temperature lower than its melting-point, although the total pressure is far above the triple-point pressure of camphor.

The slow volatilisation of camphor, iodine, snow, and other substances is to be explained in precisely the same way, vaporisation always taking place when the partial pressure of the vapour in the surrounding air is less than the vapour pressure of the solid substance.

Again, if the vapour of a substance which is solid at the ordinary temperature condense in the narrow neck of a retort or distillation bulb, the liquid state is first as a rule assumed, and solidification afterwards takes place; but if the same vapour be allowed to diffuse into the air, or if by any means sufficient air be mixed with it before condensation occurs, it frequently happens that the solid state is at once assumed without intermediate passage through the liquid state. This direct passage from the gaseous to the solid state must, in fact, occur if by admixture with any indifferent gas the partial pressure of the heated vapour falls below the triple-point pressure before the temperature falls sufficiently for condensation to take place.

Thus on boiling sulphur in an ordinary retort, while the vapour is rising and before the air has been expelled, the formation of small quantities of flowers of sulphur is always to be observed above the vapour; but when the air has been expelled and the sulphur vapour condenses in the neck of the retort, liquid is formed. When, however, as in the formation of flowers of sulphur on the large scale, the heated vapour is passed into a large chamber containing air, direct condensation to the solid state occurs until the temperature of the chamber reaches the point at which the partial pressure of the sulphur vapour is higher than the triple-point pressure, when liquefaction takes place.

The phenomenon is still more readily observed in the case of camphor, iodine, and other substances, the triple-point pressures of which are relatively high. Thus if we heat one of these substances in a porcelain basin and hold a cold glass funnel or a glass plate over it, the substance melts and boils in the basin, but condenses as a solid on the funnel or plate. The heavy vapour collects in the basin, so that its partial pressure in the atmosphere surrounding the substance soon rises above the triple-point pressure, when fusion takes place; but before reaching the cold glass surface the hot vapour becomes so diluted with air that the partial pressure falls below the triple-point pressure, so that when condensation takes place the solid state is at once assumed. In the purification of crude anthracene by passing steam, heated to about 230°, over the melted substance, and condensing the vapour in a chamber by jets of cold water, the steam acts as an indifferent gas, and in all probability the partial pressure of the anthracene vapour is far below the triple-point pressure when condensation takes place.

So also when condensation of moisture from the atmosphere occurs at a temperature below 0°, and when the partial pressure of the aqueous vapour is necessarily lower than 4·6 mm., there must be direct passage from the gaseous to the solid state, and the light crystalline snow flakes present all the appearance of having been formed in this way.

Although the process of sublimation is in theory quite analogous to that of distillation, yet the apparatus employed for distillation is unsuited for sublimation, for the narrow condensing tubes would rapidly become blocked by the solid sublimate. In cases of true sublimation, therefore, and also in the distillation of liquids with high solidifying points—such as anthracene, camphor, iodine, &c.—the condensing tube must be wide and comparatively short, as in the Silesian subliming pots for arsenic trioxide (*v.* ARSENIC) and in the condensers employed for the manufacture of iodine (*v.* IODINE).

The condensing tube may, indeed, be replaced by a simple flat or concave cover over the subliming pot, as in the case of ammonium chloride (Fig. 2).

The ammonium chloride is heated in the pots, and condenses in the solid state on the iron covers.

(It is true that in this case the process, under ordinary conditions, is not one of simple sublimation, since the vapour does not consist of ammonium chloride, but of a mixture of ammonia and hydrogen chloride; there is really dissociation and recombination instead of vaporisation and condensation, but practically the process is the same as that of sublimation.) It has been observed, however, by H. B. Baker (Chem. Soc. Trans. 65, 615; 73, 422) that ammonia will not combine with hydrogen chloride when both gases are very carefully dried, and that dry ammonium chloride does not undergo dissociation when converted into vapour. Johnson (Zeitsch. physikal. Chem. 61, 457) has made the remarkable observation that the vapour pressures of ammonium chloride are practically the same whether the solid is carefully dried and therefore stable or imperfectly dried and subject to dissociation.

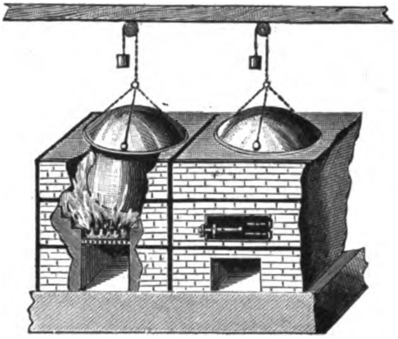

FIG. 2.

It frequently happens that when direct condensation to the solid state takes place, the substance assumes the form of a fine light crystalline powder, or of feathery flakes which are easily carried about by currents of air; hence longer flues or a succession of condensing chambers are required to prevent loss of substance. This is especially the case with such poisonous substances as arsenic or arsenic trioxide, and the condensing tubes attached to the Silesian subliming pots already referred to are supplemented by condensing chambers.

If the sublimation does not take place from a retort or pot, but from a furnace through which the hot gases pass as well as the vapour of the subliming substance, the light sublimate is very liable to be carried away, and the flues must be very long or the chambers very numerous (*v.* ARSENIC). S. Y.

SUCCINIC ACID $C_4H_6O_4$. Succinic acid and its alkyl derivatives when heated, break down into anhydrides and water. The anhydride formation takes place more readily as the hydrogen atoms of the ethylene residue of succinic acid are replaced by alkyl groups (Auwers and Meyer, Ber. 1890, 101). The alkyl succinic acids form anhydrides more readily with acetyl chloride and are more volatile in steam than their isomeric alkyl-*n*-glutaric acids (Auwers, Annalen, 285, 212) Anilic acids are produced by adding amines to the anhydride in chloroform, ether or benzene, and these on treatment with acetyl chloride or phosphorus pentachloride or by the action of heat alone yield anils.

Literature. Alkyl succinic acids, Bischoff, Ber. 1891, 1064 *et seq.*; 1890, 631; Auwers. Annalen, 285, 212; 292, 132, 152; 298, 147 *et seq.*; Bone, Chem. Soc. Lincei. 1894, i. 515; Koller, Ber. 1904, 1598. *Esters*, Bone, Sudborough and Sprankling, Chem. Soc. Trans. 1904, 534.

Succinic acid (*Bernsteinsaüre*)

$$CO_2H{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H.$$

Occurs in amber (*v.* RESINS), fossil wood, and lignite (Reich, J. 1847–48, 499); in unripe grapes (Brunner and Brandenburg, Ber. 1876, 982); in various plants; in ripe wheat and barley grains (Vaudin, Ann. Agron. 1897, 23, 232); in the wood of *Goupia tomentosa* (Aubl.) (Dunstan and Henry, Chem. Soc. Trans. 1898, 228); in the juice of the sugar cane and in the calcium precipitate formed during the treatment of beet juice (Lippmann, Ber. 1891, 3299); in *Orites excelsa* (R.Br.) and other proteaceous trees as aluminium succinate (Smith, Chem. News, 88, 135); in the castor oil plant (Gram, Chem. Zentr. 1903, ii. 450); in the urine of oxen, horses, goats, and rabbits; in meat extracts (Kutscher and Steudel, Zeitsch. physiol. Chem. 38, 101; Baur and Barschall, Chem. Zentr. 1906, ii. 1351); in putrified meat (Wolff, Beitr. Chem. physiol. Path. 1903, 4, 254; Siegfried, Ber. 1895, 515). According to Helm (Arch. Pharm. 1895, 233, 191), *succinite* (ordinary amber) contains succinic acid, but *gedanite* does not. Succinic acid is formed during various processes of fermentation. The succinic acid ferment is the name given to the microbe which develops in solutions of ammonium tartrate and nutritive salts, converting them into the ammonium salts of carbonic, acetic, formic, and especially succinic acids. It is of no danger to the sugar manufacturers as their operations require a temperature of 60°, which kills it (Teixeira, Bied. Zentr. 1885, 493). In the fermentation of sugar by yeast, succinic acid is produced. It is formed not from the sugar, but by autolytic fermentation of the protein substance in the yeast cells, whereby glutamic acid is produced, and the latter is then converted into succinic acid (Kunz, J. Soc. Chem. Ind. 1907, 108; Ehrlich, Biochem. Zeitsch. 18, 391; Effront, Compt. rend. 119, 92). It is also formed by the bacteriological fermentation of asparagine (Neuberg and Cappezzuoli, Biochem. Zeitsch. 18, 424); and the schizomycetic fermentation of malic acid through *Bacillus lactis aërogenes* or of tartaric acid through *Bacterium termo* (Emmerling, Ber. 1899, 1915; König, *ibid.* 1881, 211). Succinic acid is formed by the oxidation of fats (Bouveault, Bull. Soc. chim. 19, [iii.] 562), of stearic acid (Bromeis, Annalen, 35, 90; 37, 292), Japanese wax (Sthamer, *ibid.* 43, 346), beeswax (Ronalds, *ibid.* 43, 356), spermaceti (Radcliff, *ibid.* 43, 351), sebacic and azelaic acids (Arppe, *ibid.* 95, 242; J. 1864, 377), camphor (Bredt, Ber. 1894, 2093), and of camphene (Marsh and Gardner, Chem. Soc. Trans. 1896, 84). Harries (Ber. 1904, 2708) has obtained succinic acid from rubber through fission with ozone. For methods of separating and purifying succinic acid from the commonly occurring organic acids *v.* Schoorl, Zeitsch. angew. Chem. 1900, 367.

Succinic acid is prepared by the reduction of malic or tartaric acids with hydriodic acid (Schmitt, Annalen, 114, 106; Dessaignes, *ibid.* 115, 120); of fumaric and maleic acid with sodium amalgam (Kekulé, *ibid.* Spl. 1, 133) or with colloidal platinum (Paal and Gerum, Ber. 1908, 2273); by treating ethylene cyanide with acids or alkalis (Simpson, Annalen, 118, 375); by treating the ethyl ester of β-chloropropionic acid with potassium cyanide and hydrolysing the ester thus formed (Wichelhaus, Zeitsch. Chem. 1867, 247); by heating ethylenetricarboxylic acid at 160° (Bischoff, Ber. 1880, 2162); by reducing acetylenedicarboxylic acid with sodium amalgam (Bandrowsk, *ibid.* 1879, 2212); by the hydrolysis of ethyl ethylenetricarboxylate, obtained by the action of ethylsodiomalonate on ethylchloracetate (Bischoff and Kuhlberg, *ibid.* 1890, 634); by melting gum arabic, milk sugar (Hlasiwetz and Barth, Annalen, 138, 76) or carminic acid (Hlasiwetz and Grabowski, *ibid.* 141, 340) with caustic alkali; by treating bromacetic acid with silver powder at 130° (Steiner, Ber. 1874, 184); by the electrolysis of the potassium salt of the monoethyl ester of malonic acid and subsequent hydrolysis of the diethylester thus formed (Brown and Walker, Annalen, 261, 115); by oxidising aldehydopropionic acid with nitric acid (Perkin and Sprankling, Chem. Soc. Trans. 1899, 16); by treating the semi-aldehyde of maleic acid with sodium carbonate and potassium cyanide (Fecht, Ber. 1905, 1272); by condensing sodium ethylcyanacetate with formaldehydecyanhydrin and hydrolysing the product (Higson and Thorpe, Chem. Soc. Trans. 1906, 1460); by oxidising glutamic acid with hydrogen peroxide (Daking, J. Biol. Chem. 5, 409); by oxidising furfural with Caro's acid (Cross, Bevan, and Briggs, Ber. 1900, 3132); by treating pyrrole with potassium hydroxide and hydroxylamine whereby the dioxime of succinic acid results (Zanetti, Atti. R. Accad. Lincei. 1891, i. 344).

Properties. Succinic acid crystallises in colourless monoclinic columns; melts at 182·7° (Reissert, Ber. 1890, 2244), at 185° (corr.) (Davidoff, *ibid.* 1886, 407), and boils at 261° (Krafft and Noerdlinger, *ibid.* 1889, 816), at 278·3° (corr.) (Bischoff and Kuhlberg, *ibid.* 1890, 634), and by heating strongly is converted into succinic anhydride: sp.gr. 1·554 (Tanatar and Tschelebieff, J. Russ. Phys. Chem. Soc. 1892, 22, 549), 1·562 (Marshall and Cameron, Chem. Soc. Trans. 1907, 1522). Solubility in water (Lamouroux, Compt. rend. 128, 998): 100 c.c. dissolve—

Temp.	0°	15°	20°	35°	50°	65°
Grms. acid	2·79	4·9	5·8	10·6	18·0	28·1

or, according to Marshall and Cameron (Chem.

Soc. Trans. 1907, 1522), 100 grms. of water dissolve—

Temp.	0°	20°	25°	40°
Grms. acid	2·77	6·84	8·59	14·86

At 15°, 100 parts of dry ether dissolve 1·193 parts, 96 p.c. alcohol 9·986 parts, methyl alcohol 15·73 parts and acetone 5·544 parts of succinic acid (Rau, Zeitsch. anal. Chem. 32, 483).

By heating succinic acid to a high temperature, it decomposes into carbon dioxide and water (de Coninck, Bull. Acad. Roy. Belgique, 1903, 633); heating with glycerol gives rise to acrolein and some acrylic acid (de Coninck and Raynaud, Compt. rend. 135, 1351), and fusing with caustic alkali decomposes it into oxalic and acetic acids. By the distillation of the dry calcium salt, diketohexamethylene is obtained in small quantity (Feist, Ber. 1895, 738), and also *cyclo*pentanone and furfuran (Metzner and Vorländer, *ibid.* 1897, 1885). Hanriot (Compt. rend. 101, 1156) states that by distilling the acid with excess of quicklime, ethane and carbon dioxide are obtained. By the electrolysis of a solution of the potassium salt, ethylene and carbon dioxide are the chief products (Petersen, Chem. Zentr. 1897, ii. 519). In acid solution, succinic acid is scarcely acted on by potassium permanganate (Perdrix, Bull. Soc. chim. 23, [iii.] 645); electrolytic oxidation converts it into tartaric and oxalic acids, carbon monoxide and dioxide, methane and ethylene (Clarke and Smith, J. Amer. Chem. Soc. 1899, 967), whilst hydrogen peroxide yields tartaric acid (Zinns, Mon. Scient. 16, ii. 493). Fittig and his co-workers have studied the condensations of aldehydes and sodium succinate in the presence of acetic anhydride. Acetaldehyde and its higher homologues, chloral and benzaldehyde, yield substituted paraconic acids (Annalen, 255, 18, 43, 56, 68, 96, 97, 142; Stobbe and Kloeppel, Ber. 1894, 2407), salicylaldehyde yields dicoumarin (Fittig and Politis, Annalen, 255, 275), anisaldehyde and cinnamaldehyde yield substituted *iso*crotonic acids (Fittig, *ibid.* 255, 293; 331, 151), whilst furfuraldehyde yields αγ-difurfurylidenepropionic acid and difurfurylidenesuccinic anhydride (Titherley and Spencer, Chem. Soc. Trans. 1904, 183; *v.* also Fichter and Scheuermann, Ber. 1901, 1626). Stobbe has studied the condensations which ethyl succinate undergoes with ketones in the presence of sodium methoxide. In this way γγ-disubstituted itaconic acids and γ-alkylenepyrotartaric acids are produced, the latter chiefly from ketones which contain a methylene group near the carbonyl group, and the former from ketones not containing a methylene group. Condensations have been effected with benzophenone, benzil, benzoin, cyclic ketones, &c. (Stobbe, Annalen, 308, 67 *et seq*; 314, 111; 321, 94, 105; Ber. 1895, 1122, 3192; 1899, 3354; 1904, 2232). The esters of succinic and cinnamic acids condense to form β-phenylbutane-αγδ-tricarboxylic acid (Stobbe and Fischer, Annalen, 315, 232), whilst ethylsuccinate condenses with valerolactone in the presence of sodium methoxide to form valactenesuccinic anhydride and valactenepropionic acid (Fittig, Salomon and Wernher, *ibid.* 331, 191). By heating succinic acid, acetic anhydride, anhydrous sodium acetate and zinc chloride, and distilling the residue in steam furfurane is obtained (Magnanini and Bentivoglio, Gazz. chim. ital. 24, i. 433), and on distillation of sodium succinate with phosphorus pentasulphide, thiophene is obtained. A mixture of mono- and dibromo-succinic acids is obtained by heating succinic acid, phosphorus and bromine in a sealed tube (Gorodetzky and Hell, Ber. 1888, 1730; Volhard, Annalen, 242, 141; Auwers and Imhaüser, Ber. 1891, 2233). By heating barium succinate with sodium methoxide, propionic acid is produced (Mai, *ibid.* 1889, 2136; *v.* also Kolbe, Annalen, 119, 173), and by heating the ethyl ester at 400° with alumina, tetrahydroquinone is produced (Bull. Soc. chim. [iv.] 5, 480). Ethyl succinate reacts with alkyl iodides in the presence of zinc to form γγ-dialkylbutyrolactones (Kasansky, Chem. Soc. Abstr. 1904, i. 367); with magnesium phenyl bromide to form tetraphenyltetramethylene oxide (Acree, Amer. Chem. J. 1905, 33, 180); and with hydroxylamine hydrochloride and sodium hydroxide and subsequent treatment with acetic anhydride to form succinylhydroxamic acid (Hantzsch and Urbahn, Ber. 1895, 74). Electrolysis of molecular proportions of ethyl succinate and ethyl malonate gives rise to glutaric and adipic acids (Vamzetti and Coppadoro, Atti. R. Accad. Lincei. 1903, 12, ii. 209).

Succinic acid is used as a standard in alkalimetry, acidimetry and iodimetry (Phelps, Hubbard and Weed, Amer. J. Sci. 23, 211; 24, 194; 26, 143). For this purpose the acid is prepared by the hydrolysis of the pure ester, obtained by passing alcohol vapour charged with pure hydrogen chloride into a mixture of succinic acid, alcohol and hydrogen chloride, together with the addition of a little pure fused zinc chloride, and distilling continuously at 100°–110°; *v.* also ACIDIMETRY and ALKALIMETRY. The succinates of the rare earths of the yttrium group are of importance, as it is by their fractional crystallisation that these elements are separated from each other (Lenher, J. Amer. Chem. Soc. 30, 572).

Detection and Estimation. Succinic acid does not char on the addition of sulphuric acid in the cold, but on warming darkens, sulphur dioxide being evolved. Silver nitrate gives a white precipitate in neutral solutions, soluble in ammonia; calcium chloride, a white precipitate on standing; and ferric chloride, a yellowish-brown precipitate; *v.* also Neuberg, Zeitsch. physiol. Chem. 31, 574. Succinic acid may be estimated in the presence of tartaric and lactic acids by the method of Bordas, Joulin and Raczkowski (J. Pharm. Chim. 1898, 7, 417; Chem. News, 78, 18). The solution containing the acids is exactly neutralised with N/10 potassium hydroxide, excess of silver nitrate solution is added, and the precipitate washed until the filtrate no longer gives a precipitate with potassium chromate. The precipitate, which consists of silver succinate, is washed back into the flask with water, one or two drops of potassium chromate solution added, and then sodium chloride solution is run in until the red colour disappears. The solution is then titrated back with N/10 silver nitrate solution (*v.* also Makowka, Chem. Zentr. 1908, i. 2207). ***Estimation in presence of citric and tartaric acids***, *v.* Micko, Zeitsch. anal. Chem. 31, 465. ***Estimation in plants***, *v.* Jörgensen, Chem. Zentr.

Salts. $KHC_4H_4O_4,2H_2O$; $KHC_4H_4O_4$; $KH_3(C_4H_4O_4)_2$ (Marshall and Cameron, Chem. Soc. Trans. 1907, 1514); $NaHC_4H_4O_4$; $Na_2C_4H_4O_4,6H_2O$ (Rammelsberg, J. 1855, 467; Minio, Zeit. Kryst. 31, 415);

$$CaC_4H_4O_4,H_2O;\ CaC_4H_4O_4,3H_2O$$

(Milojkovic, Monatsh. 14, 699); salts of the rare earths (Meyer, Zeitsch. anorg. Chem. 33, 31. 113; Morgan and Cahen, Pharm. J. 24, [iv.] 428; Tanatar and Kurowski, J. Russ. Phys. Chem. Soc. 39, 936); double potassium salts (Reynolds, Chem. Soc. Trans. 1898, 701). Solubilities of salts of succinic acid, *v.* Partheil, Arch. Pharm. 241, 412; Cantoni and Diotalevi, Bull. Soc. chim. [iii.] 33, 27.

Esters. The *dimethyl ester* is a crystalline solid, m.p. 19°; b.p. 195·3° (corr.); sp.gr. 1·1207 at 20°/4° (Emery, Ber. 1889, 3185). It may be prepared by the interaction of methyl bromacetate and magnesium (Spencer and Crewsdon, Chem. Soc. Trans. 1908, 1826). The *diethyl ester* is a liquid, b.p. 216·5° (corr.), sp.gr. 1·04645 at 15°/ (Perkin, *ibid.* 1884, 515). For preparation, *v. supra* (Phelps and Hubbard). *Ethylene ester,* m.p. 88°–90°; sp.gr. 1·345 at 17°/. Prepared from succinic acid and glycol or from ethylene dibromide and silver succinate (Vorländer, Annalen, 280, 177). *Aryl esters, v.* Bischoff and Hedenström, Ber. 1902, 4073 *et seq.* *Isobornyl ester, v.* Beckmann, *ibid.* 1907, 485. *Menthyl ester, v.* Hilditch, Chem. Soc. Trans. 1909, 1580. *Sanatyl esters, v.* Riedel, D. R. P. 208637; Chem. Zentr. 1909, i. 1442; Kalle and Co., D. R. P. 201639; Chem. Zentr. 1908, ii. 994.

Succinyl chloride $C_4H_4O_2Cl_2$. Prepared from succinic acid and phosphorus pentachloride (Gerhardt and Chiozza, Annalen, 87, 293; Möller, J. pr. Chem. [ii.] 22, 208); m.p. 16°–17°, b.p. 190°–192° (corr.) (Vörlander, Annalen, 280, 183; Perkin, Chem. Soc. Trans. 1888, 563). It is probably a mixture of symmetrical and asymmetrical compounds (Vorländer, Ber. 1897, 2268; Meyer and Marx, *ibid.* 1908, 2459).

Succinic anhydride  $\begin{array}{l}CH_2\cdot C:O\\ |\\ CH_2\cdot C:O\end{array}\!\!>O$. Prepared by heating the acid alone or with phosphorus pentoxide, acetyl chloride, acetic anhydride or benzoyl chloride (Gerhardt and Chiozza, Annalen, 87, 293; Blaise, Bull. Soc. chim. [iii.] 21, 643; Anschütz, Ber. 1877, 1833; Schulz, *ibid.* 1885, 2459); by treating the acid with phosphorus pentoxide in toluene solution (Bakunin, Gazz. chim. ital. 30, ii. 340); by treating sodium succinate in neutral or feebly alkaline solution with acetic anhydride (Oddo and Manuelli, *ibid.* 26, ii. 482). White solid, m.p. 119·6°; b.p. 261°; sp.gr. 1·1036 at 20°/4°: purified by recrystallisation from chloroform (Negri, *ibid.* 26, i. 77). Hydroxylamine hydrochloride reacts with the anhydride to form succinylhydroxamic acid which may be isolated by means of its barium salt (Errera, *ibid.* 25, ii. 25). Pyrogallol condenses with the anhydride to give pyrogallolsuccinin, a dyestuff giving reddish-brown shades with alumina mordants (Georgievics, Monatsh. 20, 450); hydroquinone undergoes a similar condensation (Meyer and Witte, Ber. 1908, 2457). Reduction with sodium amalgam and hydrochloric acid yields butyrolactone. Succinic anhydride condenses with *m*-aminophenols to form succinin-dyestuffs which are similar to the rhodamines (Bayer and Co., D. R. P. 51983; Frdl. ii. 86); with 1·8-naphthylenediamine it yields a dyestuff, green in acid solution (Bayer and Co., D. R. P. 202354; Chem. Zentr. 1908, ii. 1397) (*v.* TRIPHENYLMETHANE COLOURING MATTERS).

Succinic peroxide $C_4H_4O_4$ and *persuccinic acid* are formed by the action of hydrogen peroxide on the anhydride (Clove and Houghton, Amer. Chem. J. 1904, 32, 43; *v.* also Vanino and Thiele, Ber. 1896, 1724).

Succinimide. Prepared by heating succinic acid with ethylene cyanide (König, J. pr. Chem. 69, [ii.] 1; Miller, J. Amer. Chem. Soc. 16, 433); by distilling ammonium acetate (Landsberg, Annalen, 215, 173); by the interaction of succinonitrile and benzoic acid (Matthews, J. Amer. Chem. Soc. 1898, 650); by the partial hydrolysis of succinonitrile with sulphuric acid (Bogert and Eccles, *ibid.* 1902, 20); by heating acetonitrile with succinic acid (Miller, *l.c.*); by the action of ammonia on succinic anhydride (D'Arcet, Annalen, 16, 215); by distilling a mixture of succinic anhydride and carbimide (Dunlap, J. Amer. Chem. Soc. 18, 332); m.p. 125°–126°; b.p. 287°–288° (Menschutkin, Annalen, 162, 166). Phosphorus pentachloride reacts with succinimide to form tetrachloropyrrole, which is converted into pyrrole by treatment with zinc-dust and caustic potash (Ciamician and Silber, Ber. 1883, 2398). By electrolytic reduction in sulphuric acid, pyrrolidine is produced (Tafel and Stern, *ibid.* 1900, 2224; Zeitsch. physikal. Chem. 54, 443), whilst electrolysis of an aqueous solution yields succinic acid and ammonia (Pannain, Gazz. chim. ital. 35, ii. 94). Reduction with sodium amalgam and hydrochloric acid yields butyrolactone (Fichter and Herbrand, Ber. 1896, 1192); ammonia gas converts succinimide at −10° into succinamide (Roubtzoff, Chem. Soc. Abstr. 1886, 141); potassium hypobromite converts it into β-aminopropionic acid (Hoogewerff and van Dorp, Rec. trav. chim. 10, 4). Crystalline compounds with phenols (*ibid.* 1900, 19, 32); compound of silver succinimide with hexamethylenetetramine (D. R. P. 217897; Chem. Zentr. 1910, i. 701). The hydrogen atom of the imino group is capable of replacement by metals and organic radicles. For substituted alkyl succinimides *v.* Meister, Lucius and Bruning, Eng. Pats. 15327, 15328; J. Soc. Chem. Ind. 1894, 800. The metallic derivatives of succinimide are of importance as when dissolved in water and warmed, colloidal solutions of the metallic oxides are obtained in many cases. *Copper succinimide* (Tschugaeff, Ber. 1905, 2899; Ley, *ibid.* 1905, 2199; Ley and Werner, *ibid.* 1906, 2177). *Silver succinimide* (Ley and Schaeffer, *ibid.* 1906, 1259).

Nickel succinimide (Tschugaeff, *ibid.* 1906, 3190). Complex metallic derivatives (Tschugaeff, *ibid.* 1907, 1973).

Succinanil and **Succinanilide** *v.* Dunlap and Cummer, J. Amer. Chem. Soc. 25, 612.

Succinamide, m.p. 242°–243°, *v.* Henry, J. 1885, 1333.

Aminosuccinic acid *v.* ASPARAGINE.

***iso*Succinic acid.** *Methylmalonic acid*

$CH_3{\cdot}CH(CO_2H)_2$.

Prepared by treating *a*-cyanopropionic acid with potash (Wichelhaus, Zeitsch. Chem. 1867, 247); by the action of potassium cyanide on the potassium salt of *a*-bromopropionic acid (Lassar Cohn, Annalen, 251, 349) or on ethyl *a*-brompropionate (Pusch, Arch. Pharm. 232, 186; Byk, J. pr. Chem. ii. 1, 19); by the dry distillation of the esters of methyloxalacetic acid (Wislicenus and Kiesewetter, Ber. 1894, 796); by boiling silver cyanoform with water, isolating the nitrile and hydrolysing the latter with sodium hydroxide (Hantzsch and Osswald, *ibid.* 1899, 648).

Properties. Crystallises in colourless prisms, m.p. 135° (W. and K.); sp.gr. 1·455 (Tanatar and Tchelebieff, J. Russ. Phys. Chem. Soc. 22, 548); solubility in water (Massol and Lamouroux, Compt. rend. 128, 1000): 100 c.c. dissolve

Temp.	0°	25°	50°
Grms. acid	44·3	67·9	91·5

Readily soluble in alcohol, ether, and acetic acid. Electrolysis of an aqueous solution of the acid yields acetaldehyde, ethylene, carbon dioxide, carbon monoxide, oxygen and hydrogen (Petersen, Chem. Zentr. 1897, ii. 519; Zeitsch. physikal. Chem. 33, 698; *cf.* Lassar Cohn, Annalen, 251, 349). Potassium permanganate oxidises it to acetic acid, carbon dioxide and water (Perdrix, Bull. Soc. chim. iii. 23, 645); nitric acid converts it into carbon dioxide, acetic acid and trinitromethane (Franchimont, Rec. trav. chim. 5, 281). The potassium salt of the monomethylester yields on electrolysis the diethyl esters of the two symmetrical dimethylsuccinic acids (Brown and Walker, Annalen, 274, 42). Ethylsodiomethylmalonate condenses with ethyl *a*-bromobutyrate to form symmetrical methylethylsuccinic acid (Auwers, Annalen, 298, 147); with ethyl *a*-brom*iso*butyrate to form *aa*-dimethylglutaric and trimethylsuccinic acids (Auwers and Jackson, Ber. 1890, 1611; Bischoff, *ibid.* 1891, 1046; Auwers and Köbner, *ibid.* 1891, 1929); with ethyl *γ*-chlorobutyrate to form *a*-methyladipic acid and *β*-dimethylglutaric acid (Montemartini, *ibid.* 1896, 2058; Gazz. chim. ital. 26, ii. 259; *cf.* Bone and Sprankling, Chem. Soc. Trans. 1899, 849); with ethyl *β*-iodopropionate to form *a*-methylglutaric acid (Auwers and Titherley, Annalen, 292, 209); with ethyl-*a*-brom*iso*valerate in alcoholic solution to form *cis*-methyl*iso*propylsuccinic acid and in xylene solution to form a mixture of *cis*- and *trans*-methyl*iso*propylsuccinic acids (Bentley, Perkin and Thorpe, Chem. Soc. Trans. 1896, 270); with esters of unsaturated acids to form esters containing a four carbon atom ring (Michael, Ber. 1900, 3731; Svoboda, Monatsh. 1902, 842).

Dimethyl ester. Colourless liquid, b.p. 178°–179·5° (770 mm.).

Diethyl ester. Prepared from diethyl sodiomalonic ester and methyl iodide (Perkin, Chem. Soc. Trans. 1896, 1476; Michael, J. pr. Chem. ii. 72, 537); colourless liquid, b.p. 198·5°–199° at 765 mm. (corr.).

Methylmalonamide $CH_3{\cdot}CH{<}^{CONH_2}_{CONH_2}$. Prepared from malonamide, methyl iodide, sodium methoxide and methyl alcohol, or from methylmalonyl chloride and aqueous ammonia (Meyer and Bock, Annalen, 347, 104); m.p. 212° (Conrad and Schulze, Ber. 1909, 730). The *anilide* melts at 214° (Comanducci and Lobello, Chem. Soc. Abstr. 1905, i. 271; 1907, i. 409).

Amino-methylmalonic acid *v.* ASPARAGINE.

SUCCINITE *v.* AMBER.

SUCRAMINE. The ammonium salt of saccharin: known also as 'Lyons sugar.'

SUGAR (Fr. *sucre*; Ger. *Zucker*) is the generic name for a group of bodies belonging to the class of compounds known as carbohydrates, which occurs naturally in the vegetable or animal kingdom, or may, in some cases, be formed synthetically.

The sugars in general possess a more or less sweet taste, are crystallisable, are readily soluble in water, less soluble and in some cases insoluble in alcohol, and are insoluble in ether and similar solvents immiscible with water. They are optically active, *i.e.*, their solutions rotate the plane of polarised light to the right or left; whilst some precipitate cuprous oxide from Fehling's solution, an alkaline solution of cupric sodium tartrate. Another important property of some sugars is their behaviour towards phenylhydrazine, insoluble compounds being formed, a reaction which proves of much value in special cases of differentiation. Then certain of the sugars undergo alcoholic fermentation with yeast, and behave in a characteristic manner with mineral acids, both dilute and concentrated. Each individual member of the sugar group may be considered either as an aldehyde or as a ketone of hexatomic alcohols, the first being termed aldoses, and the latter ketoses. The sugars are divided into three groups: (1) Mono-saccharides, having the formula $C_6H_{12}O_6$, which may be further subdivided into bioses, trioses, hexoses, &c., according to the number of atoms of carbon they contain. This group includes dextrose (glucose, grape sugar, or starch sugar), mannose, galactose, lævulose (fructose, honey sugar, or fruit sugar), sorbose, arabinose, and xylose. (2) Di-saccharides, having the formula $C_{12}H_{22}O_{11}$ which may be considered as composed of two mono-saccharide residues, less a molecule of water. This group includes sucrose (cane sugar, saccharose, or crystallisable sugar), lactose (milk sugar), maltose and melibiose. (3) Tri-saccharides, which have the formula $C_{18}H_{32}O_{16}$, the best known member of which is raffinose (melitriose or gossypose) (*v.* CARBOHYDRATES).

Properties of sucrose, saccharose, or cane sugar.[1] The disaccharide sucrose crystallises

---

[1] So as to avoid confusion in the nomenclature of this article, it may be pointed out that 'cane sugar' implies the commercial product, whether it be obtained from the sugar cane or the sugar beet. 'Sucrose' is applied to the chemically pure body, the principal constituent of the commercial product. By the term 'reducing sugars' is meant a mixture of dextrose and lævulose in unequal proportions; while 'invert sugar' implies a mixture of the same two sugars, but in equal proportions.

from its pure aqueous solution in the monoclinic system. When pure it has a sp.gr. of 1·589 at 15°. It is freely soluble in water, in direct proportion to the temperature; a saturated aqueous solution at 15·5° contains 66 p.c. of sugar and has a sp.gr. of 1·326. It is sparingly soluble in absolute alcohol, its solubility in this medium increasing with the amount of water present. On very slowly evaporating an aqueous solution of sucrose, large crystals of 'sugar candy' are produced. The rapidity of crystallisation is influenced not only by the concentration and temperature of the solution, but also by the nature and amount of the foreign substances present, reducing sugars, certain salts, and organic non-sugar bodies having an inhibitive effect.

Sucrose rotates the plane of polarised light to the right, its specific rotatory power being $[\alpha]_D^{20^\circ}66{\cdot}5$. When heated alone it melts at 160°, but in presence even of traces of water it is decomposed at temperatures above 100°, when a dark-coloured mixture of various bodies collectively termed 'caramel' results. Treatment with dilute mineral acids, or with the enzyme *invertase*, hydrolyses sucrose to a mixture of equal parts of dextrose and lævulose (invert sugar), but if concentrated mineral acids be employed decomposition occurs. Sucrose is capable of uniting with alkalis and alkaline earths, to form sucrates or saccharates, the most important of which are the calcium, barium, and strontium compounds. The mono- and di-basic calcium saccharates are soluble in water, but the tri-basic compound is insoluble. On passing carbon dioxide slowly into a fine suspension of tri-basic calcium saccharate in water, the sucrose is liberated and calcium carbonate precipitated. With salts, such as the alkali chlorides and nitrates, sucrose also forms double compounds. On mixing sucrose with an alcoholic solution of α-naphthol in presence of sulphuric acid, a characteristic colour appears, a reaction that is extremely delicate, and for this reason much used for detecting traces of sugar in very dilute solution.

Occurrence of sucrose. Sucrose is found most abundantly in the sugar beetroot (*Beta vulgaris* [Linn.]), in the sugar cane (*Saccharum officinarum* [Linn.]), in sorghum (*Sorghum vulgare* [Pers.]), in maize (*Zea Mays* [Linn.]), in the maple (*Acer saccharinum* [Wangenh]), and in certain palms (such as *Caryotaurens Nipa fructicans*, *Borassus flabellifer* [Linn.], *Cocos nucifera* [Linn.], and *Avenga saccharifera* [Labill.]). It is also present in the sap of nearly all the higher plants; but only a few of these contain it in sufficiently large amount, and in a pure enough state to permit of its profitable extraction.

Production of sugar for consumption. The sugar consumed in civilised countries is obtained, almost entirely, from (1) the sugar beetroot, and (2) the sugar cane. A small proportion of the world's production of sugar is also derived from the maple and palm trees, and from sorghum. Whereas the sugar produced from the beetroot and the sugar cane is roughly 6,600,000 and 8,600,000 tons per annum respectively, or a total of 15,200,000 tons per annum, that from the maple and palm is only 500,000 and 150,000 tons per annum, or about 3 and 1 p.c. respectively of the total beet and cane production.

(1) **The sugar beetroot**. As now grown, the sugar beetroot (*Beta vulgaris*) is a hardy biennial plant, long under cultivation in France, Germany, Austria, Russia, Holland, Belgium, Norway, Sweden, Denmark, Italy, Spain, and more recently introduced into the United States, Canada, Australia, and New Zealand.

From the original Silician white beet, the Vilmorin and the Wanzleben types have been derived, and from these a great number of varieties, differing not only in the shape of the root but also in the form and size of the leaves, have been created by the different seed growers. Of these may be mentioned Wohanka's 'W.E.R.' and 'W.Z.R.'; Dippe's 'Best'; Aderstedter's 'A,' 'B,' and 'C'; and the various Désprez, Simon-Legrand, Knauer, and Jules-Roberts varieties.

In shape a good beet is rather long and conical (see Fig. 1); it is regular and not forked, and does not throw out 'fingers and toes.' Its flesh is firm, not very soft, and gives juice only under pressure, and its colour may be white, rose, or grey. In weight the beetroot, without its leaves, may vary between 1 and 2 lbs., according to the seed and the conditions of climate and cultivation.

FIG. 1.

By means of patient cultivation and selection, the sugar content of the beetroot has been raised during the past fifty years from 10 to 18 p.c.

(2) **The sugar cane.** The sugar cane is a kind of gigantic grass. It belongs to the natural order *Gramineæ*, the tribe *Andropogoneæ*, and the genus *Saccharum*. It may be divided into the roots; the stalk, which is made up of a series of joints or internodes (see Fig. 2); and the leaf, in which under the influence of chlorophyll and sunlight the starch is elaborated, to be afterwards transformed into sugar and stored in the stalk. According to the colour, the length and girth of the stalk, and the length of the internode, a great number of varieties are differentiated. Formerly much confusion in the nomenclature of different canes had arisen, but now the classification has, to some extent, been systematised by the work of the different experiment stations and botanical

gardens. Eckert and Deerr[1] have done much towards collating the literature of the subject, and have arranged the most important varieties of the sugar cane as follows: (1) The Otaheite (which is stated to be identical with the Bourbon, Lahaina, Louzier, Keni-keni, Portii, and Cuban); (2) Cheribon canes, including the Yellow Violet, Purple Violet, the Transparent or Ribbon cane, and the Tibboo Batavee of the Straits Settlements; (3) Tanna Canes, which may be striped, white, or black; and (4) the Salangore, Cavangerie, Uba and Bamboo canes. The sugar cane is essentially a tropical plant. It thrives to the greatest perfection in a warm climate that is moist, with moderate intervals of dry heat tempered by sea breezes. Rain is very necessary, though it may be replaced to a great extent by a rational system of irrigation. The propagation of the cane is usually effected by means of cuttings from the stalks, the upper joints nearest the leaves (the so-called 'cane tops') being mostly used for this purpose. From each eye or bud, a new plant is put forth, and these gradually form roots of their own, ultimately becoming independent of the parent cutting. Previous to 1885, it was believed that the sugar cane was incapable of producing fertile seeds; but shortly after Harrison and Bovell of Barbados demonstrated, not only that the sugar cane could produce fertile seeds, but also that from these seeds new varieties possessing superior qualities, as regards high sugar content and resistance to disease and drought, can be propagated by a system of selection. As to the chemical composition of the cane, considerable differences may occur according to the variety and the conditions of the soil and climate, but the limits are fairly represented by the following figures; sucrose, 11 to 16 p.c.; reducing sugars, 0·5 to 1·5 p.c.; fibre, 8 to 15 p.c.; organic non-sugar, 0·5 to 1·0 p.c.; and ash, 0·5 to 1·0 p.c. The reducing sugars consist of dextrose and lævulose, the former sugar generally predominating. Amongst the organic non-sugars are included (*a*) nitrogenous compounds as albumins, nucleins, albumoses, peptones, amines, amino acids, and (*b*) non-nitrogenous bodies, as cellulose, fat, wax, gum, chlorophyll, &c. In addition the following organic and inorganic acids and bases are found: malic, succinic, oxalic, glycollic, acetic, sulphuric, phosphoric and silicic acids; potash, soda, lime, magnesia, alumina, iron and manganese oxides.

FIG. 2.

Raw and refined sugars. In the manufacture of sugar from the beet or cane, 'raw sugar,' which may vary in colour from dark brown to pale yellow, according to its quality, is first produced in the factory; but before being put on the market for consumption, raw sugar is generally refined in the refinery or sugar-house, which usually is an establishment separate from the factory. Sometimes, however, sugars made in the factory are consumed directly, without being refined, as in the case of high-class beet and cane sugars, so-called 'direct consumption sugars,' or in that of 'moist' sugars, such as Demerara, having a distinctive cane flavour, or of 'plantation whites.'

In this article, an account will be given of: (*a*) the manufacture of raw beet sugar; (*b*) the manufacture of raw cane sugar; and (*c*) the refining of raw beet or cane sugar.

(*a*) MANUFACTURE OF RAW SUGAR FROM THE BEET.

Briefly stated, the operations involved in the manufacture of sugar from the beetroot are as follows: (1) extraction of the juice from the beetroot; (2) clarification of the juice; (3) concentration of the juice to syrup; (4) crystallisation of the sugar from the syrup; (5) separation of the crystals; and (6) treatment of the separated syrup and the working-up of the after-products.

Extraction of the juice from the beetroot. On arriving in the neighbourhood of the factory, the roots are placed in heaps or silos, to be there stored until they can be passed into manufacture. From the place of storage, they are transported along a hydraulic carrier, provided with stone and sand catchers, to the factory building, and raised by means of a bucket elevator to the washers (Fig. 3) to be cleansed from all adhering stones and mud. After washing, the beets are lifted to an upper floor of the building, usually by a bucket elevator, to the weighing machine, which may be either an ordinary scale, or, preferably, may be of the more modern automatic type, taking about 10 cwt. in each weighing. From the hopper of the weighing machine, the beets are directed into the slicer (Fig. 4), to be there cut up into fine, long shreds, technically known as

---

[1] Bulletin 26, Hawaiian Sugar Planters' Association.

'cossettes' 'slices,' or 'chips,' somewhat resembling vermicelli, in which form the extraction of the sugar is most readily effected.

In the early days of beetroot manufactured sugar, extraction of the juice was accomplished by submitting the rasped roots to hydraulic pressure, but now extraction is always carried out by means of a process of systematic lixiviation, so-called 'diffusion,' in a battery of 10 to 14 vessels termed 'diffusers' or 'cells,' arranged usually, in up-to-date factories, in a straight line, but sometimes in a circle. In shape, diffusers vary somewhat, but the general and approved type is that of a vertical cylinder, with top and bottom in the form of truncated cones (Fig. 5). Both top and bottom openings are provided with securely fitting covers, the top one being opened usually by turning to one side, while the bottom one is generally counterpoised, and provided with an hydraulic joint. At the side of each diffuser is the 'calorizator,' which re-heats the juice as it passes from one cell to another in the battery. The battery of diffusers is provided with suitable pipe connections, so that either water may be admitted to each vessel, or else the liquid contained in any vessel may be passed to its neighbour or drawn off when the operation is completed.

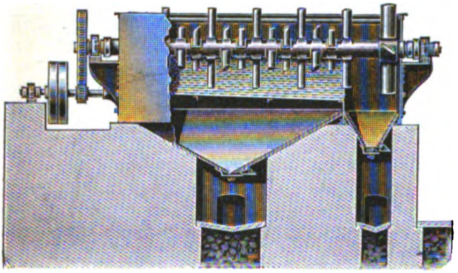

Fig. 3.

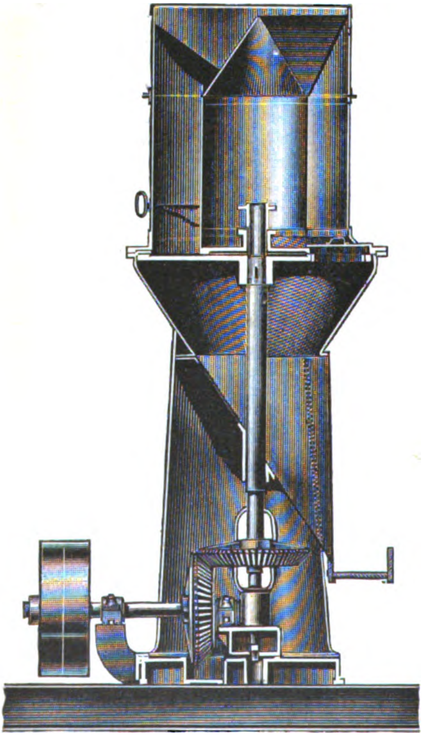

Fig. 4.

On commencing diffusion, the cossettes or slices or chips are conveyed from the slicers by a travelling band and directed by shoots into the top of the vessel to be filled, which is then securely closed. After filling the 10 or 14 diffusers with cossettes, hot water at 87°-90°C. from a tank situated at a convenient height is turned into the first diffuser, entering at the bottom, and rising up through the mass.

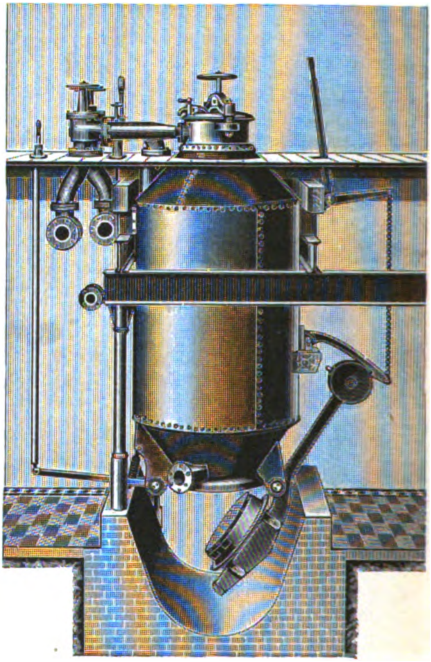

Fig. 5.

Dialysis of the soluble constituents in the cells of the cossettes, *i.e.* of sugar and certain mineral and organic non-sugar substances, now takes place through the cell-wall into the surrounding water. In cossettes there are, however, a certain number of ruptured and torn cells, usually from 6 to 7 p.c., so that during 'diffusion' the contents of these cells are simply dissolved by the water. After a few minutes, the liquid in the first diffuser, now a weak solution of sugar and non-sugar substances, is passed through the calorizator, in which it is heated, into the second vessel. From the second vessel, the liquid is sent through the calorizator into the third, and so on till it reaches a vessel, generally the sixth, in which dialysis practically ceases, the density of the juice in the cell being almost equal to that of the solution outside. After passing the sixth vessel, therefore, the solution termed 'diffusion juice' is sent to the storage tank to be ready for the next stage of manufacture, viz. clarification. Immediately the contents of the first diffuser are passed to the second, another lot of hot water at 87°–90° is run in, after which the same process is repeated, this liquid going through the several vessels, finishing, however, at the seventh instead of the sixth. This operation continues until the whole battery of diffusers is at work. After a time, the cossettes in the first diffuser are exhausted, at which stage the circuit is broken and the second diffuser becomes the first. From the diffuser out of circuit, the exhausted cossettes are discharged through the bottom opening, usually by means of compressed air. This vessel is again filled and placed in circuit, becoming the last member of the battery, the cycle of operations then going on continuously. As to the temperature to which the liquid is heated in the calorizator on passing from one diffuser to the next, and the time of treatment in the various diffusers, these vary, often considerably, in almost every factory, and depend largely on the plant and the nature of the cossettes being worked.

(2) *Clarification of the juice.* When the diffusion juice leaves the battery it is cloudy, contains some matter in suspension, and is more or less dark in colour. It has a density of 14°–17°Brix, and contains 12–15 p.c. of sugar, as well as the greater part of the soluble constituents of the beet, such as the potassium and sodium salts of phosphoric, sulphuric, hydrochloric, oxalic, and tartaric acids, proteins, pectins, &c., and a small amount of invert sugar. In reaction it is slightly acid.

In order to separate the suspended fibre, cellular tissue, and coagulated albumen, the juice is passed through a pulp-separator, which generally consists simply of a vertical cylinder containing a perforated sheet-iron basket, and from thence it goes through a juice-heater (Fig. 6). There it is heated to 75°–80°, which has the effect of coagulating a portion of the albumen present, besides preparing it for clarification.

In the beet sugar factory, clarification is always carried out in two stages: in the first, lime is added to the heated juice; and in the second the lime is removed by precipitation with carbon dioxide.

In the first stage, termed 'defecation,' or 'liming,' either dry caustic lime in powder, or else slaked lime in the form of milk at 20°Bé., may be used; and the addition is made in an ordinary tank provided with an agitator and steam coil, although it is sometimes carried out continuously in a special liming apparatus. Various views have been expressed on the relative merits of 'wet' and 'dry' defecation, but reliable investigations indicate that both yield equally satisfactory results, provided certain precautions are observed. Whichever method be used, the temperature should be at least 75°, and preferably 80°–85°, but not higher than 90°C., and the duration of contact between lime and juice should be from 5 to 10 minutes. As to the quantity of lime to be used, it may be stated that true defecation can be effected in the laboratory with only 0·5–0·75 p.c., on the weight of juice; but that this small amount is never feasible in practice, as juice thus treated can be filtered only with great difficulty. From 1·0–1·5 p.c. of lime may be used; but then it is necessary, especially when working roots that are not fresh or not fully ripe, to facilitate filtration by the addition of a little kieselguhr. In most factories, it is usual to add 2–3 p.c. of lime; and with this amount it is generally found that the juices are well defecated, light in colour, and filter readily, giving a good cake in the filter-presses.

Regarding the action of the lime on the diffusion juice, it may be pointed out that partial precipitation and partial decomposition of the non-sugar bodies occur. The free acid and acid salts present are neutralised; and insoluble salts formed with organic and inorganic acids, particularly oxalic and phosphoric acids, while potash, soda, and the organic bases present are liberated. Albumen is decomposed more or less completely, with the formation of albumoses, peptones, polypeptides, and amino acids; whilst the invert sugar is resolved into saccharic and lactic acids. In addition to its chemical effect, lime also acts mechanically, since it entrains particles and filaments of the root suspended in the juice.

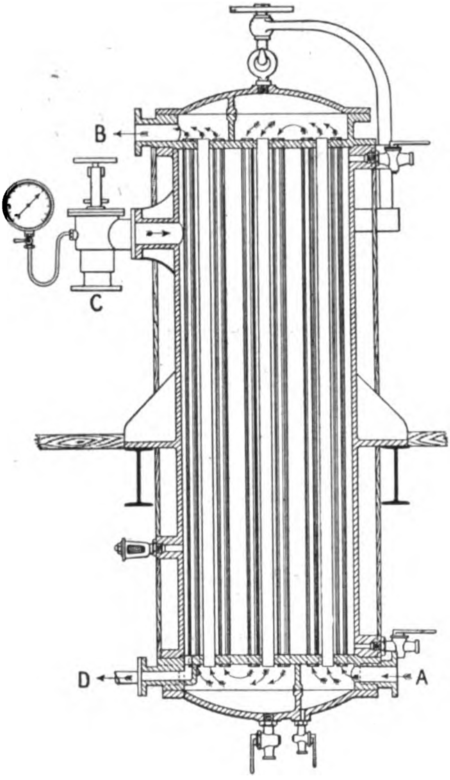

FIG. 6.

After liming, the juice is ready for the second stage of the clarifying process, namely 'carbonatation,' 'carbonation,' or 'saturation'; and for this purpose it is run into tanks, in which the treatment with carbon dioxide can be suitably effected. Carbonatation or saturation tanks may be circular or rectangular (Fig. 7), and are provided with steam coils for heating, and a special gas distributing apparatus designed to effect the best utilisation of the carbon dioxide during the operation.

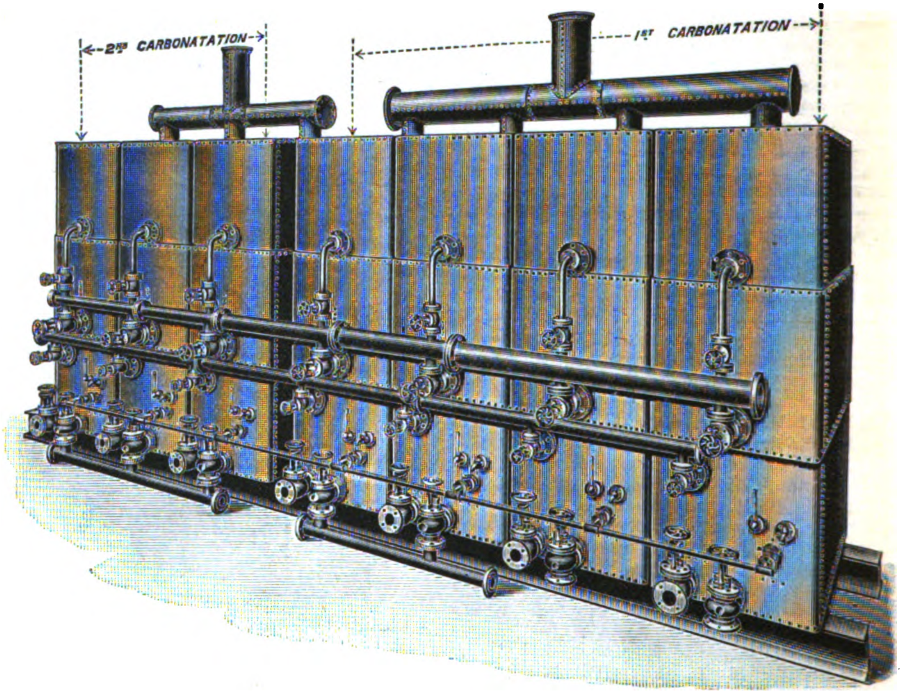

Fig. 7.

On passing the gas into the limed juice, at first there is formed a complex combination of calcium oxide, calcium sucrate, and calcium carbonate, the so-called 'sucro-carbonate of lime,' which is very gelatinous. As the operation proceeds, this body is gradually decomposed, finally with the formation of sugar and calcium carbonate. Saturation must be carefully carried out, and is continued until samples taken from time to time show that the precipitate, technically termed the 'scums,' is granular, and separates readily, leaving the supernatant liquid quite clear. Usually the gas is passed in

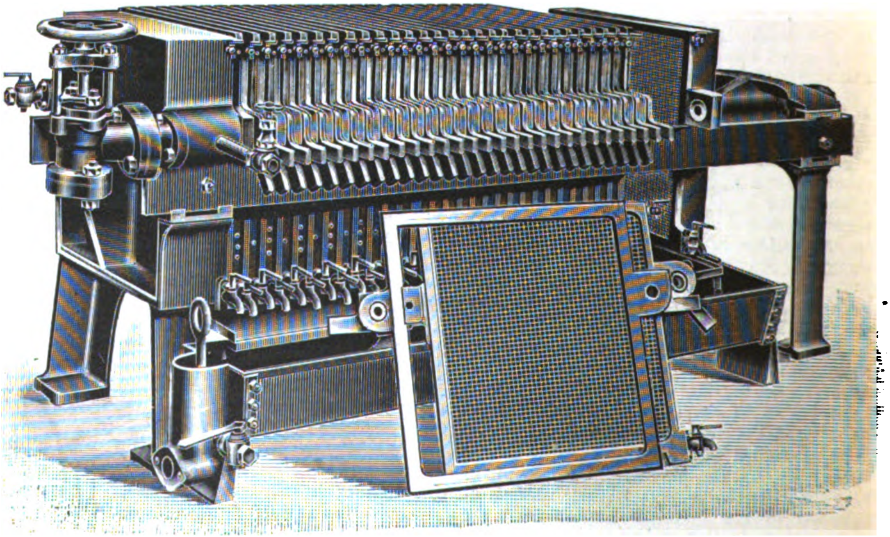

Fig. 8.

until the alkalinity on titration is about 0·1 p.c. calcium oxide, using phenolphthaleïn as indicator, but not longer, otherwise the precipitated impurities including some of the colouring bodies, commence to re-dissolve. In order to eliminate the remaining alkalinity, the 'first saturation juice,' after being passed through a filter-press (Fig. 8), must be submitted to the 'second saturation.' This is now nearly always carried out continuously, after sometimes adding a small amount of lime, about 0·5 p.c.; and generally in this operation both carbon dioxide and sulphur dioxide are used. If only carbon dioxide be used, a separate 'third saturation,' employing sulphur dioxide follows, but in any case the final alkalinity is reduced to 0·01–0·04 p.c. calcium oxide. Whether two or three saturations have been used, the juice obtained is filtered, often through presses as before, after which it is ready for evaporation to the state of syrup. It is therefore pumped up to the evaporator supply tank for this purpose.

It may here be pointed out that the saturation treatment has a slight effect in purifying the juice otherwise than by removing the lime added during defecation, since a small amount of mineral and organic matter is thrown down. As to the exact *rôle* of sulphur dioxide, continental authorities differ, but it is generally agreed that the juices are slightly decolorised, that lime salts unacted upon by the carbon dioxide are precipitated, that juice thus treated subsequently crystallises better owing to decreased viscosity, and finally that the sugar obtained keeps better on storage.

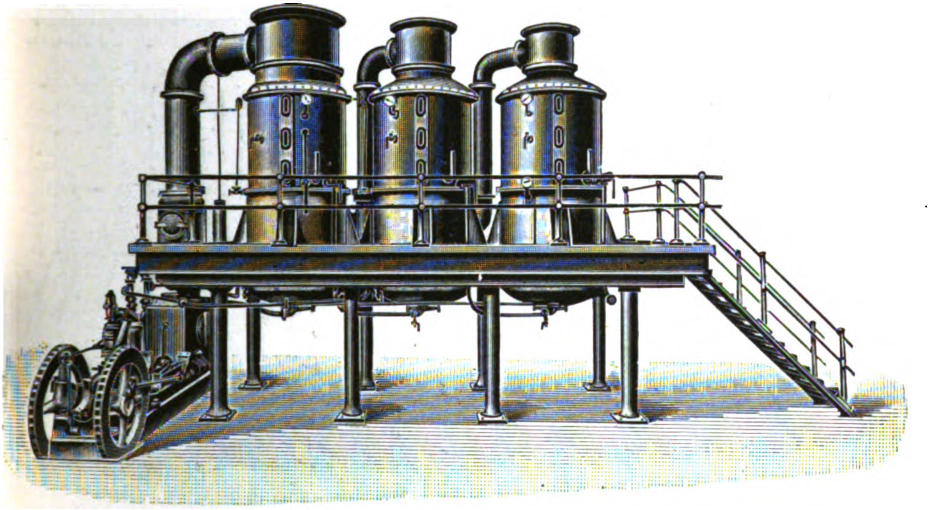

FIG. 9.

(3) *Concentration of the juice.* If the process of clarification has been well conducted, the juice should now be of a fine amber colour. Usually this 'thin-juice' has a density of 12°–13°Brix. It is next concentrated to a 'thick-juice' or syrup of 55°–60°Brix, about 80 p.c. of its water thus being removed.

This is done in one or other of the large number of multiple effect evaporators, which vary greatly in construction, and may be classified as follows: (1) the vertical, submerged tube type, the so-called 'Standard' system (Fig. 9), such as the Stillman, the Hagemann, or the Chapman evaporators; (2) the horizontal submerged tube type, such as the original Rillieux, and the Wellner-Jelinek evaporators; and (3) those of the film type, such as the Yaryan, the Lillie, and the Kestner (Fig. 10) evaporators.

It is now general to supply the first vessel of the multiple effect with exhaust steam. For heating purposes in other parts of the factory, such as the vacuum pans, the different juice and syrup heaters, or the calorizators of the diffusion battery, it is usual to take the necessary steam from one of the vessels of the triple or quadruple effect. Such an arrangement of utilising vapour is termed an 'extra steam' system.

In beetroot factories, in which the necessary amount of exhaust steam is not available for supplying the evaporators owing to centralisation of the motive power, and in which high pressure steam must consequently be used for other heating purposes, it is now becoming general to use a 'pre-evaporator' of the Pauly-Greiner or other type. This apparatus receives steam at a pressure of about 30 lbs., and in it the juice is partly concentrated, giving off vapour at about 15 lbs., which is used for the vacuum pans, juice-heaters, &c. Although in this way the juice may be heated to 115°–120°, it has been fully established that no decomposition of sucrose takes place, provided that the juice be kept sufficiently alkaline. By the use of such an apparatus, the heating surfaces of pans, heaters, &c., may be made proportionately small.

As the juice concentrates, certain salts are thrown out of solution, and are mostly deposited on the heating surfaces. Such an incrustation or scale conducts heat very badly, and greatly diminishes the efficiency of the evaporato Numerous mechanical devices have be proposed for preventing or diminishing scale formation during evaporation; but these are not widely used, so that it is necessary during the Sunday intermission to resort to chemical cleaning by boiling out with dilute sodium hydroxide or carbonate, followed by hydrochloric acid, after which the residue may generally be readily removed by means of brushes and scrapers. Pellet has made a special study of the scale of the effect of the beet sugar factory,[1] indicating the varying composition according to the particular vessel.

While evaporation is proceeding, a small amount of the juice may be 'entrained' or carried over with the vapour, sugar thus being lost. This may be prevented by the use of suitable baffles, or one or other of the patent forms of preventers, or again by a larger vapour space. It is, nevertheless, customary to periodically test the condensed water of the evaporators for sugar by means of a-naphthol, underlaying with a little concentrated sulphuric acid.

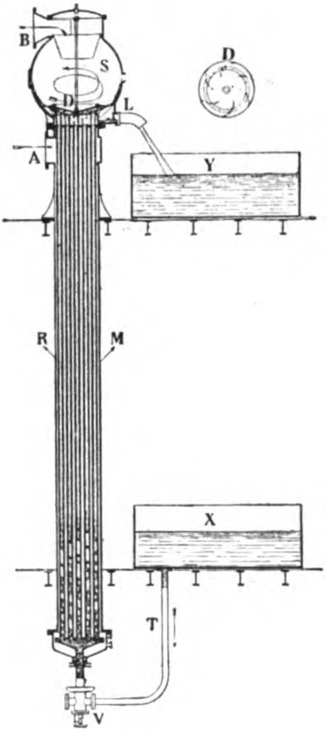

FIG. 10.

It was stated above that the alkalinity (to phenolphthaleïn) of the juice entering the evaporators is generally between 0·01 and 0·04 p.c. calcium oxide. When the juice is concentrated to 55°–60°Brix, this alkalinity should become 0·05–0·20 p.c., but it does not reach this figure, owing principally to the volatilisation of the ammonia present and the decomposition of amino acids and acid amides, and is usually reduced to about 0·02–0·03 p.c. Nevertheless, the alkalinity is generally too high to be sent directly to the next stage, viz. crystallisation in the vacuum pans; and it is customary to further reduce it to about 0·005–0·010 p.c. by first bringing the juice almost to boiling-point in a thick-juice heater, and then treating with either carbon dioxide or sulphur dioxide in some form of continuous apparatus, until the desired alkalinity is reached. Lastly, the juice is filtered through a press or sand filter.

(4) *Crystallisation of the sugar from the syrup.* As previously stated, concentration is continued in the multiple effect as far as 55°–60°Brix. Beyond this density, operations have to be very carefully conducted, and crystallisation or 'graining,' in order to be fully under control, must be conducted under reduced pressure in a single effect apparatus, otherwise known as a 'vacuum pan' (Fig. 11).

Usually vacuum pans are vertical, with a conical bottom, and are heated by coils, which may either be superimposed or else arranged in one plane on the 'lyre' system. Vacuum pans of the horizontal type are not much used now. As to size, in general, it may be said that a large pan, although it requires less attention, is not altogether advantageous, chiefly on account of the large amount of steam it takes from the evaporators on starting. In beet factories, the capacity of the pans used may vary between 20 and 50 tons.

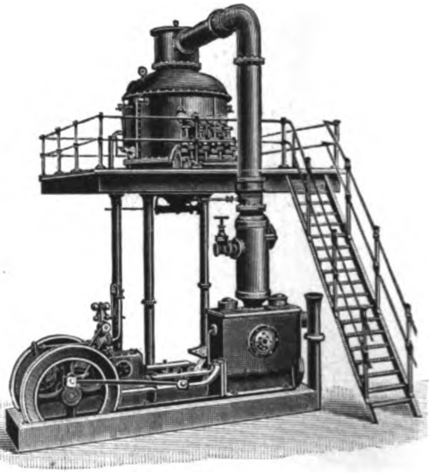

FIG. 11.

When boiling, the object of the pan-man is to form a certain amount of crystals or 'grain' in the thickened syrup, and then to allow the sugar passing out of solution during evaporation to grow on these already formed crystals, without the formation of new, small crystals, technically known as 'false grain,' which subsequently cause difficulty in the centrifugals, passing through the basket into the molasses. During the process of boiling, the pan-man is entirely guided by the appearance of the sample which he takes from the pan by the 'proof-stick' and from certain empirical tests, such as 'string proof,' 'bubble proof,' 'water proof,' 'hook proof,' &c.

Briefly described, the process of boiling down the syrup in the pan is as follows: The

---

[1] D. Zuckerind. 1910, 35, 596.

air pump is started and when a sufficient vacuum has been reached, an amount of syrup, depending upon whether large or small crystals are desired, is drawn into the pan. As the syrup concentrates, crystallisation or 'graining' occurs. More syrup is then gradually drawn into the pans, either continuously or intermittently, and as concentration proceeds the sugar is deposited on the already formed crystals, so that a mixture of crystals and mother-liquor, technically known as 'massecuite,' is formed. When the pan is full, the syrup supply is shut off, and concentration is continued until the massecuite reaches a certain consistency, generally containing from 5 to 10 p.c. of water. At this point the contents of the pan, called the 'strike,' are 'struck out,' and allowed to drop into either (*a*) mixers, in which case treatment in the centrifugals is carried out directly, or (*b*) else into crystallisers, in which instance the massecuite is slowly cooled and crystallisation completed as fully as possible before centrifugalling.

The mixer is a large receiver, fitted with a stirrer, and is placed immediately over the centrifugals. It is usually of such a size as to take the entire contents of the pan. The crystallisers generally used consist of horizontal vessels, either open or closed, provided with a suitable stirring gear for imparting a gentle motion to the massecuite, and also with a steam jacket or other arrangement for heating or cooling the contents.

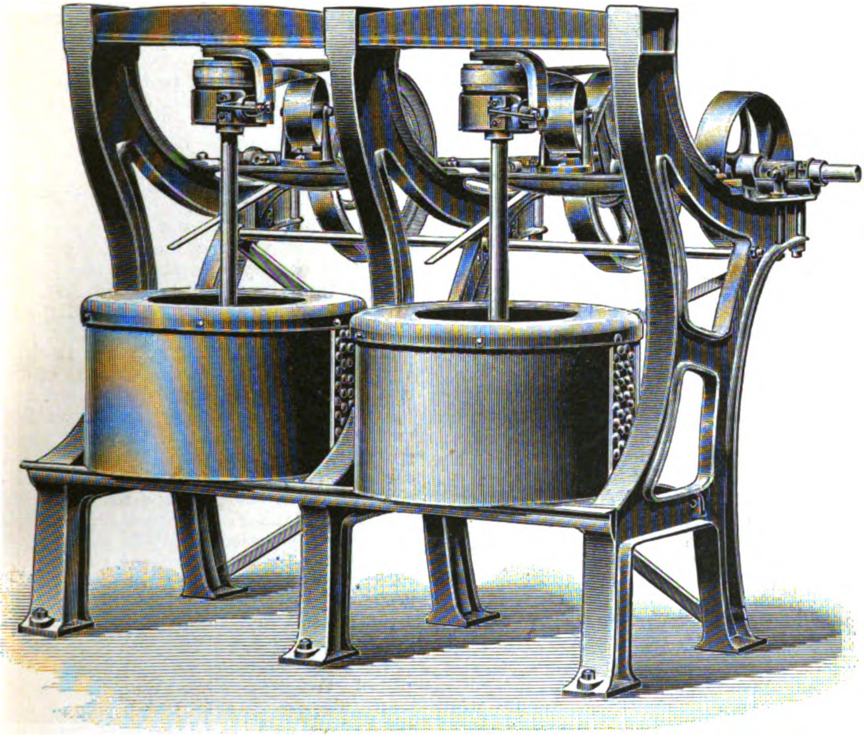

FIG. 12.

It may be mentioned that Curin (Österr.-Ungar. Zeitsch. Zuckerind. 1894, 756) has introduced an apparatus, termed a 'brasmoscope,' and Claassen (Zeitsch. Ver. deut. Zuckerind. 1897, 779) a similar instrument for enabling the workman to control the boiling and produce a uniformly good sugar.

(5) *Separation of the crystals.* It now remains to separate the crystals from the mother-liquor, or molasses, which operation, termed 'spinning' or 'machining,' is universally carried out in the beet sugar industry in a special centrifugal machine (Fig. 12).

Usually a centrifugal having a basket 40 to 50 ins. in diameter is employed. In the beet factory, both the suspended and standing types are employed, but German manufacturers still adhere largely to the latter system, although the former evidently has the greater advantages. The machine may be driven either singly or in groups, at a rate between 800 and 1500 revolutions per minute. Usually the ordinary steam power of the factory is used, electric or water-driven machines not having come into general use.

It is convenient to arrange the pans and crystallisers above the centrifugals, so that the introduction of the massecuite may be effected by gravity through a spout or gutter. If, however, this is not possible, either compressed air or a special form of pump carries the massecuite into a mixer, placed at a suitable height from which the centrifugals may be fed.

For many years past, efforts have been made to construct a continuous centrifugal, *i.e.* one into which the massecuite may be fed, and from which the machined sugar may be discharged without stopping; but none of these has given really promising results in actual working.

By 'spinning' or 'machining' the massecuite in the centrifugals, the greater part of the mother-liquor or molasses is thrown off, although a small amount always remains adhering to the crystals. The mother-liquor that is thrown off is known as 'green syrup,' or 'centrifugal syrup,' and it subsequently undergoes the procedure described under (6) *Treatment of the centrifugal syrup and working-up of the after-products.* When it is advantageous to make a raw sugar of high rendement, the amount of the adhering molasses may be reduced somewhat by a longer duration and higher rate of machining.

In making a white (unrefined) sugar for direct consumption, the syrup is removed from the crystals as completely as possible, by washing it off while still in the machines with steam, water, or concentrated sugar liquor, doing this in such a way that none, or but very little, of the crystal is dissolved. Moreover, in making white direct consumption sugar in the beet factory, a little ultramarine may be used in the pan, whilst a little may also be added to the water used for washing in the machines, or 'covering,' as the operation is sometimes called.

White sugar obtained in this way may be sold after sieving and drying as a cheap quality of 'granulated,' or it may be ground to a form of 'powdered sugar,' or, again, the crystals may be worked to 'pressed loaf sugar.' It should, however, be pointed out that such products are not to be regarded as equal to refined sugars, although they find a ready cheap market, especially on the Continent. They have not the brilliant whiteness of refined sugars, which can only be made by a further purifying treatment, involving the use of animal charcoal.

After machining, the sugar is discharged from the centrifugals into shaking gutters, which pass it to an elevator, which in turn sends it to the sieves, after which the finished raw sugar is sacked and stored.

As to the quality of a good raw beet sugar, this does not simply depend on the sucrose content, but also upon other factors. The sugar crystals should be well defined in shape and of uniform size and colour. Of more importance than the colour of the syrup adhering to the crystal is the colour of the crystal itself. If not white, a pale yellow is to be preferred to a grey, since a grey sugar is generally difficult to refine. Further, the raw sugar should have a sufficient alkalinity to phenolphthaleïn, otherwise it does not keep well on storage.

(6) *Treatment of the centrifugal syrup and the working-up of the after-products.* The syrup spun off the massecuite in the centrifugals, the so-called 'green syrup,' has a purity value of 70°–80°,[1] and contains an appreciable amount of crystallisable sugar, which is always extracted, giving a low-grade sugar termed an 'after-product.'

It was formerly the custom, and it still is to a small extent in the smaller and older Continental factories, to boil the centrifugal syrup 'blank,' *i.e.* to concentrate it to supersaturation with little or no formation of grain and allow the separation of the sugar crystals to take place in tanks, with or without the addition of inciting crystals or 'seed.' In using this method, it is necessary to repeat the boiling operation twice in order to exhaust the syrup to the purity of true molasses, and the second boiling must stand for some months before complete crystallisation is effected. Consequently, this method is a very expensive and inconvenient one, operations having to be continued after the campaign proper has terminated, although there is no doubt that the modifications introduced by Ehrhardt and Fölsche have been of much service in improving it.

According, however, to the modern method of working, in which the centrifugal syrup is boiled to grain and afterwards allowed to crystallise out while being gradually cooled and agitated in a special apparatus, called a 'crystalliser-in-motion,' this disadvantage is satisfactorily overcome.

As a rule, the vacuum pan for graining in after-product working does not differ much from that employed in boiling the thick-juice, except that it often contains an agitating apparatus to hasten the operation, since with the viscous after-product the motion during boiling is slight. Boiling may last 12–24 hours, and the finished massecuite consists of crystals and a mother-syrup of 65°–70° purity.

Generally speaking, the crystalliser-in-motion is a cylindrical vessel, preferably jacketed, provided with a horizontal shaft carrying paddles and geared to revolve very slowly. From the pan, the massecuite is run into the crystalliser at a temperature of 85°–90°C., and gradually cooled to 25°–40°C. during 4 to 5 days, water being added from time to time in such amount that the supersaturation of the liquor is kept at the optimum for regular crystallisation (*vide* Herzfeld, Zeitsch. Ver. deut. Zuckerind. 1892, 174; and Claassen, *ibid.* 1897, 809), without the formation of 'false grain.' When crystallisation is completed, the massecuite goes to the centrifugals to be separated into sugar crystals and mother-liquor. After two such operations, the mother-liquor is 'exhausted molasses,' *i.e.* molasses from which no more sugar can be obtained by crystallisation, except after some special extra treatment. It usually has a purity value of 58°–60°, if the crystallisation has been conducted in the proper manner.

In an up-to-date after-product plant, such as the Claassen (Fig. 13), or the Bock, the boiling apparatus is so arranged that its contents fall directly into the crystalliser, the contents of which are again directed through steam-jacketed channels into the centrifugals, which are immediately below.

Brief mention may be made of modifications of the general method of treating after-products that are used to a more or less extent at the present time. In the Grossé procedure, boiling and crystallisation are both carried out in a special pan, fitted with a spiral agitator, in addition to the ordinary steam coils. According

---

[1] By the 'purity,' or 'quotient of purity,' is meant the percentage of sucrose in the total solid matter $= \frac{\text{sucrose} \times 100}{\text{total solids}}$.

to the Mathis method, the syrup is boiled blank to a high Brix content, filled into a special crystalliser at 95°–100°C., and there boiled under reduced pressure, graining being induced by the introduction of high-pressure steam or air. Karlik and Czapikowski have designed a horizontal graining pan in which the heating arrangement is in the form of a cross revolving about a hollow shaft at the rate of only 1–3 revolutions per minute.

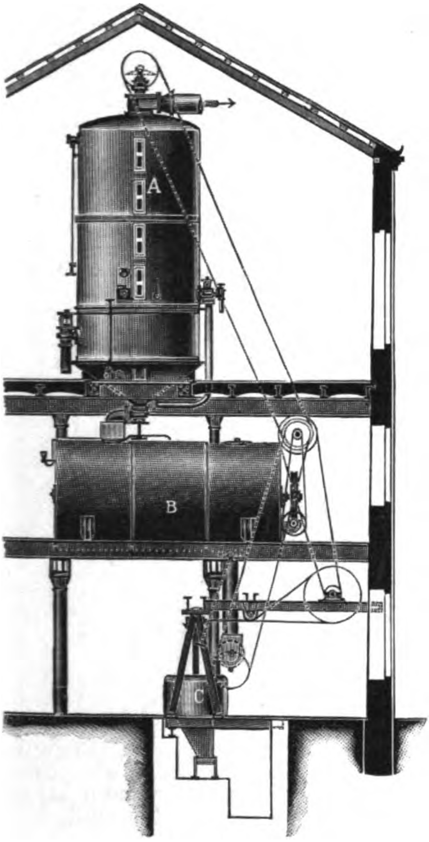

Fig. 13.

Generally the after-product obtained by one or other of the methods given above is sold directly as a low-grade sugar, but sometimes it is re-dissolved in the thin-juice, which is then worked up in the usual way. Re-solution in the thin-juice is also used in white sugar factories, *i.e.* those in which a white (unrefined) direct consumption product is made.

As to the utilisation of the 'exhausted molasses,' this may be done in several ways. On the average, the composition of the product is: sucrose, 50 p.c.; non-sugars, including mineral matter, 30 p.c.; and water, 20 p.c. From this analysis it will be observed that there is present a large amount of non-sugars, and it is these that prevent the further crystallisation of the sucrose.

In order to recover some of this sucrose, the exhausted molasses is sometimes treated by: (1) the 'osmose' process, in which, by osmosis, a syrup is obtained of higher purity; or (2) by the Steffen or Schreibler processes, or modifications of them, in which an insoluble calcium or strontium saccharate is precipitated, separated by filtration through presses, and subsequently decomposed with carbon dioxide into sugar and calcium or strontium carbonate.

Exhausted molasses, however, on the Continent especially, is now largely used for the manufacture of 'molasses cattle food,' by mixing with dried exhausted cossettes (beet pulp), dried brewers' grains, peat, alfalfa meal, or other suitable absorbent. To a large extent, also, it is sold to the distiller for the production of spirit; while a small proportion is employed in the manufacture of blacking, dyewood extracts, disinfectant solutions, &c.

(*b*) Manufacture of Raw Sugar from the Sugar Cane.

In cane sugar manufacture, the several stages are, broadly speaking, the same as those obtaining in beet sugar manufacture, but the methods used in the first two, namely, (1) the extraction and (2) the clarification of the juice, differ somewhat. In place of extraction of the juice by diffusion, milling is universally used; whilst, instead of clarification by the defeco-carbonation process, simple defecation with a small amount of lime is most generally applied. Other operations, such as (3) the concentration of the juice, (4) the crystallisation of the syrup, (5) the separation of the crystals, and (6) the working-up of the after-products, are practically the same, so that much that has been said under *Beet Sugar Manufacture* (p. 213) applies here also, and need not be repeated.

(1) *Extraction of the juice by crushing in mills.* After the cane has been cultivated, harvested, and conveyed to the factory, it is passed through mills consisting of three heavy iron or steel rollers, set with their centres at the angles of an isosceles triangle, the vertical angle of which is generally about 83°, and driven by a powerful engine through suitable massive spur and pinion gearing. In this way the cells of the cane are ruptured, and the juice containing the sugar is expressed. After falling from the rollers to the bed of the mill, the juice flows into the juice-tank, in the upper part of which is fixed a strainer to separate the grit and fine 'cush-cush,' or crushed particles of the rind and pulp of the cane. From the juice-tank, the strained juice is pumped to the clarifiers, there to be subjected to further treatment.

Formerly, the cane was simply passed through a mill consisting of only three rollers, *i.e.* it was 'dry crushed' in a 3-roller mill, and in this way it was possible to obtain an extraction of only about 60 p.c. of the sugar in the cane. According, however, to modern methods of working, in which a much higher extraction is effected, the cane is first subjected to a preparatory crushing by means of the Krajewski or similar apparatus, consisting of two rollers with pointed zigzag corrugations, and then passed through a train of 2, 3, or 4, 3-roller mills, set in tandem (Fig. 14). In addition to this, it is now customary also to treat the cane between any two mills either by (*a*) maceration, *i.e.* immersion in a bath containing dilute juice returned from the last mill; or by (*b*) imbibition, *i.e.* spraying with hot or cold water or juice. Using the Krajewski crusher, a 12-roller mill, and imbibition with 20 p.c. of water on the weight of cane, it is possible to effect as high an extraction as 90–95 p.c. of the sugar originally present in the cane. Even a higher extraction than this may be effected by using a larger amount of water; but it is not always economical to proceed so far, as with the increase of extraction the purity of the juice falls, while the extra cost of fuel for evaporation and an increased capacity of plant to deal with the greater volume of juice, must obviously also be taken into consideration. According to the different methods of milling, the extractions obtainable are as follows (British Guiana Sugar Planters' Association's Report to the West India Commission): single crushing, 76 p.c.; single crushing, with preliminary crusher, 80 p.c.; double dry crushing, 83 p.c.; double dry crushing with preliminary crusher, 85 p.c.; double crushing, with 10 p.c. imbibition, without crusher, 86 p.c.; double crushing, with 10 p.c. dilution, with crusher, 88 p.c.; treble crushing, with crusher and 20 p.c. dilution, 92 p.c.; and quadruple crushing, with crusher and 20 p.c. dilution, 94 p.c.

As to the more or less exhausted, crushed residue of cane, termed 'bagasse' or 'megass,' this is generally utilised as fuel in the sugar factory for generating the steam for evaporation, being burnt either in the wet or air-dried state, in specially constructed furnaces.

It should be pointed out that attempts were made by French and German engineers about 20 years ago to establish the diffusion process (*see* under (*a*) *Beet Sugar Manufacture*, p. 213) in the cane sugar industry. For a time it seemed probable that diffusion would become a permanent method of sugar extraction from the cane; but with the introduction of improved methods of milling, such as preliminary cutting and crushing, maceration and imbibition, the superiority of diffusion has entirely disappeared, and the process is used only in one or two places, where the economic conditions are quite exceptional. For diffusion processes in general, it is claimed (1) that they extract 96–98 p.c. of the sugar from the cane; that (2) a purer juice is obtained; and (3) that there is less danger of the stoppage of the factory from a breakdown, since if one vessel is out of order, it may be disconnected, and the work carried on with the others. On the other hand, the disadvantages are (1) that the juice is very much diluted, so that extra fuel and plant are required for evaporation; (2) that more hands are necessary; (3) there is considerable expenditure in working and maintaining the slicing plant; and (4) that the exhausted cane slices must be pressed and dried before being available for fuel.

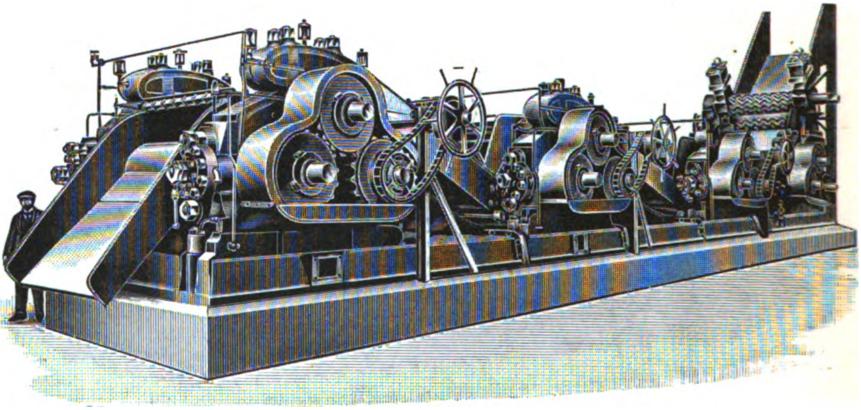

FIG. 14.

Several processes, combining milling and diffusion, have been elaborated, and of these may be mentioned the Kessler (International Sugar Journal, 1902, 4, 460), and the Geerligs-Hamaker (*ibid.* 1903, 5, 571) methods.

(2) *Clarification of the juice.* As the juice comes from the mills, it is cloudy and yellow, or dirty green in colour. In addition to sucrose, it contains as impurities gummy, protein, and colouring substances, together with mineral matter, and a more or less amount of reducing sugars, technically known as 'glucose.'

Depending upon the nature of the cane worked, the country, and the method of milling, the composition of the raw juice may vary somewhat, but generally it averages the following: sucrose, 13–18 p.c.; reducing sugars, 0·5–1·0 p.c.; gummy, protein, and colouring substances, 0·2–0·5 p.c.; mineral matter, 0·25–0·70 p.c. In now submitting it to the process of clarification, the object is to eliminate from it these non-sucrose constituents as completely as possible, so that the subsequent operation of crystallisation and separation of the crystals can be the more readily accomplished. At the present time, the two agents that are in general use in cane factories as the most economical and efficient are heat and lime, while very often either sulphurous or phosphoric acids, or both, are also employed. There are, however, considerable variations in the method of carrying out this treatment, depending upon the class of sugar, whether (*a*) refining crystals, (*b*) yellow crystals, or (*c*) white, ready consumption sugar, is being made.

(*a*) In making refining crystals, the raw juice may be passed first through a juice-heater

(Fig. 6, p. 215), in which it is raised to boiling-point, and then run into clarifying tanks (Fig. 15), where it is 'tempered' with the necessary amount of slaked lime to effect the precipitation of as much of the gummy, protein, and other impurities as possible. After settling, the clear liquor is carefully separated from the muddy deposit or 'bottoms,' and then passed on to the next stage, namely concentration. Often this method of clarification is made a continuous one, as in the Hatton system.

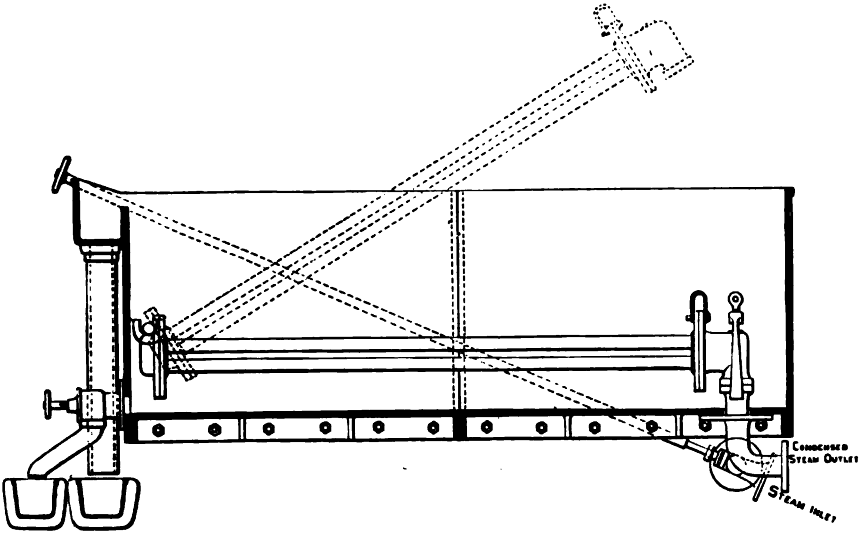

Fig. 15.

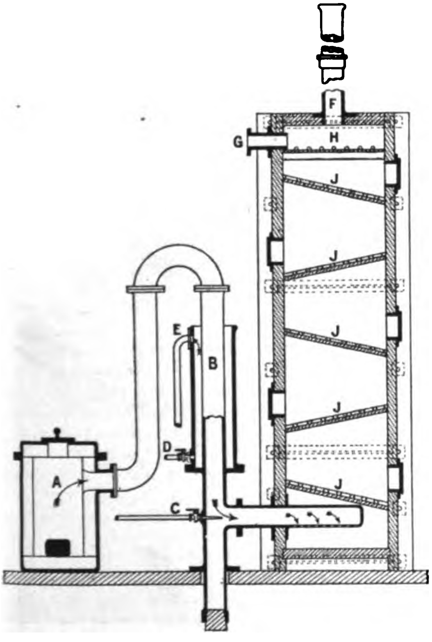

Fig. 16.

(*b*) In making yellow or Demerara crystals, it is most customary to first treat the raw juice in the cold with sulphurous acid, obtained by burning sulphur in a sulphur oven (Fig. 16). After 'sulphuring,' or 'gassing,' as it is technically termed, the juice is passed through a juice-heater (Fig. 6, p. 215) to raise it almost to boiling-point, and then run into clarifying tanks, in which it is limed, and then allowed to settle. Next the clear juice enters the eliminators (Fig. 17) or tanks provided with steam coils, where it is heated with phosphoric acid, either in the form of 'Newlanite,' or as concentrated superphosphate of lime solution, the dirty 'scums' which rise to the top surface being removed by skimming off into gutters arranged around the edge of the vessel. In this way, a pure yellow juice, free from any tinge of green, and therefore well suited for the manufacture of Demerara crystals is obtained. It is then ready for concentration. The scums and bottoms obtained in this method of treatment are boiled with lime, and clear liquor aga

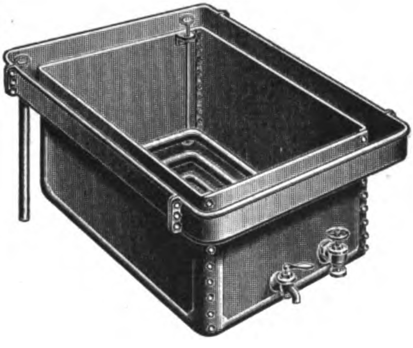

Fig. 17.

separated, either by subsidence or passing through sand-filters or filter-presses.

(*c*) In making white sugar for ready consumption, several different procedures for clarification may be followed. Until quite recently, the carbonatation process (*see* (*a*) *Beet Sugar Manufacture*, p. 215) was much in vogue; but it is now being recognised that this procedure may be replaced by a cheaper and equally efficient one, the clarification stage of which is carried out as follows (International Sugar Journal, 1911, 13, 178-179): The raw juice is mixed in the cold with 5–6 litres of milk of lime at 15°Bé. per 1000 litres, and 'sulphured' to neutrality. It is then heated to boiling-point, and run into settling tanks, the clear juice going to the evaporators, while the 'bottoms' and scums are sent through filter-presses, and the resulting clear juice also sent to the evaporators.

(3) *Concentration of the juice to syrup.* After clarification by one or other of the methods mentioned above, the juice, which may have a density of about 15°Brix, is evaporated to a syrup of about 27° to 30°Bé., or about 55 p.c. of dry substance.

In the early days of sugar manufacture, evaporation was generally effected in a series of shallow, open vessels, termed a 'copper-wall'; and, indeed, this primitive method, wasteful alike of sugar and fuel, is still used to some extent in the West Indies and on small *haciendas* in Central America and Brazil.

In the majority of cane sugar factories at the present time, however, concentration is effected *in vacuô* in some form of multiple effect apparatus (Figs. 9 and 10). What has already been said on the concentration of the juice under (*a*) *Beet Sugar Manufacture*, p. 218, applies here also, but it may be pointed out that the Pauly-Greiner pre-evaporator system of using high-pressure steam has not yet been installed in the cane sugar industry, although Deerr (International Sugar Journal, 1911, 13, 341 *et seq.*) has carried out a number of valuable researches demonstrating that this might be done with advantage.

As in the beet sugar industry, trouble is caused during evaporation by the deposition of scale on the heating tubes of the effect, the efficiency of the apparatus being thus decreased. Such scale may have a somewhat different composition to that precipitated from beet juices, and from analyses made by Pellet, the proportion of the various salts increases or diminishes according to the particular vessel of the effect, as follows:

	First vessel	Second vessel	Third vessel
Water and organic matter	29·80	26·70	18·60
Silica	0·40	23·40	69·80
Iron and alumina . .	3·80	9·98	2·80
Lime	46·30	25·80	6·80
Magnesia	1·36	0·81	1·08
Phosphoric acid . .	17·10	11·70	trace
Sulphuric acid . .	absent	absent	trace
Copper	trace	trace	trace
Undetermined . .	1·24	1·61	0·92

In cane sugar factories, the scale may also contain a more or less amount of wax, derived from the rind of the cane. In the steam chamber of the first vessel, a troublesome layer, containing oil, oxides of iron and copper, and carbon, the former coming from the steam used for heating, is sometimes observed. This deposit is best removed by treatment with petrol or benzene.

Peck (International Sugar Journal, 1911, 13, 357) has investigated the most suitable solvent for the removal of scale, containing mostly calcium sulphate, and has found that the best result is obtained with sodium carbonate followed by hydrochloric acid.

Although the greater part of the mineral and organic substances thrown out of solution during concentration deposits on the walls and tubes of the vessels of the effect, some remains in suspension in the syrup, rendering it turbid. It is of importance when making a good quality sugar to remove this impurity, since it becomes enveloped in the sugar during crystallisation, imparting a dark colour to it which cannot be removed by washing in the centrifugals.

Often, therefore, the syrup is subjected to treatment before being sent to the vacuum pans. In the case of refining crystals, the syrup may simply be allowed to stand, in order to separate the greater part of the insoluble matter. When, however, yellow crystals or white direct consumption sugars are being made, the syrup may be again 'sulphured,' or treated with phosphoric acid, then passed through sand, bag, or other suitable filters.

(4) *Crystallisation of the sugar from the syrup.* When the syrup comes from the evaporators, it has a density of about 55°Brix, and is next concentrated in the vacuum pan (Fig. 11, p. 218) to a massecuite or magma of crystals, of 92°–94°Brix.

In the cane sugar industry, owing to the demand for large pans, iron is now generally used in place of copper formerly employed; the coils are, however, made of copper or gun-metal.

In the manufacture of Demerara crystals, the fine transparent yellow colour is due largely to careful treatment during the clarification stage, and also sometimes to the addition of a minute amount of stannous chloride to the massecuite during boiling, or else to the massecuite in the centrifugals. The 'bloomer,' as it is called, produces a bright yellow colouring matter, the exact nature of which has not been determined.

When making white sugar for direct consumption, a small amount of sodium hydrosulphite ('Blankite'), or of calcium hydrosulphite ('Rédo'), about 1 part to 10,000 parts of dry sugar is often drawn into the vacuum pan a few minutes before graining. These preparations have a much more powerful reducing action than sulphur dioxide alone, and produce a marked decolorising effect on the massecuite when properly applied.

Sometimes, also, ultramarine is used in the same way, that is just at the graining point, so that each crystal may receive sufficient blue to neutralise the yellow tinge of the crystals when fully grown. As a rule, however, ultramarine is used in the centrifugals. Other colours, such as aniline blue, are now also employed for neutralising the complementary yellow of the crystal.

As in beet sugar manufacture, after boiling, the contents of the pan are 'struck out' either into mixers or else into crystallisers-in-motion, which latter may be open or closed, jacketed or unjacketed, but have a stirring gear revolving at a rate of only one revolution per minute.

(5) *Separation of the crystals.* In order to separate the crystals from the massecuite, 'machining' in centrifugals (Fig. 12, p. 219), as applied in beet sugar manufacture, is now almost always used. The primitive and wasteful method of drainage, either in a cask with a perforated bottom, or in a vacuum chest, with or without 'claying,' is now practically abandoned, even in making a low quality 'muscovado,' being only employed in the manufacture of a very crude sugar in India, parts of Central America, and elsewhere.

In the cane sugar industry, suspended and overdriven machines, with a basket 30–48 ins. in diameter, are most generally employed.

(6) *Working up the after-products.* So as to recover the sugar spun off the crystals in up-to-date cane factories crystallisers-in-motion are always used, and what has already been said about this under *Beet Sugar Manufacture*, p. 220, need not be mentioned again.

It should, however, be pointed out that some cane factories still use the obsolete method of tank crystallisation; and also that in some the old method of obtaining two, three, four, and even five crops of sugar by repeatedly boiling down the molasses, crystallising, and centrifugalling is yet in vogue.

A better scheme is to redissolve the low grade third or fourth crop sugars in the clarified juice, or else use them as 'seed' in the pan, thus recovering them as a high grade 'first' sugar. In many factories, the molasses from the first massecuite is returned to the pan, and worked up with the syrup obtained in the ordinary way; after boiling this mixture of syrup and molasses to grain, the massecuite is submitted to crystallisation-in-motion, centrifugalled, and the resulting molasses again boiled to grain, when exhausted molasses is generally obtained. Then, again, may be mentioned the so-called 'Java process' of entirely suppressing low products, by systematically returning all molasses to the pan in amounts depending upon its purity, the only final products being a good first sugar and entirely exhausted molasses.

During the cooling of low-grade massecuites, a peculiar phenomenon, characterised by the sudden evolution of gases, and termed 'froth fermentation' is often observed. It has been conclusively shown by Tempany (International Sugar Journal, 1911, 11, 588) and others that this is not due to the action of micro-organisms, but to the spontaneous decomposition of glucinates, and other products of the decomposition of reducing sugars by lime.

As to the disposal of exhausted cane molasses, it may be used for cattle food, generally using the interior pith of the cane as absorbent ('molascuit'); for the manufacture of rum, for manure, for fuel, and to a comparatively small extent for direct consumption.

(c) SUGAR REFINING.

Raw sugar, obtained from the beet or cane by one or other of the procedures given above, is seldom consumed as such, but is first refined, the products made being generally: (*a*) loaf; (*b*) cube; (*c*) granulated; (*d*) crystal; (*e*) yellow crystals; (*f*) soft pieces; and in a comparatively small amount also (*g*) castor and icing sugars.

Refining consists of the following stages: (1) preliminary washing treatment in centrifugals; (2) melting; (3) filtration; (4) decolorisation by animal charcoal; (5) boiling to grain; and (6) separation of the crystals in centrifugals or in moulds.

Generally, raw beet sugar of the quality known as 88° and 75° nett is employed by refiners, but one or two use cane sugar alone, while all replace the beet more or less by cane when the latter is the cheaper.

(1) *Preliminary washing treatment in centrifugals.* Raw sugar, as previously pointed out, consists of crystals and adhering molasses, so that by washing off the latter the purity of the sugar is considerably raised, the process of refining thus being facilitated. In the refinery, this preliminary washing treatment, sometimes called 'affining,' is best effected by mixing the sugar with syrup, so as to render it sufficiently liquid, and running it into a centrifugal machine (Fig. 12), either of ordinary or of special construction, the speed of which is generally 800 to 900 revolutions per minute. While machining, steam, water, or sugar solution, is admitted into the interior of the basket, but discontinued when the syrup leaving is light coloured, the machine then being stopped as quickly as possible.

Using this process and a large-grained raw sugar, the yield of purified product may be from 80 to 90 p.c., but with low grade sugars it is usually only 65 to 70 p.c., the balance of the sugar remaining in the syrup. The treated sugar, if made from a good, 'grainy' sugar, will contain from 99 to 99·5 p.c. of sugar, but if from a raw sugar of lower quality, only 97·5 to 98·5 p.c.

As to the time required for the operation, this varies from 10 to 40 minutes, according to the quality of the raw sugar treated. With regard to steaming, the exhaust steam from the engine driving the machines will be more than sufficient. Its pressure should not exceed 5 lbs. in the pipes leading to the machines and it should be kept as dry as possible.

(2) *Melting.* After the preliminary washing treatment, the sugar is elevated to the 'blow-up' or melting pans, which are generally situated on an upper floor of the refinery (Fig. 18). These blow-ups are cylindrical in shape, and are made of cast iron. Each blow-up is capable of holding from 3 to 10 tons of sugar, and the water sufficient to dissolve the same; it is provided with a stirring gear and a copper coil, which is heated by low-pressure steam, or the coil is perforated with holes so as to blow in open steam. Thus by means of hot water and steam the sugar is rapidly dissolved, and by the addition of more sugar or water, as the case may be, the solution is brought to the required density and temperature, viz. about 28°Bé. and 160°F. Some cane sugars of low quality give a solution which is very difficult to filter, and some suitable defecant is therefore added

(3) *Filtration.* After the liquor leaves the blow-up it is run through a Taylor filter (Fig. 19).

The outer part of this consists of a chamber made of cast iron, of various dimensions, provided with doors. At the top of the chamber is a receiving tank from 6 ins. to 1 ft. deep, covering the entire surface, and in the bottom of this tank are a number of holes about an inch in diameter and about 9 ins. apart. Each of these holes is provided with a screw socket to receive the upper end of a bell-shaped brass nozzle which is screwed into it, and round these nozzles the

FIG. 18.—MELTING AND CHAR DEPARTMENTS OF A SUGAR REFINERY.

filter-bags are tied. The filter-bags are made of fine twilled cotton cloth, and are about 6 ft. long and from 18 ins. to a yard wide, and each of them is crumpled longitudinally and slipped inside a sheath made of coarse hempen cloth of an open texture. The sheath is a little longer than the filter-bag, and is from 6 ins. to 9 ins. in diameter. After the bags are inserted in the sheaths they are tied round the nozzles, which are then screwed into the sockets. . Should any one of the bags give turbid liquor the hole at the top of it should be stopped up. After the liquor has ceased to flow freely, the bags are washed repeatedly with hot water until all the 'sweet' has been extracted. This bag-water is used for melting raw sugars, steam being introduced outside the bags to keep the water hot.

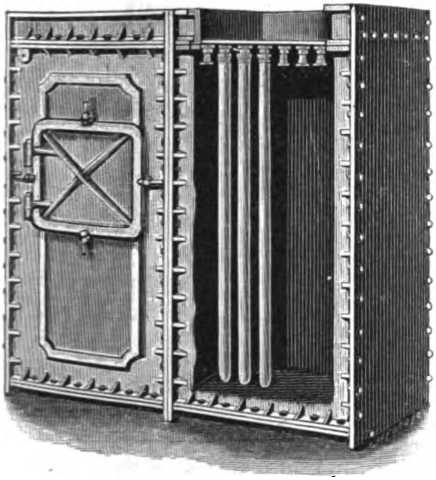

FIG. 19.

The door of the chamber is next opened, and when the filters have cooled down the nozzles are unscrewed, each bag removed from its sheath, and then turned inside out and washed several times in separate tanks. By turning the bag inside out and pushing it under water, the imprisoned air, in escaping, drives before it a good deal of the muddy impurities contained in the bag. This process is repeated several times, each time using cleaner water, and washing the dirtiest bags in the last water. In some refineries the bags are taken direct from the filters in the sweet state, and are washed in the tanks as above described, the mud being afterwards removed from the 'sweet water' by means of a filter press. A little lime is sometimes added to the muddy water to prevent fermentation and assist filtration. For most kinds of raw cane sugar it is necessary to employ Taylor filters, but beet sugar can often be satisfactorily dealt with by means of a filter-press. Various substances—including lignite, carbonised infusorial earth, brown coal, wood charcoal, animal charcoal, sawdust, &c.—have been suggested to assist the passage of liquor through the filter-press.

(4) *Decolorisation by animal charcoal.* For this purpose animal charcoal (*v.* BONE BLACK) placed in char cisterns consisting of cast- or wrought-iron cylinders, usually about 10 ft. diameter by 18 ft. high, is employed. Each cistern is provided with manholes, one at the top for introducing fresh char, and the other at one side near to the bottom for emptying out the char which has been exhausted. Each cistern has also a false bottom made of wood or iron, perforated with numerous holes and covered with scrim cloth, or blankets, so that the clear liquor coming from the char may be deprived of any char dust and may come through perfectly bright. The cisterns are filled with well-burnt char to within a short distance of the top, and the warm 'liquor,' that is, the solution of raw sugar at 28°Bé., is then allowed to flow in at the top, the cock at the bottom of the cistern having been opened to allow the air to escape. When the cistern is full, and the liquor begins to come through at the bottom, the cock is turned off, and the whole is generally left at rest for several hours, so as to 'settle.' The cock is then opened, and the decolorised liquor is allowed to flow into a tank. More raw liquor is at the same time admitted at the top of the char cistern. The speed of flow is so adjusted that the liquor may be sufficiently long in contact with the char to thoroughly utilise its power of removing the colouring and certain organic matters from solution. As long as the liquor passing through the char is colourless, it is allowed to flow into the same tank and is used for making white refined sugar. When, however, the liquor begins to assume a yellowish tinge, it is diverted into another tank, and is used for producing a lower grade of sugar. It is usual to proceed in this manner until the liquor passing away from the cistern is of a light-orange colour. The liquor is then turned off at the top, and hot water is run on to drive out the solution of sugar, but as the water mixes to some extent with the liquor a quantity of weak sugar solution is always made. This is known as 'char water,' and is employed in dissolving raw sugar, or it is sometimes, owing to its turbidity and the impurities it contains, treated separately from the liquors. It is a frequent custom to start a char cistern with good liquor, and afterwards to follow this up with lower-quality liquors. The char water, too, is often run into liquor tanks when above 18°Bé., or as long as it remains bright. When this ceases to be the case, it is run into other tanks until its density is reduced to 1° or 2°Bé., and when this point is reached it is no longer worth saving, and is therefore run down the drain. The washing of the char with boiling water is continued for some hours so as to remove, as far as possible, all organic and other impurities. The char is then allowed to drain, and is removed from the cistern to be dried and reburnt, or, as it is termed, 'revivified,' in the char kilns.

The kilns employed for this purpose may be divided into two classes, viz. revolving kilns and pipe kilns. The first consist of cast-iron cylinders, revolving in an inclined position and heated externally by fire, through which the char is passed continuously, being turned over in its passage by lifting shelves, and discharged at the lower end into an air-tight chamber. These kilns have of late been almost entirely replaced by the pipe kilns, of which various modifications are employed, one of the best being shown in Fig. 20. In this apparatus, the char is introduced through the two hoppers at the top, first into drying pipes, then into the retort pipes, where it is heated uniformly to a temperature of about 1050°F., and finally into the cooling pipes, from which it is passed into an automatic discharging apparatus, being drawn off in measured amounts at given intervals of time. After revivification, the charcoal is conveyed as required by a travelling band and elevator to a hopper placed above the char cistern.

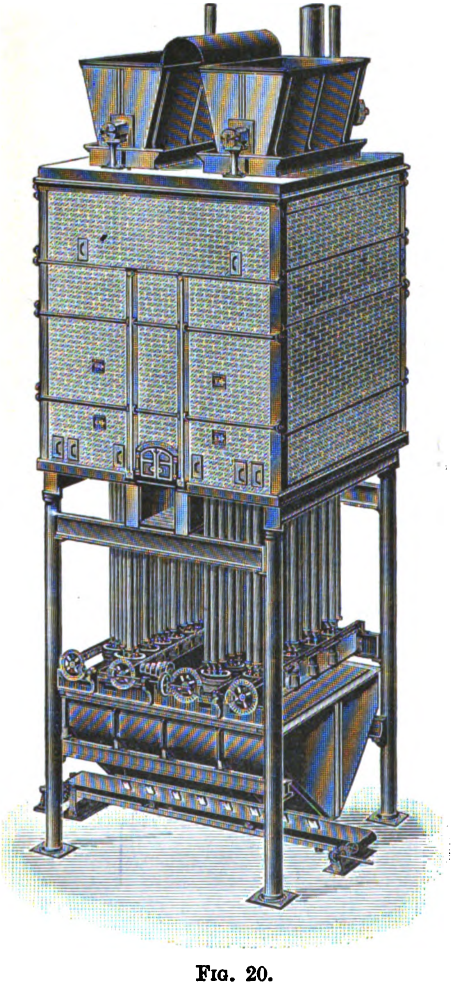

Fig. 20.

(5) *Boiling to grain.* After being sufficiently decolorised in the manner described above, the liquor is next evaporated to crystallisation point, or 'boiled to grain.' In the refinery triple or quadruple evaporators, as described under (a) *Beet Sugar Manufacture* (p. 217), are not employed for concentrating the liquors, vacuum pans being always used. If large grain be desired, when the pan is nearly full a considerable portion of its contents is allowed to run out, and the valve is then closed. Fresh liquor is now introduced until the pan is again nearly full, and, the boiling being continued, the sugar from this is deposited upon the surface of the crystals left in the pan. This operation, known as 'cutting,' is repeated several times, yielding each time larger and larger grain. It is generally the practice to raise the temperature of the massecuite 10° to 15°F. before discharging or 'letting-go' to render the mass less viscous. When large crystals are required, crystals are often put in the pan with the first liquor. If the object be to produce soft sugars, or 'pieces,' a larger quantity of liquor or of syrup from a previous operation is introduced into the pan, and on this being boiled down to the crystallising point, yields a greater number of small crystals, each of which, acting as a centre of crystallisation, lessens the time of boiling, thereby producing a massecuite of smaller grain. The larger crystals are boiled at a comparatively high temperature, from 160° to 190°F., and the 'pieces' at from 120° to 140°F. The time of boiling, in the former case, is about three times longer than in the latter. A pan of crystals will thus take from 8 to 12 hours to boil, whilst a pan of pieces or loaf-sugar will take from 2½ to 4 hours, the time varying with the heating surface of the pan, the density of the liquor, &c.

(6) *Separation of the crystals in the centrifugal machines.* On leaving the vacuum pan, the massecuite passes into the 'heaters.' These are either made cylindrical, or in the shape of a trough, and are generally fitted with stirring gear, being also sometimes heated with steam jackets. In the refinery various means are employed to convey the massecuite from the heater to the centrifugal machines. Metal trucks running on rails are often used, each being large enough to charge one centrifugal machine. The truck is run below the heater, and a valve at the bottom of the latter is then opened until the truck is full of massecuite. The full truck is next run over the top of a centrifugal machine, which has been already set in motion, and is running at a somewhat low speed. A sliding valve at the bottom of the truck is now opened, and its contents fall into the moving machine. The velocity is then increased, and a little water is sometimes added towards the end of the operation to assist in washing out the adhering syrup. When the sugar is deemed to be sufficiently dry, the machine is stopped, and the sugar is removed through openings in the bottom of the machine, which have been closed up during the machining, or it is sometimes taken out from the top.

If the massecuite machined is of low quality, the resulting sugar, on leaving the machine, is allowed to fall upon a riddle which is kept moving backwards and forwards, and any syrup knobs are broken up by hand and mixed with the rest of the sugar.

The syrup from the centrifugal machines is again concentrated and yields another crop of sugar; or it is mixed with the 'bag-washings' and the 'sweet-water' from the char, and used for making a lower quality of raw liquor.

In many of the Scotch, and also in some English refineries, no molasses is turned out, but the syrup resulting from the last products of one day is returned to form part of the next day's melting. To work this system with success it is necessary to employ raw sugars of a good description. The products of this mode of working are a first, second, and sometimes a third quality of white sugar in the form of small crystals, and two or three lower kinds of what is known as 'moist sugar' or soft 'pieces,' to be mentioned further on.

The use of this system favours the production of a large turn-out, owing to the rapidity with which the sugar is refined, the first product being often ready for sale the day after the raw sugar has entered the refinery, and the remaining products within two or three days.

Having described the process of refining as far as the production of the massecuite and the separation of the crystals in the centrifugal machine, the methods used in the manufacture of: (*a*) loaf; (*b*) cube; (*c*) granulated; (*d*) crystal; (*e*) yellow crystals; (*f*) soft pieces, and (*g*) castor and icing sugars will now be given.

(*a*) *Loaf sugar*. Liquor of good quality is boiled in a vacuum-pan to a fine-grained thick massecuite, which, after being heated in a steam-jacketed heater to about 180°F., is run into conical sheet-iron moulds. The moulds are placed on the floor at the basement of the refinery, the room being termed the 'fill house.' They are arranged in rows, touching and supporting each other. Before being filled, the small hole at the pointed end, or nose, of each mould is closed by means of a screwed-up rag, or, better, by a wooden spigot. The moulds remain in the fill-house from 10 to 12 hours, during which their contents are stirred up until the mass becomes thick and there is no danger of the crystals settling out and so rendering the loaf of unequal texture. When their contents are set, the moulds are removed to one of the upper floors of the refinery, and the plug closing the hole in the nose of each mould being removed, a pointed iron rod is inserted into the sugar to the depth of 2 or 3 ins. to facilitate the drainage of the syrup. The moulds are next placed in holes in racks or stages, and the so-called 'green syrup' drained away into gutters placed beneath. The stages are generally made of wood, and the holes are arranged at such a distance apart that the rims at the top of the moulds may touch and afford mutual support. After remaining on the stages for about 24 hours the green syrup ceases to run, and the soft surface of the sugar is then removed, and mixed with a perfectly colourless and nearly saturated solution of sugar (fine liquor) forming a magma which is then replaced in the mould, thus making a flat, porous surface, through which the fine liquor, afterwards employed for washing the sugar, passes in a slow even stream. By this means the danger of the fine liquor taking a short passage through the loosest part of the loaf is avoided. When the surface of the magma has become dry more fine liquor is run on, and this operation is repeated several times until the syrup running away is colourless. When such is the case, the sugar is allowed to drain until only a few inches of the pointed end or nose remains in a moist state; the syrup from this may be removed by suction or centrifugal force, but the usual practice has been to cut the moist end off. The upper surface of each loaf must also be removed, the sugar obtained in each of these operations being used for making fine liquor. The loaves are now taken from the moulds by inverting the latter and striking them on the rim against a hard block of wood. Each loaf is next placed on its base, in racks, one above the other, heated by steam pipes or hot air to about 120°F. Sometimes the loaves are covered with paper before they are dried in the stove to avoid the danger of cracking through accidental currents of cold air. The time occupied in these various operations depends in a great measure upon the quality of the raw sugar employed, and the grain of the fine sugar produced, but it may generally be said that the process from beginning to end occupies from 10 to 14 days, and that the sugar is for about half this time in the stoves.

(*b*) *Cube sugar*. Attention has been directed to the importance of finding some more rapid mode of working, and the result has been that numerous inventions have been brought out and patented for this purpose. These inventions may be divided into two classes, (1) those producing moulded sugar from massecuite in the form of slabs or sticks; and (2) those producing sticks or cubes of sugar, by means of pressure, from soft white sugar which has been dried and purified in a centrifugal machine. Under the first named category, the most important is Langen's process. In this the massecuite is run into small segmental moulds divided every ⅞ in. or so by means of movable iron plates. The moulds are placed one upon another, with a perforated plate, the edges of which are covered with cloth, to make a joint, and they are held down to the top of an iron truck. They are then filled, and allowed to remain till the sugar has set, when the moulds are taken apart and placed in a special centrifugal machine, by which the green syrup is removed. Then they are taken to another centrifugal machine, in which the sugar is washed by fine liquor, this process being repeated, if necessary. These two operations are sometimes effected in the same machine. The sugar slabs are afterwards dried in a stove and cut up into cubes. In the Adant process, a modification of Langen's, the principal advantage is that the slabs are placed edgewise in the centrifugal, their removal thus being rendered easier. Duncan and Newlands have also devised a plan of producing moulded sugar, in the form of sticks, which has been somewhat largely used.

(2) The principal processes in use for making pressed cubes are those of Hersey and of Pzillas. By means of the Hersey cube machine (Fig. 21), cubes are made in the following way: Perfectly white moist sugar of good quality from the centrifugal machine is fed into the hopper at the top of the machine, and is then automatically mixed with a small quantity of liquor, just sufficient to cause the grains to bind together. At the bottom of this hopper is a hollow revolving drum, in the periphery of which are rows of moulds, each of the size of the cube it is intended to make These moulds are open at the top, but are closed at the bottom by movable plungers connected together by iron bars placed parallel

with the axis of the drum. These bars are caused to advance or retreat by means of a cam arrangement. The sugar falls from the hopper into the row of moulds which happens to be under it, and in which the plungers are withdrawn by the action of the cams to their fullest extent; the drum then moves, causing another row of empty moulds to receive their charge. The full moulds pass behind an iron 'press plate,' extending about half way round the drum, which closes up the top openings, and against this plate the sugar is gradually squeezed, by means of the plungers, until the filled moulds reach the bottom of the press plate, when the cubes are pushed out in rows on to small tin plates, which are carried on a band moving in unison with the drum. The plates containing the comparatively soft moist cubes are then placed in a stove heated by steam pipes, and the sugar on drying becomes hard enough to pack into barrels. The greater portion of the hard sugar consumed in the United States is made by this process. One such machine will convert 250 tons of soft sugar into cubes, weekly, with a comparatively small amount of manual assistance.

The Pzillas cube machine, which is largely used on the Continent, was invented prior to the last-described machine, and resembles it in many respects. The sugar, however, is turned out in the form of sticks, and requires to be cut into cubes by means of a cutting-machine. This latter consists of a table on which the sticks, after being arranged side by side, are moved by an endless band, passing on their journey between knives having a reciprocating movement, causing them to cut the sugar into cubes or tablets. Other machines have been devised for pressing sugar, but as they have not come into general use, it is only necessary to say that most of them consist of tables on which are placed metallic plates perforated with square holes which are filled with soft sugar, and are then automatically moved under a plunger, the bottom of which is made with cube-shaped projections which fit into the holes in the plate and press the sugar. The plate is then moved on again over a portion of the table which is perforated in a similar way, and the cubes are pushed through the holes, by means of plungers, on a travelling band.

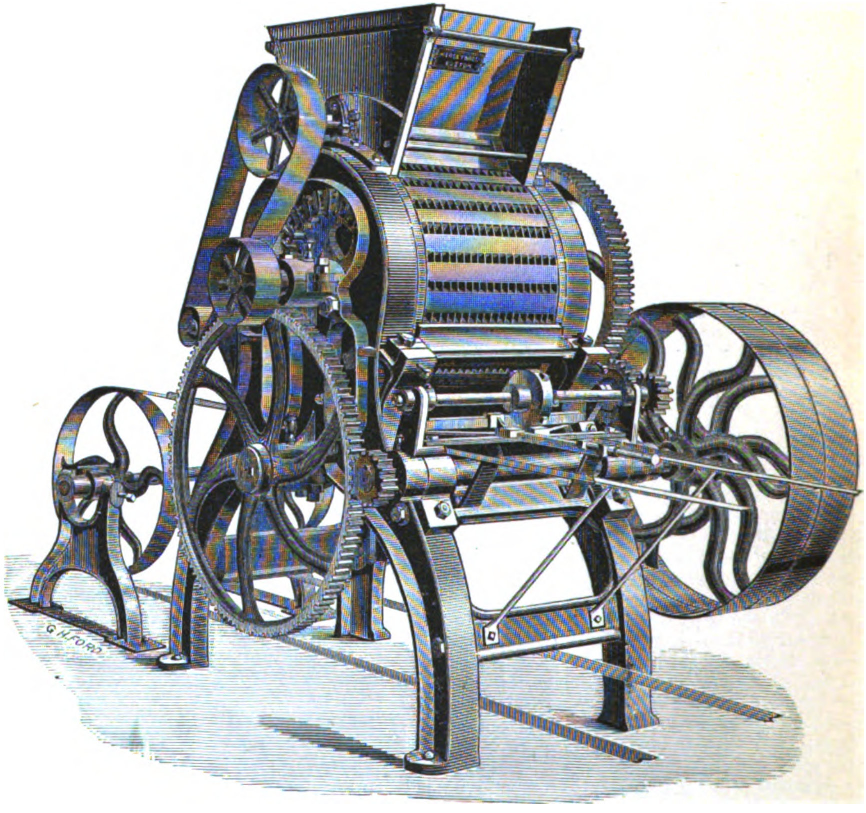

FIG. 21.—HERSEY CUBE MACHINE.

(c) *Granulated sugar*. An important process for drying or granulating sugar, known as the 'Hersey granulating process,' is now in operation in almost every refinery in the United States and Canada, and is also adopted in many refineries in Europe and elsewhere. The machine employed for this purpose is illustrated in Fig. 22, which shows a longitudinal section through the centre of the machine, and a transverse section on the line AB, seen in the longitudinal section.

The heating-cylinder—which is situated inside the conveyor-cylinder and revolves with it—is filled with steam through a pipe in one end; and the water of condensation is delivered from the opposite end, through a discharge pipe, so that the heating-cylinder is always full of steam.

The sugar is fed at one end through a spout by a set of rolls placed above the machine, or by a screw-feed; and by lifting-shelves placed on the inside of the outer cylinder, it is carried up and dropped in a continuous shower upon the heating-cylinder, and rolled off by the rotation of the machine, to be again carried up, working forward to the opposite end by the inclination of the apparatus, and there delivered into a screen for separating into the different grades. The heater-cylinder is placed centrally within the conveyor-cylinder, and is adjusted and secured by means of suitable adjusting screws. The conveyor-cylinder is made of iron; and the heater of steel plate. The conconveyor-cylinder is 23 ft. long and 6 ft. in diameter, with the heater-cylinder 20 ft. long and 3 ft. in diameter, and makes six revs. per minute. There is a striker for the purpose of removing any sugar that may adhere to the cylinder on first entering the machine, and it is worked by cams. The machine is made to rotate by means of gearing upon the outside of the conveyor-cylinder, driven by a pinion on a shaft. The current of air constantly passing through the machine carries off the moisture from the sugar through an exit pipe.

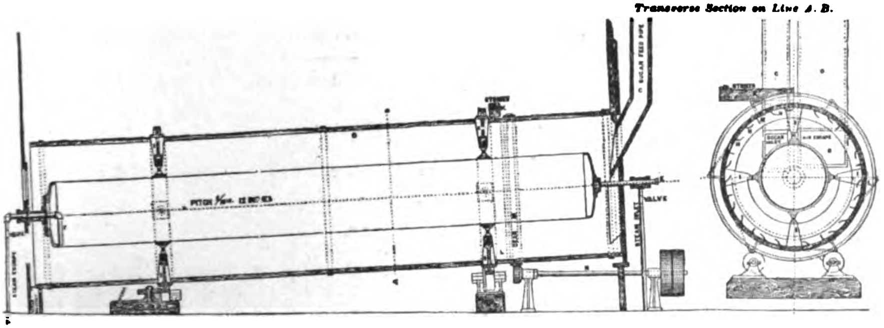

FIG. 22.—HERSEY GRANULATOR.

One important feature of the machine is that the sugar being delivered from the end into which the cold air is passing is cool, so that it does not cake, and can be immediately barrelled, and will not cause the barrels to shrink. The sugar being granulated or dried, not so much from extreme heat but by the moisture being constantly carried from the machine, is brought out clear and white.

(*d*) *Crystal sugar.* This class of sugar is produced by boiling the contents of the vacuum pan to about the same size of grain as in the case of that required for granulated. When this is done, half the massecuite is 'struck out,' and its place taken by fresh liquor, which is gradually drawn in, boiling being recontinued, so that the existing crystals increase in size, instead of fresh ones being formed. This operation is repeated, until the crystals attain the desired size after which the contents of the pan are 'let go,' being finally machined in the usual way.

(*e*) *Yellow crystals.* This sugar is made either from refined crystal, or from raw 88° beet sugar of good colour, previously washed in centrifugals with steam or water, by simply mixing with about 2 p.c. of golden syrup and a minute amount of Newlands' 'Golden Bloom' (Boake, Roberts and Co., Stratford, London). The mixing may be done by hand by spreading the sugar on a floor in a layer about a foot deep, watering it with the 2 p.c. of syrup and bloom, and turning the whole over with shovels; or it may perhaps preferably be carried out in a trough in which the sugar, syrup, and bloom are incorporated by means of a worm conveyor.

(*f*) *Soft pieces.* Soft pieces is a second quality sugar boiled from the syrup spun off the massecuite for granulated or for crystal sugar, after it has been passed over char. As a rule, 'soft pieces' is quite a low sugar, polarising less even than the raw sugar initially employed, but, of course, much improved in colour.

(*g*) *Castor and icing sugars.* Castor is a very small-grained granulated sugar; while icing is simply the finely ground and sifted lumps and pieces from the manufacture of cube and loaf sugars. There is, however, comparatively little trade done in these two products.

STATISTICS.

World's production of raw sugar. According to recently published reliable statistics (Board of Trade White Paper, 1911, No. 281), the estimated production of raw beet and raw cane sugar, for the entire world, during the years 1907, 1908, 1909, and 1910 inclusive, was as tabulated on p. 232.

Relative cost of production of beet and cane sugars. In the case of beet sugar, the cost of production is stated to be between 8*s.* 6*d.* and 9*s.* 10*d.* per cwt., depending upon the richness and quality of the roots, and the extraction in the factory. For cane sugar, the cost of production appears to vary from 6*s.* 6*d.* to 9*s.* 6*d.* per cwt., according to the country, the mode of

The International Sugar Journal, London; The American Sugar Industry, Chicago; The Louisiana Planter, New Orleans; Journal des Fabricants de Sucre, Paris; Bulletin de l'Association des Chimistes de Sucrerie, Paris; La Sucrerie Belge, Brussels; Revista Industrial, Tucuman; Centralblatt für die Zuckerindustrie, Magdeburg; Die deutsche Zuckerindustrie, Berlin; Zeitschrift des Vereins der deutschen Zuckerindustrie, Berlin; Österreichisch-Ungarische Zeitschrift für Zuckerindustrie, Vienna; Zeitschrift für Zuckerindustrie in Böhmen, Prague; Archief voor de Suikerindustrie in Nederlandsch-Indië, Soerabaia, Java.

The writer is obliged to Mr. James P. Ogilvie, Technical Editor of The International Sugar Journal, for reading the proofs of this article; and to the following firms for illustrations: Messrs. Wohanka and Co., of Prague and Vienna (sugar beet); Messrs. the Maschinenfabrik Grevenbroich, of Grevenbroich, Niederrhein, Germany (washer, slicer, diffuser, saturation tanks, and after-product plant); Messrs. Mirrlees Watson and Co., Ltd., of Glasgow (cane mill, defecator, triple effect, vacuum pan, and centrifugals); Messrs. Fawcett Preston, of Liverpool (juice-heater, and sulphur apparatus); Messrs. J. Buchanan and Son, of Liverpool (eliminator and char kiln); and Messrs. S. H. Johnson and Co., Ltd., of Stratford, London (filter-press).

B. E. R. N.

SUGAR ANALYSIS.

The methods to be described in this article are selections from the most modern, which have been found to give accurate results in the writer's hands. Since they are all empirical it has been necessary to give a large number of tables. These, in most cases, have been condensed from the originals, so that intermediate values must be obtained by interpolation.

Qualitative reactions of the sugars. The power of reducing alkaline solutions of metallic salts (*see* pp. 246, 255) and that of forming phenylosazones (*see* p. 261), are exhibited by those sugars which contain a free carbonyl group. Some of the latter class of sugars form characteristic phenylhydrazones. Thus the phenylhydrazones of mannose, fucose, rhamnose, and rhodeose are very insoluble and separate almost immediately when a solution containing equal parts of phenylhydrazine and 50 p.c. acetic acid is added to a cold aqueous solution of either of the above sugars. The use of substituted derivatives of phenylhydrazine as reagents for identifying different sugars is often of service both as regards the formation of hydrazones and of osazones. Methylphenylhydrazine gives a characteristic osazone with lævulose, but does not form an osazone with dextrose or mannose. The sugars also give characteristic colour reactions with different phenols. For a description of these and other reactions the reader is referred to the article on CARBOHYDRATES (vol. i. p. 631).

Polarimeters. The theory and construction of polarimeters are dealt with in a special article on POLARIMETRY (vol. iv. p. 309). The article, however, deals exclusively with instruments in which the rotation of the plane of polarised light is measured by rotating the analyser, and no description is included of those instruments, exclusively used in sugar technology, in which the rotation is measured by quartz compensation. These instruments are generally known as saccharimeters, because their use is restricted to sugars, and more especially to sucrose (cane sugar), for which they were originally designed. It was the French physicist, Soleil, who in 1848 devised a method of determining the strength of sugar solutions polarimetrically which would obviate the use of monochromatic light, which presents many inconveniences and difficulties in practical work. Soleil's method was based on the fact that the rotation of the plane of polarised light by solutions of sucrose and by solid rock crystal (quartz) respectively, runs approximately parallel for light of different degrees of refrangibility. In other words, solutions of sucrose and solid rock crystal have substantially the same rotatory dispersion. Soleil therefore constructed an instrument in which the polariser and analyser were fixed, and in which the rotation of the plane of polarised light by a sugar solution could be compensated by means of a definite thickness of quartz rotating the plane in the opposite direction. The principle of this method of compensation may be seen by the aid of the following diagrams.

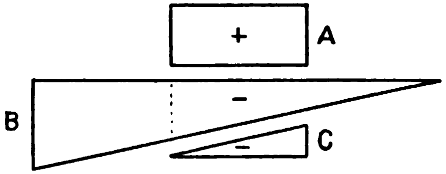

Fig. 23.

In the single-wedge system, Fig. 23, the plate A of dextro-rotatory quartz is stationary, whilst the wedge B of lævo-rotatory quartz is capable of being moved in a lateral direction, and the wedge C of lævo-rotatory quartz is again stationary. The system as arranged in the diagram is at the zero-point, that is to say the two lævo-rotatory quartz wedges exactly compensate the dextro-rotatory quartz plate. If now a dextro-rotatory sugar solution is placed in the instrument and the equilibrium thereby destroyed, the movable lævo-rotatory quartz wedge B is moved from left to right until the alteration caused by the sugar solution is exactly compensated. Obviously by employing a plate and wedges the rotation of which is of opposite sign, an instrument for lævo-rotatory sugars might be constructed.

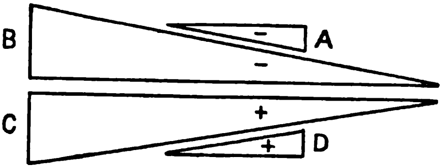

Fig. 24.

The double-wedge system, Fig. 24, is adapted for either dextro- or lævo-rotatory sugars. It will be seen that in this system there is no quartz plate but two small wedges A and D of opposite rotation, which are fixed, and two large wedges, B and C, also of opposite rotation, which can be moved in a lateral direction as already explained.

The earliest instruments to which the principle of quartz compensation was applied were the Soleil-Duboscq in France, and the Soleil-Ventzke Scheibler in Germany. In both these instruments the measurements are made in terms of the mean yellow ray. Two half discs of quartz of opposite rotation, cut perpendicularly to their optic axes, and each having a thickness of 3·75 mm., are cemented together. If such a plate be interposed between two Nicol prisms the principal planes of which are parallel, and white light be passed through the system, the two halves of the field will be of a uniform rose colour, due to the blending of the spectral colours, minus the yellow which is extinguished. The slightest rotation of the analyser (or in the case of quartz-compensating instruments, movement of the quartz wedge) will change one half of the field to blue, and the other to red, or *vice versa*. This is the so-called transition tint, which is complementary to the medium yellow or *jaune moyen* of Biot. If a sugar solution be placed in an instrument employing this device, the equilibrium in colour of the transition tint will be destroyed and can only be restored by rotating the analyser a certain number of degrees or by quartz compensation.

In former times most of the measurements of specific rotatory power were made in terms of this transition tint, the results being denoted by the symbol $[\alpha]_j$ (j=French *jaune*).[1] For a full discussion of the principle of these instruments the reader is referred to special works. Instruments employing the transition tint have, however, long since ceased to be used generally. Among their disadvantages is the fact that they cannot be used by those who are colour blind, and moreover in sugar technology one of the chief reasons for their abandonment is the difficulty of examining coloured solutions with them.

Modern double-field saccharimeters are the so-called penumbra or half-shadow instruments, employing white light and quartz compensation. Two of these may be mentioned, namely the German instrument of Schmidt and Haensch, and the French instrument of Laurent. The first is constructed for the Ventzke scale, whilst the second employs the French scale. The principles of both of these scales will be dealt with later.

In the earliest form of the German instrument, the half shadow effect is produced by the use of a Jellet-Cornu prism as polariser (Jellet, Report British Assoc. 1860, 13; Cornu, Bull. Soc. chim. 1870, [ii.] 14, 140). An ordinary Nicol prism is divided into halves along its whole length corresponding to the plane of the shortest diagonal. A small wedge $\alpha/2$ is ground from the surface of each half, and the two are then reunited by means of Canada balsam. This makes a double Nicol prism which has two principal planes, making the half-shadow angle α with an ordinary Nicol prism as analyser, the principal plane of the latter being set at right angles to the bisectrix of the principal planes of the divided prism. In the Laurent instrument the half-shadow effect is produced by means of a half disc of quartz (*see* vol. iv. p. 317). The Lippich prism is now more generally used as polariser in the German instrument. By its means a triple field is given (see vol. iv. p. 318).

The Schmidt and Haensch half-shadow saccharimeter with Jellet-Cornu prism as polariser is shown in Fig. 25.

The more modern form of the instrument, furnished with a Lippich polariser, is shown in Fig. 26. This particular instrument has the double-wedge system of compensation, the wedges being protected in a case.

Saccharimeters are furnished with an arbitrary scale, which gives percentages of sucrose direct when a solution of definite concentration is examined in a tube having a length of 2 dm. The weight of pure sucrose which dissolved in

---

[1] For the relation of readings on this scale to those when sodium light is employed, see p. 237.

water and made up to 100 c.c. gives a reading of 100 divisions when examined in a 2-dm. tube is called the normal weight. The German and French instruments employ different normal weights.

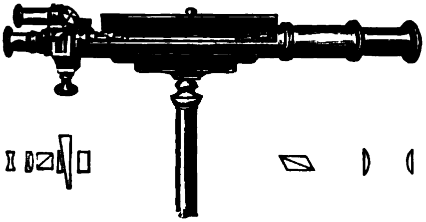

FIG. 25.

Saccharimetry—Ventzke, or German scale. With the object of dispensing with weighing in saccharimetric work, Ventzke took as his normal solution one of sucrose, which had a sp.gr. of 1·1 at 17·5°/17·5°, his idea being that since such a solution possesses unit excess gravity, the percentage of sucrose might be determined in a solution having approximately the concentration of the normal by taking its polarimetric reading in a 2-dm. tube and its specific gravity. It was soon found, however, that as the mineral matters and organic matters other than sucrose present in raw sugars had a different effect on the specific gravity than had sucrose, such a method was inaccurate. A solution of sucrose of the above specific gravity contains 26·048 grms. of sucrose dissolved in 100 Mohr's cubic centimetres.[1] The Ventzke normal weight when metric cubic centimetres are employed is 25·9872, or for practical purposes 26 grms. The International Commission, at its third meeting in Paris in 1900, recognising the confusion arising from the two standards of volume, recommended the abandonment of the Mohr for the metric cubic centimetre, and they also recommended that all readings should be made at 20°C. The change in temperature from 17·5°C. to 20°C. necessitated a recalculation of the normal weight owing to the difference in the specific rotations of sucrose and quartz at these two temperatures. The normal weight thus found is 26·0082 grms., and it was decided to fix it at 26 grms.

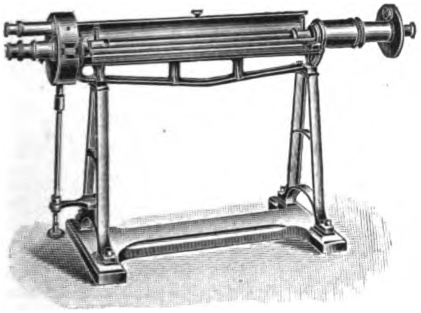

FIG. 26.

The normal weight used in the scale adopted by saccharimeters of French manufacture was fixed in 1896 at the meeting of the International Congress of Applied Chemistry in Paris as 16·29 grms. of sucrose dissolved in water and made up to 100 metric cubic centimetres at 20°C. If Mohr's cubic centimetres are used the normal weight was fixed at 16·33 grms.

It is a fact known to all who are engaged in accurate saccharimetric work that the normal weights of different saccharimeters vary, and that it is always necessary to determine the exact weight for each instrument. The German firm, Messrs. Schmidt and Haensch, are, however, particularly careful in the graduation of their scale, as may be seen from the following extract from a letter addressed to Dr. C. A. Browne (*see* A Handbook of Sugar Analysis, 1912, p. 117).

'The establishment of the scale divisions of our saccharimeters is made at a temperature of 20°C. After fixing the zero-point the linear distance of the 100-degree division is determined by means of a normal quartz plate reading exactly 100 degrees, and standardised at the Physikalisch-Technische Reichsanstalt. This linear distance is then divided into 100 exactly equal parts, the intermediary divisions being also verified by means of corresponding normal standardised quartz plates. The surfaces of the quartz wedges are made perfectly plane, so that a quartz stratum of half thickness corresponds to a half value in the division. Slight errors cannot be prevented, as it is impossible to obtain quartz wedges of the necessary length which are absolutely optically homogeneous throughout. The variableness in the specific rotation of sucrose with concentration of solution is not taken into consideration in the establishment of the scale division, and this must be corrected for by calculation. Aberrations in the scale division caused by impurities in the quartz can be detected by the control observation tube.'

Verification of the saccharimeter scale. For this purpose accurately ground quartz plates, standardised by the Physikalisch-Technische Reichsanstalt can now be obtained, but it is obviously prohibitive to purchase a sufficient number of these to check the entire scale. It is, moreover, desirable that this shall be done by means of solutions of pure sucrose of different concentration. Commercial sucrose, although of a high degree of purity, cannot be employed for this purpose, but it must be purified as follows. A concentrated solution of the purest loaf or cube sugar is prepared at the lowest possible temperature. This is further concentrated by evaporation under a partial vacuum, such that the boiling-point never exceeds 80°C. The syrup is then thinned down to twice its volume with a little redistilled commercial alcohol, mixed in a Winchester quart bottle with two to three times its volume of redistilled commercial alcohol, and the mixture vigorously shaken until the crystals separate in the form of

---

[1] The Mohr cubic centimetre, introduced in 1855, is the volume occupied by 1 gram of water at 17·5°C., weighed in air with brass weights. The writer of this article has, for many years, employed the fluid gram at 15·5°C. for all volumetric determinations except those which concern gas analysis. The advantages are that the instruments can be so readily checked, and that specific gravities are usually taken in commercial laboratories at 15·5°/15·5°.

a magma. These crystals are filtered from the mother liquor on a Buchner funnel, washed with alcohol, again dissolved in water, and the operations repeated. After two precipitations the sugar is usually pure. It should be dried on a porous plate over sulphuric acid in a vacuum desiccator, and finally heated for a short period at 80°C. The sugar so prepared should then be examined in various ways to ascertain its purity. The mineral matter should be estimated on at least 10 grms. (*see* p. 262), its behaviour towards Fehling's solution should be ascertained, and the specific rotatory power should be determined in a polarimeter making use of sodium light, in which the measurement is made by rotation of the analyser.

The scale having been checked with sugar solutions of different concentration, or by the control tube (*see* below), and the results corrected for the different conditions as described below, any further checking of the instrument can be accomplished by means of standard quartz plates.

One of the most convenient ways of checking the scale of a saccharimeter is by means of the Landolt control tube, the latest form of which, as sold by Schmidt and Haensch, is illustrated in Fig. 27.

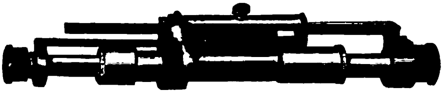

FIG. 27.

The tube can be adjusted to any length from 220 to 420 mm. by means of a telescopic arrangement. The length of a solution is read off on a scale by means of a vernier to 0·1 mm. A funnel is used to receive the overflow of solution as the tube is shortened. For filling the tube the funnel is removed and the opening closed by means of a plug. The tube is then drawn out to its full length, and after moving one of the caps, filled in the usual way.

The following is the way in which the tube is used. A sugar solution is prepared of such a concentration that it gives a reading of 100 divisions at a length of about 400 mm. This will serve to test the scale at a point a few divisions above 100, and at all points below 100 to 55. For further information the reader is referred to Landolt (The Optical Rotating Power of Organic Substances, 1902, p. 441).

In verifying a saccharimeter by means of sucrose, account must be taken of the effect of concentration on the specific rotatory power of that sugar. The useful table shown in the next column has been calculated from the independent experiments of Schmitz and of Landolt by Browne (Handbook of Sugar Analysis, 1912, p. 118).

When cane sugar solutions are examined in a quartz compensating polarimeter with white light, errors due to the difference of rotatory dispersion of cane sugar and quartz produced by light of higher refrangibility are introduced. In order to eliminate this source of error Schönrock (Zeitsch. Ver Deut. Zuckerind., 54, 521) suggests that the white light should be filtered through a layer of 1·5 cm. thickness of a 6 p.c. solution of potassium dichromate.

TABLE I.—*Effect of Concentration of Sucrose on Saccharimeter Readings.*

Scale division.	Concentration grams sucrose, 100 true cubic centimetres, 20°C.	Specific rotation sucrose, 20°C.	Actual sucrose value of scale division.	
			By Landolt's formula.	By Schmitz's formula.
100·00	26·00	66·502	100·00	100·00
96·00	24·96	66·506	96·00	95·98
95·00	24·70	66·507	94·99	94·98
90·00	23·40	66·510	89·99	89·97
85·00	22·10	66·513	84·99	84·96
80·00	20·80	66·514	79·99	79·95

20·00	5·20	66·474	20·01	19·95
15·00	3·90	66·465	15·01	14·96
10·00	2·60	66·456	10·01	9·97
6·00	1·56	66·443	6·01	5·98
5·00	1·30	66·442	5·00	4·98

Effect of temperature. This effect in the case of a quartz compensating instrument, apart from the change in the specific rotation of sucrose at different temperatures, is threefold as shown by Schönrock (*l.c.*). Thus: (1) the change in shape of the quartz wedge by expansion or contraction; (2) the change in the specific rotation of quartz; and (3) the change due to the expansion or contraction of the material of which the scale is composed. For quartz compensating Ventzke saccharimeters, having a scale of the alloy, nickeline, the polarisation value at any temperature P^t of a sugar solution is $P^t = P^{20^\circ}[1+0{\cdot}000148(t-20)]$. When the scale is etched on the quartz wedge, the correction coefficient is 0·000130. C. A. Browne (*l.c.*, p. 127) has compiled some very useful data on the effect of temperature in saccharimetry. He points out that the increase in the reading of quartz with the temperature produces a lowering of the saccharimetric readings, since a lesser thickness of quartz is required for compensation. With sugars which undergo a decrease of rotation with increase in temperature, the combined influences of quartz and sugars are in one direction, and the error introduced may be considerable. Thus with sucrose the temperature coefficient at 10°C. is (0·000148+0·000242), at 20°C. it is (0·000148+0·000184), and at 30°C. it is (0·000148+0·000121)

The following table giving the variation in the Ventzke reading per 1°C. according to different observers, is quoted from Browne's treatise.

Andrews (Technology Quarterly, Mass. Inst. Technology, May (1889), 367)	0·0300
The United States Coast and Geodetic Survey	0·0293
Wiley (J. Amer. Chem. Soc. 21, 568)	0·0314
Prisen Geerligs (Archief Java Suikerind, July, 1903)	0·0300
Watts and Tempany (West Indian Bull. vol. iii. p. 140)	0·0310
Average	0·0303

The average temperature coefficient 0·000303 is thus very close to Schönrock's value for 25°C. (0·000148+0·000152)=0·000300. For temperatures between 20° and 30° C. the general equation $P^{20^\circ}=P^{t}\,1+0{\cdot}00030\,(t-20^\circ)$ may be used for correcting Ventzke readings to 20°C.

The temperature coefficients of other of the better known sugars for readings on the Ventzke scale have been calculated by Browne, and are given in the following table :—

TABLE II.—*Temperature Co-efficients of Different Sugars of Ventzke Scale.*

Sugar.	A. $[\alpha]_D^{20^\circ}$	B. Change in $[\alpha]_D^{20^\circ}$ for 1°C. increase.	C. Temperature coefficient $\frac{B}{A}$.	Temperature coefficient of reading upon Ventzke scale for 1°C. increase. C+coefficient for quartz (−0·000148).	
Fructose	−92·50	+0·625	−0·006757	−0·006905	→ 0
Invert sugar	−20·00	+0·312	−0·015600	−0·015748	→ 0
Lactose	+52·53	−0·070	−0·001332	−0·001480	0 ←
Maltose	+138·04	−0·095	−0·000688	−0·000836	0 ←
Glucose	+53·23	No change.	No change.	−0·000148	0 ←

In the case in which a mixture of sugars is examined in a saccharimeter, the combined influence of the temperature coefficients of each sugar must be taken into account.

In order to obviate errors arising from inequalities of temperature in polarimetric work where great accuracy is required, the readings are conducted in a chamber kept at a constant temperature.

C. A. Browne (*l.c.*, p. 145) has calculated the following useful table, showing the relation between the Ventzke sugar scale, the French sugar scale, and degrees of arc (sodium light)—

Scale.	Equivalent.
1° Ventzke sugar scale=0·34657°	angular rotation D.
1° angular rotation D =2·88542°	Ventzke sugar scale.
1° French sugar scale =0·21666°	angular rotation D.
1° angular rotation D =4·61553°	French sugar scale.
1° French sugar scale =0·62516°	Ventzke sugar scale.
1° Ventzke sugar scale=1·59960°	French sugar scale.

The factor for converting divisions of the Ventzke scale into angular degrees (sodium light), differs slightly for the different sugars. Thus Landolt (Ber. 21, 194) gives the following factors for five sugars—

Sucrose	0·3465
Lactose	0·3452
Glucose	0·3448
Invert sugar	0·3432
Raffinose	0·3450

Brown, Morris and Millar (J. Chem. Soc. Trans. 71, 92) give the following values—

Sucrose, 10 p.c. solution	0·3469
Maltose, 10 p.c. solution	0·3449
,, 5 ,, ,,	0·3457
Glucose, 10 p.c. solution	0·3442
,, 5 ,, ,,	0·3454
Starch products, 10 p.c. solution	0·3458
,, 5 ,, ,,	0·3454

Herzfeld (Ber. 28, 441), using a solution containing 11·29 grms. of anhydrous maltose in 100 c.c., found the value of the factor to be 0·3471. For ordinary practical purposes, the writer employs the factor 0·346 for converting divisions of the Ventzke into degrees of arc (sodium light) for all sugars.

The following table gives the rotation of some sugars in angular degrees and in divisions Ventzke as determined by Morris.

TABLE III.—*Rotation of some Sugars in* 10 *p.c. Solution at* 20°*C.*

(According to Morris (J. Fed. Inst. Brewing, 1898, 4, 174).)

—	$[\alpha]_D$	Reading in a 2 dm. tube in the half-shadow polarimeter employing white light. Ventzke divisions for 1 gram of sugar in 100 c.c.
Dextrin	202·0°	11·66
Maltose (anhydrous)	138·0°	7·97
Cane sugar	66·5°	3·84
Dextrose	52·8°	3·05
Lævulose	−92·0°	−5·31
Invert sugar	−19·6°	−1·13

For the specific rotatory powers of other sugars the article on CARBOHYDRATES (vol. i. p. 631) should be consulted.

Much of the older work is recorded in terms of the mean yellow ray $[\alpha]_j$ as measured by the transition tint. Indeed, in certain laboratories, transition tint instruments are still in use. To convert degrees $[\alpha]_j$ to degrees $[\alpha]_D$, the former must be multiplied by the factor 0·9. There has been, however, much confusion with regard to what is meant by the medium yellow ray. Thus Brown, Morris and Millar point out (J. Chem. Soc. Trans. 71, 86), that whereas the original medium yellow ray of Biot was that which was rotated 24° of arc, by a quartz 1 mm. in thickness, as measured by the transition tint, Montgolfier and also Landolt, when dealing with the medium yellow ray, refer to one having a decidedly higher refrangibility with a millimetre-quartz rotation of 24·5°.

Polarimeter tubes. The following illustration gives the tube most usually employed with the Ventzke instrument. It will be noticed that one end is considerably wider than the other. The object of this is to obviate the necessity of filling the tube completely, by which work can be conducted in a much more cleanly manner. Air bubbles collect in this wide end of the tube in a position outside of the field of vision.

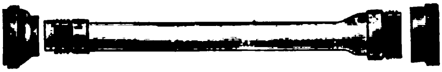

FIG. 28.

Polarimeter tubes are usually made of glass, but in some cases metal tubes are employed. These latter are not to be recommended on account of the fact that metal has a very much higher coefficient of expansion than glass.

The next illustration shows a tube which is furnished with a brass jacket in order that water may be circulated round the internal glass tube, which is T-shaped. This is for the purpose of controlling the temperature. The tube is filled by a funnel-shaped projection in the middle, which funnel also serves for the insertion of a thermometer to measure the temperature of the solution. Tubes of this kind are used in saccharimetry for the Clerget process (*see* p. 242).

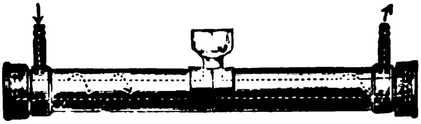

FIG. 29.

Methods for the polarisation of raw sugars. For this purpose the normal weight of the sample is dissolved in water, clarified with basic lead acetate, a little alumina cream added, the solution made up to 100 c.c., and the filtrate observed in a 2-dm. tube. The weighing out of the sugar is conveniently carried out in a special form of nickel boat. It is usual to dissolve the sugar at the room temperature.

Basic lead acetate is prepared in the writer's laboratories as follows: Lead acetate in fine crystals (150 grms.) is mixed in an evaporating basin with litharge (45 grms.) and water (25 c.c.). This paste is allowed to remain at the room temperature for 2–3 hours with frequent stirring. At the end of this time the lead acetate and most of the litharge have gone into solution. It is, however, gently warmed on a piece of wire gauze or a sand-bath by means of a burner. The cream, which is now quite limpid and devoid of colour, is poured into 500 c.c. of water and allowed to remain until the small amount of undissolved sediment settles out. It is desirable to filter the solution. The sp.gr. of the clear filtrate is about 1·20.

Alumina cream is made by pouring a cold 2–3 p.c. solution of alum contained in a pottle bottle into dilute ammonia of sp.gr. 0·98. The converse method of precipitation yields an unsatisfactory granular product. The alumina is allowed to subside and washed in the bottle by decantation twice a day until the supernatant liquid gives no reaction with barium chloride. This usually takes about a week.

The amount of basic lead acetate to be used varies with the kind of sugar. The purest centrifugal sugars require only from 0·5 to 2 c.c.; darker products require up to 10 c.c., whilst molasses require much more. The volume of alumina cream to be used for the normal solution is about 5 c.c.

The following rules were drawn up by the International Commission on Methods of polarising Raw Sugar (Paris, 1900):—

'In general all polarisations are to be made at 20°C.

'The verification of the saccharimeter must also be made at 20°C. For instruments using the Ventzke scale 26 grms. of pure dry sucrose, weighed in air with brass weights, dissolved to 100 metric c.c. at 20°C., and polarised in a room, the temperature of which is also 20°C., must give a saccharimeter reading of exactly 100·00. The temperature of the sugar solution during polarisation must be kept constant at 20°C.

'For countries where the mean temperature is higher than 20°C., saccharimeters may be adjusted at 30°C., or any other suitable temperature, under the conditions specified above, provided that the sugar solution be made up to volume and polarised at this same temperature.

'In effecting the polarisation of substances containing sugar employ only half-shade instruments.

'During the observation keep the apparatus in a fixed position, and so far removed from the source of light that the polarising Nicol is not warmed.

'As sources of light employ lamps which give a strong illumination such as a triple gas burner with metallic cylinder, lens and reflector; gas lamps with Auer (Welsbach) burner; electric lamp; petroleum duplex lamp; sodium light.

'Before and after each set of observations the chemist must satisfy himself of the correct adjustment of his saccharimeter by means of standardised quartz plates. He must also previously satisfy himself of the accuracy of his weights, polarisation flasks, observation tubes, and cover-glass. (Scratched cover-glasses must not be used.) Make several readings and take the mean thereof, but no one reading may be neglected.

'In making a polarisation use the whole normal weight for 100 c.c., or a multiple thereof, for any corresponding volume.

'As clarifying and decolorising agents use either sub-acetate of lead, alumina cream, or concentrated solution of alum. Bone-black and decolorising powders are to be excluded.

'After bringing the solution exactly to the mark at the proper temperature, and after wiping out the neck of the flask with filter paper, pour all of the well-shaken clarified sugar solution on a rapidly acting filter. Reject the first portions of the filtrate and use the rest, which must be perfectly clear for polarisation.'

At the seventh meeting of the International Commission for Uniform Methods of Sugar

Analysis, which met at the Columbia University, New York, in September, 1912, it was decided that in commercial analyses the use of temperature correction tables should be dispensed with, as far as possible.

Errors attending the use of basic lead acetate as a clarifying agent. These are threefold, *e.g.* precipitations of certain reducing sugars, especially lævulose, volume occupied by the precipitate, and the fact that in methods of inversion, such as the Clerget method, the stronger hydrochloric acid is replaced by the weaker acetic acid.

Sachs (Zeitsch. Ver Deut. Zuckerind. 30, 229) has devised the following method for correcting the error due to the volume occupied by lead acetate precipitate. The precipitate obtained by the clarification of a sugar solution is washed with cold and hot water until free from sugar. It is then transferred to a 100 c.c. flask, half the normal weight of sucrose added, and the solution made up to 100 c.c. The filtrate is polarised in a 4-dm. tube. The volume of the precipitate is then calculated as follows :—

$$v=\frac{100(P'-P)}{P'}$$

in which v is the volume of the precipitate, P the polarisation of the sucrose used, and P′ the polarisation of the sucrose with the precipitate.

Wiechmann (Proc. 5th Inter. Cong. Applied Chem. vol. 3, p. 118) determined the specific gravity of dried lead precipitates from various raw cane sugars in petroleum. His results are given in Table IV.

TABLE IV.

Sugar.	Weight of precipitate in grams.	Specific gravity H_2O =1·00.	Volume in cu. centimetres.
Jamaica Muscovado	0·4559	1·88	0·24
Maceio Muscovado	0·8112	1·65	0·49
San Domingo centrifugal	0·2525	2·91	0·09
Sandwich Island centrifugal	0·1378	2·84	0·05
San Domingo concrete	1·0139	3·80	0·27
Porto Rico molasses sugar	0·8959	4·35	0·21
Sandwich Islands	1·0195	4·38	0·23
Cebu mats	1·5400	2·17	0·71
Manila mats	1·3350	2·22	0·60

Horne (J. Amer. Chem. Soc. 26, 186) has suggested the use of dry basic lead acetate to obviate the error due to the volume of the precipitate. This is carried out as follows :—

The normal weight of sugar is dissolved in water in a 100 c.c. flask and made up to the mark without defecation. Small quantities of powdered anhydrous basic lead acetate are added to the solution until the impurities are nearly all precipitated. This point is as easily determined as in the defecation by a solution of the same salt. The organic and mineral-acid radicles in the solution combine with and precipitate the lead and lead oxide of the dry salt, whilst the acetic-acid radicle of the basic lead acetate passes into solution to combine with the bases originally united to the other acid radicles.

The results given in Table V show the very close agreement between the polarisations corrected by Sach's method, and by the use of dry defecation.

TABLE V.

Pellet (Bull. assoc. chim. sucr. dist. 23, 285) contends that the increase in polarisation due to the volume of the lead precipitate is not as great as calculated owing to the decrease in polarisation caused by the retention of sucrose in the precipitate which frequently counterbalances the error due to the volume of the precipitate. Horne (J. Amer. Chem. Soc. 29, 926) has since shown, however, that there is no appreciable retention of sucrose when dry basic lead acetate is used in minimum quantity. A possible error, to which attention has also been called by Pellet, is that any lead which passes into solution by the dry defecation method will increase the volume by the solution.

Hall (Bull. 122, U.S. Bur. of Chem. p. 225) carried out a series of experiments on a Philippine mat sugar to ascertain the effect on the polarisation of increasing amounts of dry basic lead acetate. The lead dissolved in the clarified filtrates was determined and the dilution calculated by allowing an increase in volume of 0·22 c.c. for 1 grm. of dry basic lead acetate dissolved in 100 c.c. of the solution (*v.* Table VI.).

TABLE VI.

Clarifying agent.	Amount of clarifying agent used.	In 100 c.c. filtrate. PbO.	In 100 c.c. filtrate. Basic lead acetate.	Estimated dilution.	Polarisation.
		grms.	grms.	c.c.	
Basic acetate solution .	3·0 c.c.	0·2678	—	—	86·70
Dry basic acetate . .	0·5 grm.	Trace	—	Trace	Too dark to read
,, ,, . .	1·0 grm.	0·1530	(0·20)	0·05	86·50
,, ,, . .	2·0 grms.	0·7203	(0·94)	0·20	86·60
,, ,, . .	4·0 grms.	2·1078	(2·73)	0·60	86·50

On these results C. A. Browne (*l.c.*, p. 214) remarks as follows :—

'It is noted that with an estimated dilution of 0·2 c.c. instead of a decrease in polarisation, as would be expected, there is an increase. With an estimated dilution of 0·6 c.c. the reading is the same as that first obtained, so that the combined effect of the dry lead upon the precipitation of fructose, and upon the lowering of the rotation of the fructose in solution is seen to be most pronounced. With sugar-cane products the use of dry basic lead acetate to the point of satisfactory clarification would seem to involve no decrease in polarisation. With low-grade sugar-beet and other products, which are comparatively free from fructose, there is, however, a danger of too low polarisation, since there is no compensating influence for the dilution caused by the excess of lead sub-acetate dissolved.'

It has been shown by Bates and Blake (Bull. U.S. Bur. of Standards, 3, [1] 105) that the presence of a large excess of basic lead acetate solution exerts a large influence on the rotatory power of sucrose. The results given in Table VII. are some of those obtained with normal solutions of sucrose :—

TABLE VII.

Cubic centimetres of basic lead acetate solution (sp.gr. 1·25) per 100 c.c.	Differences in divisions Ventzke between the polarisation of a solution containing no lead, and one containing the volumes of lead mentioned in the first column.
2·0	−0·13
4·0	−0·06
6·0	0·00
8·0	+0·09
10·0	+0·19
20·0	+0·45
40·0	+0·77

Some commercial sugar products can be defecated by a solution of neutral lead acetate, which is generally used as a solution of sp.gr. 1·25. Herles (Zeitsch. Zuckerind. Böhmen, 13, 559; 14, 343; 21, 189) suggested basic lead nitrate as a clarifying agent, especially for low-grade products which are being dealt with by the Clerget method. The replacement of hydrochloric acid by nitric does not influence appreciably the velocity of the hydrolysis of sucrose. The volume of the lead precipitate is, however, largely due to that of the basic nitrate itself, and reducing sugars are precipitated by the reagent.

Heron (J. Fed. Inst. Brewing, 1, 113), and also Zameron (Bull. Assoc. Chim. Sucr. Dist. 16, 337), have suggested clarifying sugar solutions with hypochlorite. Insufficient work has been carried out to test the validity of this method, which *prima facie* does not seem one that could be recommended.

There are certain hydrosulphites on the market which are employed in factory work on the large scale for decolorising purposes. Two of these are known by the names of 'Blankit' and 'Redo.' It has been suggested that these should be used in the laboratory for decolorising sugar solutions. They introduce errors, however, by reacting with reducing sugars to form oxy-sulphonates (*see* Bryan, Bull. 116, U.S. Bur. of Chem. p. 76). Another hydrosulphite derivative, sold commercially as 'Rongalite,' is free from this objection. It is sodium formaldehyde sulphoxylate.

Purified animal charcoal has been used for decolorising sugar solutions, but the error introduced by the adsorption of sucrose is considerable.

The results shown in Table VIII. were obtained by Bryan (*loc. cit.*, p. 71) and indicate the effect of different clarifying agents on the polarimetric reading. The reading with alumina cream alone is taken as the true polarisation.

TABLE VIII.

Clarifying agent.	Amount of clarifying agent used.	Direct polarisation.
Alumina cream . .	5 c.c.	89·00°V.
Basic lead acetate solution .	3·5 c.c.	89·50°

Basic lead nitrate solution .	4 ,,	89·00°
Dry basic lead acetate .	1·5 grms.	89·05°
Sodium hydrosulphite .	1 grm.	88·60°

Analysis of sugar beets. The estimations ordinarily made are the following: Percentage of sugar in the roots, percentage of sugar in the juice, and specific gravity of the juice (degree Brix). From these data are calculated the coefficient of purity from the formula 100S/B, where S is the sugar in the juice and B is the specific gravity of the juice in degrees Brix.

The writer has a record of many hundreds of analyses of sugar beets grown in different parts of England during the past three years. As will be seen from the following tabulated results the roots are quite up to the standard of those grown on the Continent:—

Method of sampling. In taking samples the field is divided longitudinally into strips and roots are lifted in diagonal lines from one end to the other of each of these strips. The roots, having been washed, cleaned, and topped, not less than half a dozen from each strip, and preferably more, should be taken for analysis.

There are several ways of estimating the sugar content of the roots, but each requires that an average sample shall be obtained of the roots reduced to pulp. In the writer's experience the best machine for this purpose is that made by Robert Kiehle of Leipzig, which is illustrated in Fig. 30. It stands about 3 ft. 7 ins. in height, and is capable of being screwed to the floor. A parallel slice is taken out of the centre by means of a rasp wheel, the root being fixed on a carrier and pressed against this wheel longitudinally while it is being rotated, which may be done either by hand or by other power. The pulp is collected in the box S.

In order to justify the soundness of the principle of taking a median longitudinal slice from the root, attention may be drawn to the fact that the percentage of sugar varies in different zones of the root. The following analyses of transverse sections of one and the same root (*see* Fig. 31),[2] made by the writer, illustrate this.

Estimation of the percentage of sugar in the roots. The following modification of the hot water digestion method is the one adopted by the writer. The normal weight of pulp is washed into a 200 c.c. Kohlrausch flask with about 150 c.c. of hot water. Basic lead acetate solution (6 c.c.) is then added, and the flask and contents are placed in a bath of boiling water to digest for half an hour. The contents are then cooled, 5 c.c. of alumina cream added, made up to a volume of 200 c.c. After well mixing, the extract is filtered and the filtrate polarised in a 2-dm. tube. The reading in degrees Ventzke doubled and multiplied by 0·994 (to correct for the volume occupied by the marc)[1] gives the percentage of sugar in the roots.

[1] This correction is not strictly accurate for all samples as the percentage of marc is subject to variation.

extraction with alcohol gives more accurate results than the aqueous digestion method; but, taking into account their inconvenience, these methods cannot be recommended for general purposes. It is not necessary to describe here in detail any of these methods, it will suffice to refer to the alcohol extraction method of Scheibler (Neue Zeits. für Rübenzuckerind. 2, 1, 17, 287; 3, 242) and the various hot and cold methods of digestion with water and with alcohol respectively.

Estimation of sugar in the juice. The juice having been expressed from a sample of the pulp enclosed in a filter cloth by means of a screw press, the normal weight is washed into a 100 c.c. flask, 2 c.c. of basic lead acetate solution, and 5 c.c. of alumina cream added, and the liquid made up to 100 c.c. The polarisation of the filtrate in a 2-dm. tube gives the percentage of sugar in the juice.

The specific gravity of the juice is determined by a Brix spindle, observing the usual precautions and correcting for temperature. The principle on which the Brix scale is constructed is explained on p. 265.

Estimation of lactose in milk by the polarimeter. For this purpose the Association of Official Agricultural Chemists, hereinafter referred to as the A. O. A. C., give the following method (Bull. 107, revised, U.S. Bur. of Chem. p. 118). The normal weight for hydrated lactose $C_{12}H_{22}O_{11},H_2O$ on the Ventzke instrument is 32·9 grms. Since the percentage of lactose in milk only amounts to 2–8 p.c., double this weight of milk is taken. Instead of weighing it is convenient to measure the milk, and the following table gives the volumes of milk at different specific gravity corresponding to 65·8 grms.

TABLE X.—*Volumes of Milk corresponding to the Double Normal Weight of Lactose.*

Specific gravity of milk.	Volume of milk for a lactose double normal weight (Ventzke scale).
	c.c.
1·024	64·25
1·025	64·20
1·026	64·15
1·027	64·05
1·028	64·00
1·029	63·95
1·030	63·90
1·031	63·80
1·032	63·75
1·033	63·70
1·034	63·65
1·035	63·55
1·036	63·50

It is pointed out that for ordinary purposes a pipette graduated to deliver 64 c.c. is sufficiently exact for all milks.

The milk is clarified with a solution of mercury nitrate, or with one of mercuric iodide. These are prepared as follows :—

Mercury nitrate. Metallic mercury is dissolved in twice its weight of nitric acid (sp.gr. 1·42), and the solution diluted with an equal volume of water.

Mercuric iodide. Potassium iodide (33·2 grms.) is added to a solution of mercuric chloride (13·5 grms.), dissolved in glacial acetic acid (20 c.c.) and water (640 c.c.).

The volume of milk equivalent to the double normal weight of lactose is measured into a flask having a mark at 102·6 c.c. For clarification either 1 c.c. of the mercuric nitrate solution may be used or 30 c.c. of the mercuric iodide solution (an excess of either reagent is without effect). The mixture is made up to a volume of 102·6 c.c., the 2·6 c.c. being the estimated volume of the precipitated casein and fat. After shaking, the liquid is filtered and polarised in a 4-dm. tube. The reading divided by four gives the percentage of lactose in the milk.

Other methods have been devised for the estimation of lactose in milk. Thus, Wiley and Ewell (Analyst, 21, 182), Leffman and Beam (Analysis of Milk and Mild Products, 1896, p. 39). Richmond has also dealt with the estimation of lactose in milk (*see* article on MILK, vol. iii. p. 533).

Lactose exhibits the phenomenon of mutarotation, and when solid products are polarised the solution must be allowed to remain until a constant reading is obtained, or the mutarotation must be destroyed by making up the solution in presence of a little alkali or ammonia. This applies to other sugars which exhibit mutarotation, *e.g.* dextrose, lævulose, &c.

Under special methods for the analysis of sugar mixtures, the use of the polarimeter in conjunction with cupric reduction methods will be described.

Method of estimating sucrose by double polarisation. The method of estimating sucrose in presence of invert sugar by determining the rotatory power before and after hydrolysis with acid was first suggested by Biot in 1842. It was made a practical one by Clerget in 1849 (Ann. Chim. Phys. [iii.] 26, 175), who elaborated a formula for calculating the results. Clerget's work is to be regarded as classical, and although the details of his original method have been revised, the constants which he established have remained practically unaltered. The method gives very satisfactory results with products of a certain degree of purity. With those of low purity, however (notably with molasses), in which there are many disturbing factors, the influence of which has not been fully worked out at the present time, the errors involved are considerable. In the writer's experience satisfactory results are to be obtained with raw beet sugars which give a direct polarimetric reading of 90 divisions and above on the Ventzke scale,[1] and with raw cane sugar giving a reading of 94 divisions and above on the same scale.

In the year 1888 a modification of Clerget's method was devised and elaborated by Herzfeld (Zeits. Ver. Deut. Zuckerind. 38, 699). It is carried out in the following manner.

The half-normal weight of sucrose is dissolved in 75 c.c. of water in a graduated 100 c.c. flask, 38 p.c. hydrochloric acid (5 c.c.) is then added, and the flask, in which a thermometer is inserted, is placed in a water-bath at 70°C. The flask is shaken continuously, and in this way the temperature of the solution is raised to 67°–70°C. in about 2½ mins., after attaining which it is

---

[1] With these, however, the direct polarimetric reading, as a rule, gives the percentage of sucrose accurately enough for practical purposes.

kept constant for an additional 5 mins., when it is rapidly cooled and polarised in a water-jacketed tube, 2 dms. in length, at a known temperature. When the polarimetric observation is made at 20°C., and the reading is multiplied by 2 to raise it to that of a normal solution, the value obtained is −32·66 sugar divisions.

The formula including the correction for temperature when the observation is made at a temperature other than 20°C., is—

$$S=\frac{100K}{142{\cdot}66-0{\cdot}5t}$$

The temperature correction may also be made by Hammerschmidt's formula—

$$I_{20}=I_t+0{\cdot}0038K(20-t),$$

in which I_{20} is the reading of the inverted solution in a 2-dm. tube at 20°C., multiplied by 2, I_t the same at the temperature of observation, and K the difference between the polarisations of the direct and inverted solutions at normal concentration.

If, instead of the half-normal weight in 100 c.c., a solution of a different concentration is employed, the inversion constant varies. Table XI. gives the inversion constants for solutions containing 1–20 grms. of sugar in 100 c.c. The values under I′ are calculated by the formula—

$$I'=-\left(31{\cdot}84+\frac{i}{20}\right),$$

in which i is the polarimetric reading of the inverted solution in a 200 mm. tube, I being the same multiplied by two.

Table XI.

Sugar, grms. in 100 c. c.	I.	I′.	Sugar, grms. in 100 c.c.	I.	I′.
1	31·85	31·90	11	32·52	32·53
2	31·91	31·96	12	32·59	32·60
3	31·98	32·03	13	32·66	32·66
4	32·05	32·09	14	32·73	32·73
5	32·12	32·15	15	32·79	32·79
6	32·18	32·21	16	32·86	32·85
7	32·25	32·28	17	32·93	32·92
8	32·32	32·34	18	33·00	32·98
9	32·39	32·40	19	33·06	33·04
10	32·46	32·46	20	33·13	33·11

The corrections for both temperature and concentration are included in the formula—

$$S=\frac{P-(-I)}{141{\cdot}84+\frac{i}{20}-\frac{t}{2}}$$

P = the direct polarisation.

I = the observed polarisation of the inverted solution corrected proportionately to a normal solution.

P−(−I) = K = the observed Clerget constant at $t°$; i = the observed polarisation of the inverted solution in a 200-mm. tube without any correction.

The writer has confirmed the accuracy of these results (J. Soc. Chem. Ind. 17, 110) as Table XII. shows.

16	13·024	$I_{19{\cdot}6}=-32{\cdot}92$	−32·72	−32·66	+0·06

The principal factors which affect the accuracy of the Clerget method in raw products are the following. The volume occupied by the precipitate produced by basic lead acetate; the precipitation of lævulose, and to some extent of dextrose, by basic lead acetate; the effect on the rotation of sugars and of certain amino compounds owing to the presence of hydrochloric acid; and the effect (in the case of the most impure products) of the alkali of the basic lead acetate on the rotatory power of lævulose and of certain amino compounds which they contain.[1]

Eynon (Seventh Inter. Cong. App. Chem. 1909, Sect. V. p. 193) found that in the case of Jaggery sugar and cane molasses, the influence caused by the volume of the lead precipitate was small but more than that due to the influence of

---

[1] Andrlik and Stanek have shown (Zeitsch. Zucker-ind. Böhmen, 31, 417), that a 1 p.c. solution of glutaminic acid gave a polarimetric reading of 1·45 Ventzke in presence of basic lead acetate, 0·35 V. in water alone, and 1·77 V. in dilute hydrochloric acid.

the lead left in solution on the rotation of sucrose. Incidentally Eynon's results confirm those of Prinsen-Geerligs (Internat. Sugar J. 10, 500; 11, 276), that lævulose is partially precipitated (and also dextrose, but to a lesser extent) by basic lead acetate.

It is well known that the speed of hydrolysis of sucrose by acids varies with the concentration and nature of the acid employed. Strong acids such as hydrochloric acid, which, according to the ionic theory, exist in solution for the most part dissociated into their ions, hydrolyse much more sucrose in a given time, other things being equal, than do the weaker organic acids.

The dark after-products which are met with in the sugar industry, contain, besides sugar, other organic matters, consisting to some extent—in all probability for the most part—of the salts of organic acids. At all events, a sufficiency of these salts is present to react with the hydrochloric acid added in carrying out Clerget's process, and to replace it partially by much weaker organic acids. The matter is not improved when the solution under investigation is previously clarified, as it usually is, with basic lead acetate, for here the hydrochloric acid is to some extent neutralised by the alkalinity of the basic lead acetate, besides which it is partially replaced by the comparatively weak acetic acid, and there is some danger that the inversion of the sucrose may not have reached completion in the prescribed time. To obviate the presence of an organic acid, it has been proposed by Herles (*see* p. 240) to use a solution of lead nitrate in conjunction with one of sodium hydroxide as clarifying agent. The experiments of Herzfeld and others have shown, however, that the rotatory power of sucrose is diminished by the employment of this clarifying agent.

There is, however, another objection to the use of Clerget's method, as it is at present carried out, for the estimation of sucrose in products containing much 'other organic matter.' Although the presence of a great many definite substances has been demonstrated in the juice of both sugar cane and beetroot, the nature of this organic matter in a given sample of sugar or molasses cannot be determined. It is, however, well known that these substances are to some extent optically active, and experience shows that even after clarification with basic lead acetate some optically active substances besides sugar remain in solution.

Clerget's method presupposes that no other constituent of the sample than the sucrose suffers any change in optical activity by the treatment adopted. But since the agent employed—acid—is a general hydrolyst, we can be by no means certain that this is the case.

It is obvious that if, instead of employing a general hydrolyst such as an acid, we made use of one which would act selectively on sucrose only, the accuracy of the method would be considerably enhanced. Such a hydrolyst is the invertase of yeast, which hydrolyses, or to use the more familiar term, inverts sucrose and other substances having a similar configuration.

O'Sullivan and Thompson (Chem. Soc. Trans. 59, 46) showed that invertase of yeast might be used as hydrolytic agent in the estimation of sucrose; and Ling and Baker (J. Soc. Chem. Ind. 17, 111) proposed a modification of Clerget's method in which the hydrolysis of the sucrose was effected by heating a slightly acidified (with acetic acid) half-normal solution with 0·5 grm. of fresh-pressed yeast for 5 hours at 55°C. Working with pure sucrose in which alumina cream was the sole clarifying agent employed, the Clerget value $I_{20} = -32·56$ was obtained. With dark-coloured products defecation with basic lead acetate had to be resorted to, and this was added after the completion of hydrolysis. The method could not, therefore, give accurate results under these circumstances, for, as already observed, basic lead acetate precipitates certain reducing sugars, notably lævulose.

A method of overcoming this difficulty has been worked out by Ogilvie (J. Soc. Chem. Ind. 30, 62) by removing the lead in solution by means of sulphurous acid prior to hydrolysis. Ogilvie's method is as follows:—

Four times the normal sugar weight of the sample is transferred to a 200 c.c. flask, defecated with the minimum amount of basic lead acetate solution (sp.gr. 1·26), a little alumina cream added, and the liquid made up to the mark at standard temperature, well shaken and filtered. 100 c.c. of the filtrate are measured accurately into a small beaker, sulphur dioxide passed in from a syphon of the liquefied gas till a faint smell is perceptible (the indication that all the lead is precipitated), the liquid is then transferred to a 200 c.c. flask, made up to the mark, and well mixed. Sufficient calcium carbonate (dried) in fine powder to neutralise the excess of acidity, and a little recently ignited kieselguhr are added, after which the solution is filtered. In this way a normal solution is obtained which is sufficiently clarified to give a distinct polarimetric reading, is free from lead and excess of acidity, and is therefore well suited for the invertase inversion.

The method of hydrolysis is as follows: 50 c.c. of the molasses solution, prepared in the manner just described, contained in a 100 c.c. flask, are raised in a constant temperature bath to 50°–55°C. and 0·5 grm. of washed brewery yeast (top-fermentation) and 2 drops of acetic acid are added, the temperature being maintained as near 55°C. as possible for 4½–5 hours. At the end of this time the liquid is cooled, alumina cream or a little kieselguhr added to assist filtration, and the solution is made up to the mark at standard temperature. The clear filtrate is then polarised in a water-jacketed tube (*see* Fig. 7) at 20°C., the temperature being determined by a thermometer reading to 0·1°C.

The value obtained by Ogilvie when working with pure sucrose was $I_{20} = -31·6$, a value which, it will be observed, differs from that obtained by Ling and Baker.

A preparation of invertase may also be used for the hydrolysis. O'Sullivan and Thompson (Chem. Soc. Trans. 57, 834) prepared invertase by allowing washed yeast to remain aside in a jar until it had liquefied. Fischer (Ber. 27, 2985) found that the autolysis of the yeast might be expedited by the addition of chloroform. Hudson (J. Ind. Eng. Chem. 2, 143) has proposed the following method of preparing a solution of invertase based on these observations.

'Break up 5 lbs. of pressed yeast, which may be either baker's or brewer's yeast, add 30 c.c of chloroform to it in a closed flask, and allow it to stand at room temperature (20°C.) overnight. By the morning, the solid mass will have become liquid and it should then be filtered through filter paper, allowing several hours for draining. To the filtrate add neutral lead acetate until no further precipitate forms and again filter. Precipitate the excess of lead from the filtrate with potassium oxalate and filter. To this filtrate add 25 c.c. of toluene and dialyse the mixture in a pig's bladder for 2 or 3 days against running tap water. The dialysed solution is colourless, perfectly clear after filtration, neutral to litmus, has a solid content of about one-half of one p.c., an ash content of a few hundredths of one p.c., will keep indefinitely in an ice box if a little toluene is kept on its surface to prevent the growth of micro-organisms, and is exceedingly active in inverting cane sugar. The invertase solution does not reduce Fehling's solution.'

The invertase or yeast process takes up a considerably longer period of time than the acid hydrolysis process, but it must be remembered that it necessitates no more personal attention. However, the writer does not consider that sufficient work has yet been carried out with the method or a sufficient number of low-grade products of the sugar industry examined by it, to render it of general applicability in technological work (*cf.* below). The majority of sugar technologists have been somewhat reluctant to carry out investigations on this enzyme method, and have always shown a preference for the acid method, and numerous attempts have been made to remove the errors inherent to it when dark after-products are being dealt with. Neutralisation of the free hydrochloric acid in the inverted solution by sodium hydroxide, as pointed out by Browne (*l.c.*, p. 271), removes the influence of the acidity, but introduces a new disturbing factor, namely sodium chloride.

Pellet in 1897 (Bull. Assoc. Chim. Sucr. Dist. 15, 524) proposed to remove the lead in the direct polarisation liquid by sulphurous acid in slight excess, whilst Andrlik and Stanek in 1906 (Zeits. Zuckerind. Böhmen, 31, 417) proposed to add to the direct polarisation liquid the same quantity of hydrochloric acid as is present in the inverted solution together with a certain amount of urea or betaine to retard the hydrolysis of the sucrose by the hydrochloric acid. One objection to this method is that quite an appreciable amount of hydrolysis occurs under these conditions even 2 mins. after the preparation of the solution, and a second objection to the method has reference to the effect of the bases employed by Andrlik and Stanek on the rotation of reducing sugars when present. In the case of beetroot molasses which do not contain reducing sugars or at the most only traces, this method appears to give results which agree well with those obtained by the Pellet method (Ogilvie, *l.c.*).

Ogilvie (Internat. Sugar J. 14, 91) has compared the results obtained with invertase and acid hydrolysis respectively in the case of five samples of cane molasses, and arrives at the following conclusions: (1) The percentages of sucrose found by the acid inversion process usually employed when the direct polarisation is taken in alkaline solution are too high.[1] (2) The percentage of sucrose found when using a neutral direct polarisation liquid may likewise be too high. (3) The values found when using an acid direct polarisation liquid are in close agreement with those obtained by the invertase method.

Ogilvie's results with beet and cane molasses are given in Tables XIII. and XIV.

TABLE XIII.—*Beet Molasses.*

Sample	1	2	3	4
Direct alkaline (basic lead acetate) polarisation	48·8	—	48·6	47·0
Direct neutral polarisation	49·2	52·0	49·0	47·6
Direct acid (Andrlik) polarisation	50·4	53·25	50·0	48·4
Direct acid (Pellet) polarisation	50·3	53·3	—	48·3
Invertase inversion polarisation	−14·6	−16·0	−15·0	−14·4
Acid inversion polarisation	−13·2	−14·6	−13·6	−13·8
Clerget value by invertase	48·5	51·7	48·6	47·1
Clerget value by acid, using alkaline direct polarisation	47·0	—	47·1	46·1
Clerget value by acid, using neutral direct polarisation	47·3	50·5	47·4	46·5
Clerget value by acid, using acid (Andrlik) direct polarisation	48·2	51·4	48·2	47·1
Clerget value by acid, using acid (Pellet) direct polarisation	48·1	51·4	—	47·0

In a later paper Ogilvie (*ibid.* 14, 624) modified the Pellet method of removing the lead from the direct polarisation liquid by means of sulphurous acid, and applied it to the estimation of sucrose in beet molasses by the Clerget process. His procedure is as follows: Twice the normal weight is dissolved in water defecated with basic lead acetate and made up to 200 c.c. with water. Fifty cubic centimeters of this solution are transferred to a 100 c.c. flask, saturated with sulphur dioxide, the flask being immersed in cold water meanwhile, and subsequently made up with water to

---

[1] Exactly the opposite result was obtained by Ogilvie when working with beet molasses, which, however, as he points out, has a different composition from the cane product. In the former the disturbing factor is the presence of amino acids, whilst in the latter it is the presence of reducing sugars.

1. Alkaline (basic lead acetate) polarisation	32·20	31·40	39·50	34·30	39·70
2. Neutral direct polarisation	30·50	29·90	38·10	33·46	39·65
3. Acid (HCl and urea) polarisation) (Andrlik)	30·50	30·50	38·40	33·38	39·26
4. Acid (SO$_2$) direct polarisation (Pellet)	30·60	30·50	38·30	33·30	39·10
5. Invertase inversion polarisation	−16·40	−15·50	−17·90	−14·08	−11·40
6. Acid inversion (Herzfeld) polarisation	−16·30	−15·40	−18·02	−14·06	−12·28
7. Percentage of sucrose, using invertase as hydrolyst	35·6	34·4	42·4	36·1	38·7
8. Percentage of sucrose, using acid as hydrolyst, and the alkaline direct polarisation	36·7	35·4	43·4	36·6	39·3
9. Percentage of sucrose, using acid as hydrolyst, and the neutral direct polarisation	35·4	34·2	42·4	35·9	39·2
10. Percentage of sucrose, using acid as hydrolyst, and the acid (HCl and urea) direct polarisation (Andrlik)	35·4	34·7	42·6	35·9	38·9
11. Percentage of sucrose, using acid as hydrolyst, and the acid (SO$_2$) direct polarisation (Pellet)	35·5	34·7	42·5	35·8	38·8

100 c.c. and filtered. For the inversion solution 50 c.c. of the defecated normal solution of molasses are transferred to a 100 c.c. flask, 25 c.c. of water added, and 5 c.c. of hydrochloric acid (sp.gr. 1·19), and treated according to Herzfeld's directions (*see* p. 242). Working under these conditions it is shown that the direct polarisation liquid may be kept for 30 mins. without showing any diminution in rotation. This work appears very promising, and further experiments with both beet and cane molasses will be very welcome.

Estimation of sucrose in presence of reducing sugars by a single observation. Lemeland (Ann. Chim. anal. 15, 416) found that when a mixture of sucrose and reducing sugars is heated with hydrogen peroxide, caustic alkali and a little manganese dioxide, the reducing and optical powers of the reducing sugars are annulled, whilst the optical power of the sucrose is unaffected. Jolles (Zeitsch. Nahr. Genussm. 20, 631) suggests destroying the rotatory power of reducing sugars in admixture with sucrose by boiling 2 p.c. solutions of the mixture for 45 mins. with sufficient sodium or potassium hydroxide to make the solution have a decinormal degree of alkalinity. This method was modified by Pellet and Lemeland (Inter. Sugar J. 13, 616). Cross and Taggart (*ibid.* 14, 448) state, however, that none of these modifications gives satisfactory results. They find the following procedure to yield good results. A normal (Ventzke) solution is prepared, and 50 c.c. are transferred to a 100 c.c. flask, 6·3 c.c. of sodium hydroxide solution of 36°Beaumé added and 7·5 c.c. of hydrogen peroxide (100 volume). The mixture is cooled to prevent effervescence, and the flask is immersed in a bath of water at 55°F. for 20 mins., cooled, acidified with acetic acid, made up to the mark, clarified with dry basic lead acetate and the rotatory power of the filtrate determined. The reading in a 4-dm. tube gives the percentage of sucrose in the sample. It is shown that the results agree with those obtained by the Clerget-Herzfeld method; and Cross and Taggart recommend it for syrups and molasses.

Estimation of raffinose in beet products by the Clerget method. The method of procedure is the same as above described, but the results are calculated by Herzfeld's formulæ (Zeits. Ver. Deut. Zuckerind. 40, 194)—

$$S=\frac{0·5124P-(-I)}{0·839} \qquad R=\frac{P-S}{1·85},$$

where S is the percentage of sucrose, P is the direct polarisation of the normal solution, I the polarisation of the inverted solution at normal concentration, and R the percentage of raffinose. The formula presupposes that the readings have been made at 20°C. If not the temperature corrections given above must be applied.

Estimation of sucrose in presence of other sugars by the Clerget method. The writer has found that sucrose may be estimated with a fair degree of accuracy in presence of dextrins, maltodextrins, maltose, lactose, or glucose, or of mixtures of these carbohydrates by the Clerget method. The carbohydrates mentioned are for the most part not much affected by the Clerget inversion method; but work on the subject is greatly needed. For the estimation of lactose in chocolate by the Clerget method Dubois has devised a process (Cir. 66, U.S. Bur. of Chem., p. 15; quoted by Browne, *l.c.*, p. 280).

Reduction methods of estimating sugars. Those sugars which contain within their molecule a free carbonyl group—aldoses and ketoses—are capable of reducing metallic salts in alkaline solution. This is true of alkaline solutions of silver, mercury, and copper salts. In no case, however, does the reduction conform to a definite reaction, so that these reduction methods are all of an empirical character. They must therefore be carried out under standard conditions, otherwise accurate results cannot be obtained. With special reference to cupric salts, the old assumption that one molecule of glucose reduces five molecules of copper oxide has long since been abandoned. Indeed, different sugars under similar conditions reduce different amounts of cupric oxide.

The most important and most widely used of these reduction methods, so far as their quantitative application is concerned, for the estimation of reducing sugars, are those which depend on the reduction of alkaline solutions of cupric salts. Trommer in 1841 (Annalen, 39, 360) was the first to show that grape sugar reduced alkaline copper solutions whilst cane sugar did not, and to suggest a method of estimating the former based on this fact. Barreswil, a few years later (J. Pharm. Chim. [iii.] 6, 301), showed that the addition of an alkali tartrate to a solution of copper sulphate containing also an alkali hydroxide rendered the reagent more stable. It was not, however, until 1848 that the method of estimating sugars by the cupric reduction method was placed on a sound basis by Fehling (Annalen, 72, 106, 75). Fehling's solution, with but slight modifications, is the one most generally employed at the present time.

The first methods of estimating sugars based on their power of reducing alkaline copper solutions were volumetric. Later gravimetric methods were devised. The most recent and widely adopted form of each of these will be considered in what follows.

Volumetric methods. Passing over the earlier methods based on this principle, the first work on the subject to demand attention is that of Soxhlet in 1878 (J. pr. Chem. [ii.] 21, 227). The work of this chemist was of an important character. He was the first to show that Fehling's solution, when kept, underwent autoreduction, and to suggest keeping the copper sulphate and alkaline tartrate solutions separate and mixing them as required for use. He came to the conclusion that the volumetric method was capable of greater accuracy than any gravimetric method which was then known. Soxhlet, however, worked with very strong solutions of reducing sugars, and he employed 100 c.c. of Fehling's solution. He also used an open dish for his titrations, which leads to errors on account of the oxidising action of the air (*cf.* Kjeldahl, Res. Compte rend. Carlsberg, 4). The relative reducing powers of the most commonly occurring reducing sugars, according to Soxhlet, are as follows: Glucose 100, invert sugar 96·2, lævulose 92·4, lactose 70·3, and maltose 61·0. These values have been confirmed by numerous observers, but it has to be remembered that the reducing power of a sugar varies according to the conditions under which it was determined.

The end point in the volumetric method was first of all determined by the disappearance of the blue colour, but obviously this could not be used in the case of dark-coloured products. The use of ferrocyanide as an indicator for the unreduced copper was then suggested. It is applied in the following manner: When it is judged that the titration is nearing the end point a little of the liquid is filtered off, the filtrate acidified with acetic acid, and a *freshly prepared* solution of potassium ferrocyanide added, when, if there be any unreduced cupric salt, the well-known brown precipitate or coloration will be produced. Perhaps the most convenient way of ascertaining the end point on this principle is by means of the filter tube (described in Wiley's Agricultural Analysis, vol. 3, p. 130). It consists of a piece of glass tubing 20–25 cm. in length and 5–7 mm. in diameter. A shoulder is formed on one extremity, and over this is stretched a piece of fine linen which is fastened on by a piece of cotton. The tube is dipped into water containing finely divided asbestos in suspension, and some of this is drawn into the tube by suction at the open end. This forms a layer which will retain the cuprous oxide produced in the Fehling reducing method.

The volumetric method of estimating reducing sugars has within recent years been standardised by Ling and Rendle (Analyst, 30, 183), and Ling and Jones (*ibid.* 33, 160). These chemists performed the titration in an ordinary boiling flask, which, however, had been used by the writer and others many years before the papers cited appeared. The main point which they claim to have established by their work, however, is that of having proved that the volumetric method of estimating sugars is quite as accurate and far more convenient than any form of the gravimetric method.

It may here be mentioned that the composition of the alkaline tartrate solution employed by different chemists varies somewhat, more especially as regards the proportion of sodium hydroxide present. It is well known that the results are largely influenced by the proportion of sodium hydroxide.

The reagent used by the writer and his co-workers is prepared as follows:—

Solution No. 1. Crystallised copper sulphate (69·2 grms.) is dissolved in water and the solution made up to one litre.

Solution No. 2. Crystallised Rochelle salt (346 grms.) is dissolved in hot water and mixed with sodium hydroxide (142 grms.) also dissolved in water. After cooling the mixed solutions are made up to one litre.

Equal volumes of these two solutions are accurately measured out at 15·5°C. or any other standard temperature adopted, and this mixture constitutes the reagent.[1]

The method was standardised for a volume of the mixed solution of 10 c.c., but occasionally it is necessary to vary this volume, and Ling and Jones (*l.c.*) show that assuming the concentration of the sugar solution to be constant, the number of cubic centimetres required for any titration is directly proportional to the volume of copper reagent employed—at all events when this lies between the limits of 5 and 20 c.c.

The indicator employed by the writer and his co-workers is an acid solution of ferrous thiocyanate, which is prepared as follows:—

Ammonium thiocyanate . .	1·5 grms.
Ferrous ammonium sulphate .	1·0 „
Concentrated hydrochloric acid	2·5 c.c.
Water	10·0 „

---

[1] The measurement of equal volumes of these solutions at definite temperatures is a most important point, since the coefficient of expansion of each solution is different and differs also from that of water.

The solution prepared even from the purest reagents has invariably a brownish-red colour due to the presence of ferric salt, which latter must therefore be reduced. For this purpose zinc dust has been found to be the most satisfactory reagent, and, as a rule, a mere trace suffices to decolorise the solution.

The method of titration is as follows: The freshly mixed copper reagent (10 c.c.) is accurately measured into a 200 c.c. boiling flask. The reagent, which is not diluted with water, is heated to boiling. The sugar solution, which should be adjusted to such a strength that 20–30 c.c. of it are required to reduce 10 c.c. of Fehling's solution,*is then run into the boiling liquid in small amounts, commencing with 5 c.c. After each addition of sugar solution the mixture is boiled, the liquid being kept rotated. About a dozen drops of the indicator are placed on a porcelain or opal glass slab, and when it is judged that the precipitation of cuprous oxide is complete, a drop of the liquid is withdrawn by a clean glass rod or by a capillary tube, and brought in contact with a drop of the indicator on the slab. The test must be carried out rapidly. It is also essential to perform the titration as rapidly as possible, as an atmosphere of steam is then kept in the neck of the flask and the influence of atmospheric oxygen avoided. At the final point the liquid is boiled for about 10 seconds. As in the ordinary volumetric method, the first titration may only give approximate results, and a second or third will then be necessary to establish the end-point accurately. However, when the operator has gained experience, the first titration is as much to be relied on as succeeding ones, and this point is clearly brought out in the results cited. One titration takes from 2½ to 3 mins.

The copper reagent is standardised against invert sugar as follows: Pure sucrose (0·95 grm.) (*see* p. 235) is dissolved in water (150 c.c.), and boiled with N/2 hydrochloric acid (30 c.c.), the mixture being maintained in ebullition for 1 min., cooled, neutralised by the addition of N/2 sodium hydroxide (30 c.c.), and made up with water to 500 c.c. This solution, which contains 0·2 grm. of invert sugar per 100 c.c. is titrated against 10 c.c. portions of the copper reagent, as above described.

It should here be pointed out that whilst the thiocyanate indicator is by far the most delicate and satisfactory, it cannot be used with commercial products containing iron. With these the ferrocyanide indicator must be employed.

Ling and Jones (*l.c.*) have calculated a table for dextrose, lævulose, invert sugar, and maltose for a range of concentrations such that using 10 c.c. of Fehling's solution the reduction is complete with the addition of 20–43 c.c. of the sugar solution.

TABLE XV.

Volume of solution required by 10 c.c. Fehling's solution	Dextrose		Lævulose		Invert sugar		Maltose	
	D Dextrose in 100 c.c. of solution	D′ Fehling's solution equivalent to 1 grm. dextrose	L Lævulose in 100 c.c. of solution	L′ Fehling's solution equivalent to 1 grm. lævulose	I Invert sugar in 100 c.c. of solution	I′ Fehling's solution equivalent to 1 grm. invert sugar	M Maltose in 100 c.c. of solution	M′ Fehling's solution equivalent to 1 grm. maltose

43	—	—	0·1274	182·6	—	—	—	—

The manner of using the table is best explained by an illustration. Suppose a solution of pure lævulose is being examined, and that 25·0 c.c. of it are required to reduce 10 c.c. of Fehling's solution. Opposite 25 in the first column is found 0·2138 in column L; the percentage of lævulose in the solution titrated is thus given direct. If 25·2 c.c., or other quantity not a whole number, is required to reduce 10 c.c. of Fehling's solution, the percentage of lævulose can be easily found by interpolation between the numbers in column L.

The table gives the number of cubic centimetres of Fehling's solution equivalent to 1 grm. of the particular sugar at each concentration. These numbers, given in columns D′, L′, I′, and M′, have another purpose—namely, the separate determination of two reducing sugars in a mixture, by a modification of the method of Morris (J. Inst. Brewing, 4, 162), which depends on the reducing power and the reading in the half-shadow Ventzke polarimeter when observed in a 2-dm. tube. The application of the table for this purpose is described on pp. 259, 261.

Estimation of invert sugar in presence of cane sugar. It is well known that sucrose, although by constitution a non-reducing sugar, does reduce Fehling's solution to some extent when boiled therewith, and that in mixtures of sucrose and invert sugar, such as raw sugars, cane syrups and cane molasses, it is necessary to apply a correction when estimating the invert sugar in these by any method involving cupric reduction. Ling and Rendle (*ibid.* 33, 170) have determined the corrections to be applied for the influence of sucrose when their method is used for the analysis of mixtures such as those referred to.

In the following table:—

Column A gives the amounts in grams of sucrose present in 100 c.c. of the sugar solutions.

Column B gives the percentages of sucrose present expressed on the total sugars.

Column C gives the percentages of invert sugar present expressed on the total sugars.

Column D gives the number of cubic centimetres of sugar solution required to reduce 10 c.c. of Fehling's solution.

Column E gives the percentages of invert sugar on the total sugars found by direct experiment.

Column F gives the differences between the values shown in columns C and E.

TABLE XVI.

Each solution contained, in addition to the sucrose shown under column A, 0·2 gram of invert sugar per 100 c.c.

A	B	C	D	E	F
0·01	4·8	95·2	25·60	95·30	0·10
0·03	13·0	87·0	25·60	87·10	0·10
0·05	20·0	80·0	25·60	80·10	0·10
0·10	33·3	66·7	25·55	66·90	0·20
0·20	50·0	50·0	25·45	50·40	0·40
0·30	60·0	40·0	25·40	40·40	0·40
0·40	66·6	33·4	25·35	33·80	0·40
0·50	71·4	38·6	25·30	29·00	0·40
0·60	75·0	25·0	25·20	25·40	0·40
0·70	77·7	22·3	25·15	22·70	0·40
0·80	80·0	20·0	25·10	20·40	0·40
1·25	86·2	13·8	25·05	14·10	0·30
1·50	88·2	11·8	24·95	12·10	0·30
1·75	89·7	10·3	24·85	10·60	0·30
1·75	89·7	10·3	24·80	10·60	0·30
2·00	90·9	9·1	24·70	9·45	0·35
2·00	90·9	9·1	24·80	9·41	0·31
2·50	92·5	7·5	24·80	7·76	0·26
3·00	93·8	6·2	24·70	6·44	0·24
5·00	96·1	3·9	24·20	4·05	0·15
7·00	97·2	2·8	23·60	3·04	0·24
10·00	98·0	2·0	22·95	2·23	0·23
20·00	99·0	1·0	22·40	1·14	0·14
25·00	99·2	0·8	22·25	0·92	0·12
30·00	99·3	0·7	22·25	0·80	0·10

In addition to these results Ling and Rendle (*l.c.*) also carried out determinations for mixtures of sucrose and invert sugar when the concentration of the latter sugar was 0·15 grm. and 0·25 grm. per 100 c.c. respectively.

An examination of the table shows that the influence of sucrose is practically negligible until the proportion to the total sugars (sucrose and invert sugar) amounts to 30 p.c. (*see* column B), at which point the invert sugar is overestimated by 0·2 p.c. This influence of sucrose increases progressively until the proportion, expressed on the total sugars, 99·3 p.c. is reached, beyond which it has not been determined. At this point the invert sugar is overestimated to the extent of about 15 p.c. It must be remembered, however, that the magnitudes representing the percentages of invert sugar decrease as those representing the percentages of sucrose increase, and it will be seen that the correction to be applied (column F) is in concrete numbers the greatest when the percentage of sucrose on the total sugars is between 50 and 80. In the case of a mixture of equal parts of sucrose and invert sugar, the latter would be returned if no correction were applied as 50·4 p.c. instead of 50·0 p.c., whilst in the case of a mixture of 99 parts of sucrose and 1 part of invert sugar, the latter would be returned if no correction were applied as 1·14 p.c. instead of 1 p.c. The writer is in the habit in practice of deducting the values shown in column F of the table from the values determined by direct titration of the mixture of sugars. For this purpose, however, it is necessary to know the percentage of sucrose, not calculated on the sample, but on the total sugars (sucrose and invert sugar) in the sample. This can be determined either by the Clerget method or by the method of double titration before and after hydrolysis with hydrochloric acid, applying the formula $S=\frac{(95I'-I)}{100}$, in which S is the approximate percentage of sucrose, I is the apparent percentage of invert sugar—*i.e.* the value obtained by direct titration—and I′ is the percentage of invert sugar obtained by titration of the sample after complete hydrolysis.

The approximate value given in column F is subtracted from the value of I and added to the value of S, the respective results giving the corrected percentages of invert sugar and of sucrose. In order to express these on the sample, each of the values is multiplied by $S+I/100$. To be exact, the value added to the approximate percentage of sucrose, S, should be diminished by 5 p.c.; but the accuracy of the method does not warrant this refinement, seeing that the corrections to be applied are values of comparatively small magnitude.

In the early days when the end point in the titration method was determined by the disappearance of the blue colour, a difficulty was experienced in titrating dark coloured physiological liquids with the ordinary Fehling's solution. Nor can the ferrocyanide indicator be used with these liquids, since they invariably contain amino compounds, which partially dissolve the precipitated cuprous oxide. It is true that cuprous solutions do not give a coloration with ferrocyanide, but it is necessary to acidify with acetic acid before this indicator can be applied, and acidified solutions of cuprous salts when exposed to air rapidly oxidise to the cupric state. The writer has not found the same difficulty with his ferrous thiocyanate indicator, which, in the absence of iron, may be used for the titration of physiological solutions.

To obviate the difficulties referred to in the preceding paragraph, F. W. Pavy, in 1879 (Proc. Roy. Soc. 28, 260), proposed to employ a copper solution containing sufficient ammonia to keep the reduced cuprous oxide in solution. Since the disturbing influence of the precipitated cuprous oxide on the colour is thus prevented as well as that due to the presence of amino compounds, it is possible, in absence of air, to titrate moderately dark coloured physiological liquids, using Pavy's solution, with sufficient accuracy. The method has been applied specially for the estimation of dextrose in urine. It should be added, however, that the colour of many physiological liquids is sufficient to render accuracy impossible with Pavy's method.

Pavy's solution is prepared as follows: crystallised copper sulphate (34·65 grms.), Rochelle salt (170 grms.) and potassium hydroxide (170 grms.) are dissolved in water and made up to one litre. The copper and alkaline tartrate solutions are preferably made up separately and equal volumes mixed as required (see p. 247). To 120 c.c. of the mixed solutions is added ammonia of sp.gr. 0·880 (300 c.c.), and the liquid is diluted to one litre. Working under the conditions to be described, 20 c.c. of this solution are reduced by 0·01 grm. of glucose. If other sugars are to be estimated, the titre of the solution must be established for each of these.

The titration is performed in the following manner. A round-bottomed flask of 150 c.c. capacity is provided with a doubly-bored rubber stopper. Through one opening in the stopper the delivery end of the burette passes and through the other a glass tube bent twice at right angles, the latter being intended for the escape of the steam and to prevent the access of air. Forty cubic centimetres of the ammoniacal copper solution are introduced into the flask and after inserting the stopper the solution is raised slowly to boiling. The assay liquid is then added at the rate of 60 to 100 drops per minute, ebullition being maintained meanwhile (a special pinch cock was employed by Pavy). When the blue colour is nearly discharged, the assay liquid is added drop by drop until no more blue can be discerned. A sheet of white paper or a plate of opal glass placed behind the flask assists in determining the end point more accurately.

For the estimation of reducing sugars in small quantities, Bang (Biochem. Zeitsch. 1906, 2, 271) makes use of the principle that cuprous oxide separates as cuprous thiocyanate from a solution of cupric sulphate containing alkali carbonates (not hydroxides) and potassium thiocyanate. The unreduced copper salt is then also precipitated as cuprous thiocyanate by titration with a standard solution of hydroxylamine in the presence of an excess of potassium thiocyanate. The method is said to be accurate and to be adapted for the estimation of sugar in urine. The following solutions are employed.

Copper solution. Potassium carbonate (250 grms.), potassium bicarbonate (50 grms.) and potassium thiocyanate (211 grms.) are dissolved by warming in water (600 c.c.). To the cooled liquid is slowly added a solution of crystallised copper sulphate (12·5 grms.) in about 75 c.c. of water. The mixture is then made up to a litre.

Hydroxylamine solution. Hydroxylamine sulphate (6·55 grms.) and potassium thiocyanate (200 grms.), are dissolved in water and the solution made up to two litres.

In carrying out the titration the sugar solution (10 c.c.), which should not contain more than 60 mgrms. of dextrose, is measured into a 200 c.c. flask and 50 c.c. of the copper solution added. The mixture is heated to boiling and maintained in ebullition for exactly 3 mins. The liquid is then cooled and the hydroxylamine solution run in from a burette until the blue colour is completely discharged. The results are calculated by the following table.

TABLE XVII.

Methods have been devised in which the cuprous oxide reduced under standard conditions by sugars is collected on a filter and subsequently dissolved and the copper titrated by one of the well-known methods. These will be referred to under gravimetric methods (see p. 252).

Gravimetric methods. The preference shown by many workers for gravimetric methods as compared with volumetric methods is based on the fact that weighings can be conducted with a greater degree of delicacy than can titrations. But whilst this is true, it by no means follows that the former are less accurate than the latter. In the first place, the empirical character of methods depending on the reduction of cupric solutions by sugars must be borne in mind, for, even with solutions of pure sugars the variations of conditions in even a slight degree causes considerable alterations in the results, so that increased delicacy does not of necessity synchronise with increased accuracy. Moreover, in the case of commercial products there are other factors which tend to vitiate the accuracy of the gravimetric methods. Thus these products contain certain salts of the alkali earth metals and nitrogenous matters. The former are liable to be precipitated with the cuprous oxide, whilst the latter are capable of dissolving some of the cuprous oxide. Errors of the former kind may be avoided by dissolving the washed cuprous oxide and estimating the copper volumetrically; but it is impossible to eliminate the errors due to the solvent action of the nitrogenous matters on the cuprous oxide. Neither of these factors affect the accuracy of methods of direct titration. Concordance of results in gravimetric methods does not, therefore, of necessity indicate accuracy.

It is impossible in this article to deal exhaustively with the numerous methods which have been proposed for the estimation of reducing sugars by weighing the cuprous oxide precipitated under standard conditions. The writer must confine himself to a description in detail of some of those methods which are in most general use. Taking them in their chronological order, the principal investigators to whom we are indebted for our knowledge on this subject are Soxhlet, Allihn, Wein, Meissl, Herzfeld, Lehmann, Kjeldahl, Brown, Morris and Millar, Defren, and Bertrand.

In most of the new methods, workers have started on an entirely new basis from that adopted by those that preceded them, altering not only the composition of the alkaline copper solution but also the mode of carrying out the reduction. Thus some use a larger proportion of alkali, whilst others have departed from the original prescription of Fehling so far as to employ potassium hydroxide instead of sodium hydroxide.[1] It therefore happens that we are in possession of a large number of empirical tables which can only be used under strictly standardised conditions.

In the earlier gravimetric methods the cuprous oxide was collected on a paper filter, and after washing, the precipitate and filter were ignited and the copper weighed as cupric oxide. This method is subject to several errors, *e.g.* the paper in spite of repeated washing retains some of the copper, possibly by adsorption, and as this is by no means a constant quantity it cannot be corrected for; again, it is difficult to burn the precipitate to cupric oxide in a crucible even if, after one burning, it be treated with nitric acid and again ignited. The method has, therefore, now been superseded by one in which the cuprous oxide is collected under diminished pressure in a Soxhlet tube packed with asbestos. The following is a description of a Soxhlet tube. The tube is made of hard glass, and the total length is about 20 cm. The upper portion is a parallel-walled tube, having an internal diameter of about 1·5 cm., and is about 12 cm. long. Below this the tube is constricted to a bore of about 1 mm., and the remaining portion of the tube below the constriction tapers towards the end in order that it may be fitted into the hole of a rubber stopper which fits into the filter flask attached to the pump. The Soxhlet tube is packed with asbestos in the manner to be described. Another method of collecting the cuprous oxide obtained by the reduction of Fehling's solution is by the use of a Gooch crucible, which is also packed with asbestos.

The asbestos used for this purpose must be subjected to treatment with acid and alkali, otherwise it loses weight when the alkaline copper solution is filtered through it. The following method recommended for this purpose by Munson and Walker (J. Amer. Chem. Soc. 28, 666) may be used. The asbestos, which should be of the amphibole variety, is digested with 1 : 3 hydrochloric acid for 2 to 3 days, after which it is washed free from acid and digested for a similar period with soda solution,[1] following which it is treated with hot Fehling's solution. The asbestos is now washed free from alkali and finally digested with nitric acid for several hours, after which it is washed free from acid and suspended in water for use. It is best kept suspended in water in a wide-mouthed stoppered bottle.

To prepare a Soxhlet tube for use, a small amount of the prepared asbestos suspended in water is introduced into the tube which is in connection with the filter pump, just as it would be when being used for the collection of the copper precipitate. The tube thus charged with asbestos is then dried in the water oven and cooled in the desiccator when it is ready for use.

A Soxhlet tube, prepared as just described, is tared, and the cuprous oxide having been collected in it and washed with hot water, principally by decantation, the tube is dried in the water oven. The drying may be facilitated by washing finally with alcohol and ether before placing in the oven. The most commonly adopted plan is to reduce the cuprous oxide to metallic copper before weighing. This is done by connecting the wider end of the tube with a hydrogen generating apparatus and igniting that portion of the tube containing the cuprous oxide by a Bunsen flame, a current of hydrogen being passed through the tube meanwhile. Prior to this, however, in the most exact work, especially with commercial products, it is advisable to ignite in a current of oxygen in order to remove any organic matter that may have been precipitated with the cuprous oxide. Some chemists weigh the precipitate as cupric oxide after ignition in current of oxygen. It has also been proposed to weigh the precipitate after merely drying, and in the case of sugar solutions not containing other organic matters this appears not to be attended with any error (*cf.* O'Sullivan and Stern, Chem. Soc. Trans. 69, 1691). Ling and Davis (J. Inst. Brewing, 8, 477), employing a Gooch crucible, weighed the copper precipitate as cuprous oxide, that is to say, they merely dried it after collection, and their results show that with pure solutions this procedure is

---

[1] In this connection it should be pointed out that Glendinning (Chem. Soc. Trans. 67, 999) has shown that, other things being equal, considerably higher results are obtained when potassium hydroxide is substituted for the sodium compound.

[1] The writer uses a 50 p.c. solution of sodium hydroxide for this purpose.

justifiable on the score of accuracy. Whichever method is adopted, the Soxhlet tube or Gooch crucible, after being weighed with the copper should be treated with nitric acid to dissolve the copper, and the asbestos thoroughly washed. After drying, the tare of the tube should be the same as it was at the commencement of the experiment.

The washed cuprous oxide collected on a Soxhlet tube or Gooch crucible may also be dissolved in nitric acid or a mixture of that acid and sulphuric acid, the copper deposited electrolytically and weighed as metal (see Bull. 107 [revised], U.S. Bur. of Chem., p. 49). Peters has devised a rapid electrolytic method of estimating copper (J. Amer. Chem. Soc. 34, 426). Another electrolytic method is that of Sand described in the Report of the British Association for the Advancement of Science, 1910.

The washed cuprous oxide may be dissolved in sulphuric acid and the solution titrated with permanganate. Many methods have been proposed for this purpose (Neitzel, Jahresber. Zuckerfabrik. 1893, 104; Kalmann, Osterr. Zeit. Zuckerind., 25, 43; Thorne and Jeffers, Analyst, 30, 188).[1] The usual way in which the method is carried out is to transfer the cuprous oxide and asbestos wad to 50 c.c. of a solution containing an excess of iron alum, acidified with sulphuric acid. The solution is then titrated with N/20 permanganate (*cf.* also Bull. 107 U.S. Bur. of Chem., *l.c.*). Another method of estimating the cuprous oxide reduced by sugar solutions is based on the well-known principle of liberation of iodine by cupric salts and titration of the iodine with thiosulphate. The washed precipitate is dissolved in nitric acid, and the solution boiled until the red fumes are expelled. It is then made alkaline with ammonia and acidified with acetic acid. An excess of potassium iodide is then added and the liberated iodine is titrated in the well-known manner (Low, J. Amer. Chem. Soc. 24, 1082; Kendall, *ibid.* 23, 1947; Peters, *ibid.* 34, 422). This iodometric method gives low results as compared with those obtained by the gravimetric method (Sherwood and Wiley, Bull. 105, U.S. Bur. of Chem., p. 120).

Allihn's method. One of the best known and most widely used methods of estimating dextrose gravimetrically by the cupric reduction method is that of Allihn (J. prakt. Chem. [ii.], 22, 46), but it has not been applied to any other sugar. The copper reagent used has the following composition:—

Solution I. Crystallised copper sulphate (34·6 grms.) is dissolved in water and the solution made up to 500 c.c.

Solution II. Rochelle salt (173 grms.) and potassium hydroxide (125 grms.) are dissolved in water and the solution made up to 500 c.c.

Equal volumes of 30 c.c. of each of the two solutions are measured out into a beaker and diluted with 60 c.c. of water. A volume of 25 c.c. of a standard solution of the sample to be examined, which must not contain more than 0·25 grm. of dextrose, is added and the solution is raised to the boiling-point, ebullition being continued for 2 mins. It is important in this and in all other estimations of the kind that the beaker should be covered with a clock glass during the ebullition.[1] The cuprous oxide is collected at once in a Soxhlet tube, washed, dried, and reduced in a current of hydrogen in the manner already described. In the following table, which is an abridged form of that given for the Allihn method by the A. O. A. C. (Bull. 107 [revised], U.S. Bur. of Chem., p. 49), the weight of copper and of cuprous oxide corresponding to different weights of dextrose are given.

TABLE XVIII.—*Allihn's Table for Estimating Glucose.*

---

[1] Also private communication to the writer from Dr. L. T. Thorne.

[1] The reason that it is necessary to cover the beaker with a clock glass has already been alluded to as well as the observations of Kjeldahl (*l.c.*) on this point. Kjeldahl went even further and suggested carrying out the reduction in a flask immersed in a bath of boiling water, a current of hydrogen being passed through the solution during the ebullition. Kjeldahl's

Meissl's method for the estimation of invert sugar (Zeit. Ver. Deut. Zuckerind, 29, 1050) is carried out in the same manner as Allihn's dextrose method, but the copper solution employed was that of Soxhlet, containing 52 grms. per litre of sodium hydroxide. Wein (Tabellen für quantitative Bestimmung der Zuckerarten, 1888) used the same solution for the estimation of maltose and other sugars. The results for maltose calculated by Wein's tables were found to be 5 p.c. too low by Brown, Morris and Millar (Chem. Soc. Trans. 71, 105), and this has been confirmed by Ling and Baker (*ibid.* 509).

Standard gravimetric methods have been devised, each of which is capable of being used for the estimation of several sugars. The first of these which will be described here is that of Brown, Morris and Millar (*l.c.*) for the estimation of dextrose, lævulose, invert sugar and maltose. The method adopted is that of O'Sullivan. The copper reagent employed had the following composition. Crystallised copper sulphate (34·6 grms.), Rochelle salt (173 grms.), sodium hydroxide (65 grms.), and water to one litre.[1]

Fifty cubic centimetres of the copper solution are introduced into a beaker, the surface area of which is 44 sq. cm. The beaker is covered with a clock glass and immersed in a bath of boiling water. When the solution has attained the same temperature as that of the bath, the sugar solution is added and the mixture made up to approximately 100 c.c. with boiling water and heated in the boiling water bath for exactly 12 mins. The amount of sugar employed must be that which will give a weight of cupric oxide lying within the limits of 0·15 to 0·35 grm. The filtration is performed as rapidly as possible through a Soxhlet's tube under reduced pressure, and the cuprous oxide is either oxidised to cupric oxide in a current of oxygen or reduced to copper in a current of hydrogen. The results are calculated by Tables XIX–XXII.

Defren (J. Amer. Chem. Soc. 18, 751) has worked out a method for the estimation of dextrose, maltose and lactose. He employs, like Meissl and Wein (see above), Soxhlet's formula for Fehling's solution, but adopts the O'Sullivan method.

Bertrand (Bull. Soc. chim. [iii.] 35, 1285) has elaborated a method for the estimation of invert sugar, dextrose, galactose, maltose and lactose. His reagent has the following composition:

Solution I. Crystallised copper sulphate (40 grms.) is dissolved in water and made up to one litre.

Solution II. Rochelle salt (150 grms.) and sodium hydroxide (150 grms.) are dissolved in water and made up to one litre.

His method is carried out as follows: A sugar solution (20 c.c.) which should not contain more than 0·1 grm. of reducing sugars is transferred to a 150 c.c. Erlenmeyer flask, and 20 c.c. of each of the two solutions forming the copper reagent added. The mixture is then heated to boiling, and maintained in gentle ebullition for exactly 3 mins. The liquid is then filtered through a Gooch crucible, the precipitate washed as usual and the reduced copper estimated volumetrically by the permanganate method (see p. 252). Table XXIII. is Bertrand's table abridged from the original.

200	0·3745	0·4689	1·874	2·344
205	0·3822	0·4792	1·869	2·338

As already mentioned, numerous other metallic solutions besides that originally devised by Fehling have been used for the detection and estimation of reducing sugars. These will now be dealt with in outline.

Barfoed (Zeitsch. anal. Chem. 12, 27) proposed to use a solution one part of crystallised neutral copper acetate in 15 parts of water. To 200 c.c. of this solution are added 5 c.c. of 38 p.c. acetic acid before use. Barfoed's solution is not reduced to any great extent by the bioses maltose, lactose, &c., but although it has some value in the case of mixture of monoses and bioses, this applies to it for qualitative rather than quantitative purposes.

It has been proposed by Soldaini (Ber. 9, 1126) and also subsequently by another chemist of the same name (Zeits. Ver. Deut. Zuckerind.

---

method has been modified by Woy (Zeits. öffentl. Chem. 6, 514; 519). Working with pure sugar solutions there is no doubt that more concordant results can be obtained in this way, but with commercial products, in which this atmospheric oxidation is perhaps one of the least factors which conduce to error, the covering of the beaker with a clock glass is a sufficient precaution to guard against atmospheric oxidation. In the Allihn method the size of the beaker, the kind and height of the flame employed also influence the results. On this account the O'Sullivan method of heating in a boiling water bath as adopted by Kjeldahl, Brown, Morris and Millar (see this page), and others is to be preferred.

[1] The copper culphate solution and the alkaline Rochelle salt solution are, of course, kept separate.

39, 933; 40, 792) to employ a copper bicarbonate solution for the estimation of reducing sugars. The disadvantages of such a solution, however, outweigh its advantages, since there is always the possibility of the precipitation of cupric hydroxide, in addition to which calcium and other salts which are present in commercial products are precipitated with the cuprous oxide. More recently Ost has suggested a modification of the Soldaini reagent (Chem. Zeit. 19, 1784, 1829).

Before dismissing copper methods attention may be called to a paper by Kendall (J. Amer. Chem. Soc. 34, 317). Fehling's solution prepared with Rochelle salt is well known to be liable to spontaneous reduction, especially if the copper and Rochelle salt solutions have been kept mixed for some time. Kendall tried various other salts to replace the Rochelle salt, and finally came to the conclusion that a cupric solution containing an alkali carbonate and salicylate remained perfectly stable in absence of extraneous reducing substances. The method adopted is as follows: An appropriate volume of the sugar solution is measured out into a 200 c.c. Erlenmeyer flask and the volume made up to 100 c.c. Five grams of salicylic acid are added, 15 c.c. of copper sulphate solution (containing 2 grms. of crystallised copper sulphate) and 25 c.c. of potassium carbonate solution (containing 15 grms. of the carbonate). This order must be adhered to and the mixture must not be agitated until all the constituents have been introduced, when the flask is rotated, and as soon as all the salicylic acid is dissolved the flask is placed in a boiling water bath for 20 mins. The cuprous oxide is then collected on an asbestos filter, washed and the copper estimated iodometrically by a modification devised by Kendall (*ibid.* 33, 1947).

Knapp's alkaline mercuric cyanide solution (Zeitsch. anal. Chem. 9, 395). This reagent is prepared by dissolving mercuric cyanide (10 grms.) in 100 c.c. of sodium hydroxide solution of sp.gr. 1·145, and making up the solution to one litre. A measured volume of the reagent is heated to boiling and the sugar solution added from a burette until a drop of the filtered solution shows when acidified with acetic acid no coloration with ammonius sulphide. The final point is by no means sharp and the method is but little used at the present time.

Sachsse's alkaline mercuric iodide solution (Zeits. Ver. Deut. Zuckerind. 26, 872). To prepare this solution, mercuric iodide (18 grms.)—mercuric chloride is precipitated with potassium iodide, the precipitate washed and dried at 100°—is dissolved in a solution containing 80 grms. of potassium hydroxide. The solution is then made up to one litre. A solution of stannous chloride containing an excess of potassium hydroxide is used for determining the final point.

Composition of commercial sugars. It may be pointed out that the values given under 'Polarisation' are those obtained by reading normal (Ventzke) solutions, clarified with the minimum quantity of basic lead acetate solution, in a 2 dm. tube. It will be observed that in the case of beet products the reducing sugars which are calculated as invert sugar are given as a trace. This means that the quantity present was less than 0·05 p.c. In the case of stored beet products, however, it frequently happens that from 0·5 to 5·0 p.c. and even more of reducing sugars are present, their production being due to the action of certain bacteria on the sucrose.

Raw beet products. The direct polarisation of beet products as a rule gives a value closely approximating the true percentage of sucrose, an exception to this being when raffinose is present. In products containing raffinose, the direct polarisation must of necessity be in excess of the true percentage of sucrose, since the specific rotatory power of raffinose is greater than that of sucrose.

Table XXIII.—*Bertrand's Table for Estimating Invert Sugar, Glucose, Galactose, Maltose, and Lactose.*

100	176·5	177·8	173·6	108·4	131·4

The composition of normal beet products of different grade is as follows:—

Beet crystals. This product contains 99·8–99·9 p.c. of sucrose with 0·05 to 0·07 p.c. of ash. It is obtained in the beet factory, notably when the Steffen process is employed, by steam washing the first masse cuite in a centrifugal machine.

The raw beet sugars which go to the refiner, have the average composition shown below. The so-called 'rendement' or refinery yield is obtained by deducting five times the ash from the polarisation or sucrose percentage. This method of determining the refinery yield was first suggested by Scheibler, and was based on the fact that beet molasses[1] in his time contained on an average 50 p.c. of sucrose and 10 p.c. of ash (see below). He therefore assumed that the mineral matter in raw sugars prevented five times its weight of sugar from crystallising. It is now known that the so-called other organic matters, especially those whch are colloidal, have a far greater melassigenic effect than the mineral matters, *per se.*

---

[1] Molasses is the final product in the manufacture of sugar. Although containing sugar, this cannot be separated from it by direct crystallisation.

Raw Beet Products.

	I		II		III	
	First runnings		Second runnings		After products	
Polarisation	96·0	95·5	93·5	91·0	90·0	85·5

Ash	10·0
Water	20·0
Other organic matter	20·0
	100·0

Raw products are also met with intermediate in composition between the three grades of solid sugars above referred to. So perfect are the systems now employed in the extraction of sugar from beet that the sucrose content of the molasses is often as low as 46 p.c. It has been mentioned already that beet products are liable to contain raffinose (see this vol. p. 246). Since this sugar is more soluble than sucrose, and as it is present in small amount, it necessarily accumulates in the molasses. Hence those products which are recovered from molasses are more likely to contain raffinose.[1] In some samples of beet molasses, as much as 15 p.c. of raffinose has been found by the optical method. It will have been noticed that in normal beet products the other organic matters are invariably in excess of the ash. When this is not the case, the presence of raffinose is to be suspected. Raw beet sugars containing raffinose—and these are most frequently molasses recovery products or low after products—are, as a rule, fine grained and woolly in appearance.

The following are some analyses of raw beet sugars containing raffinose [1]:—

	I	II
Polarisation	92·1	89·4
Sucrose	91·0	86·8
Raffinose	0·6	1·4
Reducing sugar	trace	trace
Ash	1·7	2·1
Water	3·5	5·0
Other organic matter	3·2	4·7
	100·0	100·0

In certain rare cases, 3 p.c. of raffinose and more has been found in sugars recovered from molasses.

Raw cane products. These are subject to a much greater variation in composition than are raw beet products. A few typical examples only will be given.

	Java basket sugar.		Cuban centrifugal sugar.		Cuban molasses sugar.	
Polarisation	98·0	96·0	97·0	96·50	86·5	80·5
Reducing Sugar	0·5	1·3	1·0	1·30	2·2	4·5
Ash	0·3	0·6	0·5	0·55	2·7	3·5
Water	0·2	1·0	0·5	0·60	4·2	3·0
Other organic matter	0·5	1·1	1·0	1·05	4·4	8·5
	100·0	100·0	100·0	100·00	100·0	100·0

Low, dark coloured solid cane products are met with in commerce under the following descriptions: Madras Jaggery, Java Stoopes, Panela, Penang, Brazilian syrups, Mauritius syrups and Egyptian. The quantity of these low products imported into this country is much less than in former times, since with improved machinery and methods a larger proportion of high grade products is now turned out at the different cane factories all over the world. On this account also such as are imported are much less pure than formerly. The average analytical values obtained with these low products are within the following limits:—

Polarisation	85 to 60 p.c.
Invert sugar	10 to 15 ,,
Soluble ash	3 to 6 ,,

The values given under 'Polarisation' in the case of raw cane sugars are always less than the sucrose percentages determined by the Clerget method, since these products invariably contain reducing sugars which are more or less lævo-rotatory. The polarisations cannot, however, be corrected for these reducing sugars, as their rotatory constants are not always those of invert sugar.

Many raw cane sugars are sold for direct consumption, but the most popular types of these are Demarara sugars and cane products resembling them. These sugars polarise from 95–98 p.c. and contain from 1·5 to 0·5 p.c. of reducing sugar and from 1·5 to 1·0 p.c. of moisture. Occasionally the percentage of re-

---

[1] The fact that raffinose is found in the largest quantity in sugars recovered from molasses by one of the alkali earth processes, led chemists to believe that this sugar was formed by the action of the alkali earths; but von Lippmann has shown that raffinose is present in beet juice (Annalen, 232, 169). However, raffinose contains a galactose residue, and bearing in mind Lobry de Bruyn's discovery of the reciprocal conversion of dextrose, lævulose and galactose under the action of alkalis, the possibility is by no means excluded that galactose may be formed by the action of the alkali earths on dextrose and lævulose in the sugar works and that this galactose may condense with sucrose forming raffinose.

[1] The sucrose and raffinose were estimated by the method of double polarisation.

ducing sugars is higher. This is likely to be the case with products which have been stored. Products of like appearance to these types of sugar, which consist however of dyed beet sugar, have for some time been on the market. The dyes employed for the purpose are brilliant yellow S, an azo dye, and phosphine. The former gives a fine violet red colour with acids, whilst the latter remains unchanged on addition of acids. It may be detected, however, by dissolving the suspected sugar in water, rendering the solution alkaline and shaking it with ether, when a yellow coloured ethereal extract, having a greenish fluorescence, is obtained. It should be pointed out that cane products as well as beet are now dyed in the manner described, and in some cases colouring with molasses is resorted to. Another method of imparting an attractive 'bloom' to a raw cane sugar is to treat it with stannous chloride. The writer has found quantities of stannous chloride approximating to 0·001 p.c. in raw sugars.

Cane crystals. These resemble the corresponding beet product, but give a lower polarisation, *e.g.* 99·6 to 99·8 p.c., owing to the presence of a small amount of reducing sugars. They may be distinguished easily from the beet product by their pleasant aroma.

Refined sugars. As produced in this country, refined sugars are sent out at so high a degree of purity that it has been said that no other chemical substance is sold so pure. The ash content is usually less than one part in ten thousand. To give them a white lustre they are often mixed with a minute trace of ultramarine or other blue colouring matter.

Estimation of galactose and galactans. It is a special property of galactose and of all compounds containing a galactose residue to give mucic acid when oxidised with nitric acid. When the oxidation is carried out under standard conditions, the galactose or galactose residue may be estimated from the weight of mucic acid obtained. Among the sugars containing a galactose residue may be mentioned lactose, melibiose, raffinose, rhaminose, &c., whilst a number of polysaccharides, *e.g.* galactans and galactopentosans contain this residue. Many of these are constituents of the gums of commerce, whilst the so-called pectins found in apples, pears, grapes and other fruits, as well as in beetroots, carrots and the tissues of many plants, yield galactose and arabinose on hydrolysis with acids. Just as the formation of furfural constitutes a specific method for the detection and estimation of pentoses and pentosans, so also does the formation of mucic acid form a specific method for the detection and estimation of galactose and galactans. The first chemists to suggest this method of analysis were Tollens and his pupils, and the latest instructions for carrying out the method as revised by the A. O. A. C. (Bull. 107 [revised], U.S. Bur. of Chem., p. 55) are the following:

'Extract a convenient quantity of the substance, representing from 2·5 to 3 grms. of the dry material, on a hardened filter with five successive portions of 10 c.c. of ether; place the extracted residue in a beaker about 5·5 cm. in diameter and 7 cm. deep, together with 60 c.c. of nitric acid of 1·15 sp.gr., and evaporate the solution to exactly one-third its volume in a water bath at a temperature of 94°-96°C. After standing 24 hours, add 10 c.c. of water to the precipitate, and allow it to stand another 24 hours. The mucic acid has in the meantime crystallised, but it is mixed with considerable material only partially oxidised by the nitric acid. Filter the solution, therefore, through filter paper, wash with 30 c.c. of water to remove as much of the nitric acid as possible, and replace the filter and contents in the beaker. Add 30 c.c. of ammonium carbonate solution, consisting of 1 part ammonium carbonate, 19 parts of water and 1 part strong ammonium hydroxide, and heat the mixture on a water bath at 80°C., for 15 mins., with constant stirring. The ammonium carbonate takes up the mucic acid, forming the soluble mucate of ammonia. Then wash the filter paper and contents several times with hot water by decantation, passing the washings through a filter paper, to which finally transfer the material and thoroughly wash. Evaporate the filtrate to dryness over a water bath, avoiding unnecessary heating which causes decomposition, add 5 c.c. of nitric acid of 1·15 sp.gr., thoroughly stir the mixture and allow to stand for 30 mins. The nitric acid decomposes the ammonium mucate, precipitating the mucic acid; collect this on a tared filter or Gooch crucible, wash with from 10 to 15 c.c. of water, then with 60 c.c. of alcohol and a number of times with ether; dry at the temperature of boiling water for 3 hours, and weigh. Multiply mucic acid by 1·33, which gives galactose, and multiply this product by 0·9 which gives galactan.'

As will be seen, the method is empirical, the yield of mucic acid falling short in all cases of the theoretical.

Estimation of pentoses and pentosans. The pentoses, arabinose and xylose, containing as they do a free carbonyl group, may be estimated by cupric reduction methods. Pentosans, on the other hand, do not reduce alkaline copper solutions. Since, however, pentoses as well as pentosans are usually associated with hexoses, a selective method is necessary for their estimation. It has long been known that many carbohydrates yield furfural when heated with acids, and traces are formed from the ordinary hexoses under these conditions. The pentoses and pentosans, however, when distilled with hydrochloric acid under appropriate conditions can be made to yield 75 to 90 p.c. of the theoretical quantity of furfural indicated by the equations:

$$\underset{\text{Pentosan}}{C_5H_8O_4}=\underset{\text{Furfural}}{C_5H_4O_2}+2H_2O$$

$$\underset{\text{Pentose}}{C_5H_{10}O_5}=\underset{\text{Furfural}}{C_5H_4O_2}+3H_2O$$

For the elaboration of methods depending on this principle, we are indebted to Tollens and his pupils. Standard conditions of distillation having been established, it was proposed to precipitate the furfural as phenylhydrazide. This, however, necessitated neutralising the distillate, besides involving the difficulty that furfuralphenylhydrazide is a very unstable substance of low melting-point. Furfural is now precipitated as phloroglucide. The latest modification of the method is that of Tollens and Kröber (J. für Landwirtsch. 1909, 335, 1901, 7). The following are its details. A

Wurtz flask of 300 c.c. capacity is provided with doubly-bored cork so as to take a dropping funnel and the connecting tube to the condenser. The dropping funnel has a cylindrical reservoir with two graduation marks at 30 c.c., and 60 c.c. respectively. The flask is heated in a bath of Rose's alloy which melts near 100°C. Its composition is 1 part lead, 1 part tin and 2 parts bismuth. From 2 to 5 grms. of the substance under investigation, according to the quantity of pentose or pentosan it contains, are placed in the Wurtz flask together with 100 c.c. of hydrochloric acid (sp.gr. 1·06). The flask is connected with the condenser and dropping funnel, which latter is charged with hydrochloric acid (sp.gr. 1·06) up to the upper mark at 60°C. The alloy having been previously heated just above its fusing point, the flask is immersed in it. Distillation is now conducted at such a rate that 30 c.c. pass over in from 10–11 mins. after which a further 30 c.c. of acid is introduced by means of the dropping funnel. The distillate is received in a 100 c.c. graduated cylinder, the contents of which are transferred to a beaker from time to time. The process is continued in this way until a drop of the distillate no longer gives a pink coloration with aniline acetate paper.[1] As a rule, it is necessary to distil over from 1 to 12 portions of 30 c.c., depending on the quantity of pentose or pentosan present in the material.

Purification of phloroglucinol (Bull. 107 [Revised], U.S. Bur. of Chem., p. 54). Phloroglucinol, as purchased, is liable to contain diresorcenol and should be tested for this as follows: A small quantity is dissolved in a little acetic anhydride, heated almost to boiling and a few drops of concentrated sulphuric acid added. A violet coloration indicates the presence of diresorcinol. A sample of phloroglucinol which gives more than a faint coloration must be purified by the following method: hydrochloric acid (300 c.c. sp.gr. 1·06) is heated in a beaker and the phloroglucinol (11 grms.) added in small quantities at a time stirring constantly until almost complete solution has been effected. The hot solution is poured into a sufficient volume of hydrochloric acid of the specific gravity above alluded to that the total volume is 1500 c.c. The liquid is then allowed to remain aside for several days when the diresorcinol will have crystallised out. The solution should be filtered immediately before using. It may become yellow, but this is of no consequence.

Precipitation of the phloroglucide. To the distillate from the sample under investigation contained in a 500 c.c. beaker is added sufficient of the phloroglucinol solution that the quantity of phloroglucinol is about double that of the furfural expected. The solution becomes at first yellow and then changes to a greenish black when the phloroglucide $C_{11}H_3O_4$ begins to deposit. It is then made up to 400 c.c. with hydrochloric acid (sp.gr. 1·06), and allowed to remain aside over night. The supernatant liquid is then tested with aniline acetate paper to ascertain if all the furfural has been precipitated, and if so, it is filtered through a tared Gooch crucible. The phloroglucide having been collected on the asbestos, it is washed with 150 c.c. of water, taking care that the washings never drain entirely from the crucible until the final quantity of water is placed over the precipitate. The crucible is then dried in a boiling water oven for 4 hours, it being placed on a support so that the perforated portion is free to the air. After cooling in a desiccator, the crucible is again weighed. The weight of pentosan or pentose is ascertained from the following table, which is abridged from the original table of Kröber.

TABLE XXIV.—*Kröber's Table for estimating Pentoses and Pentosans.*

Furfural phloroglucide	Furfural	Arabinose	Araban	Xylose	Xylan

When a mixture of pentosans or pentoses is being dealt with, the mean of ariban and xylan values and the arabinose and xylose values respectively should be reported. For weights of phloroglucide outside the limits of the table, Kröber gives the following formulæ.

For a weight of phloroglucide *a* under 0·03 grm.

Weight of furfural $=(a\ 0{\cdot}0052\times0{\cdot}5170)$
„ pentoses $=(a\ 0{\cdot}0052\times1{\cdot}0170)$
„ pentosans $=(a\ 0{\cdot}0052\times0{\cdot}8948)$

For a weight of phloroglucide *a* over 0·3 grm.

Weight of furfural $=(a\ 0{\cdot}0052\times0{\cdot}518)$
„ pentoses $=(a\ 0{\cdot}0052\times0{\cdot}10026)$
„ pentosans $=(a\ 0{\cdot}0052\times0{\cdot}8824)$

The factor 0·0052 is the weight of phloroglucide which remains dissolved in the 400 c.c. of acid solution.

Jolles, in 1905 (Sitzungsber Wien Akad. 114, II*b*, 1191), worked out a method of estimating furfural which consisted in adding a known quantity in excess of sodium hydrogen sulphite to the faintly acid distillate obtained as already described. The excess (uncombined) sulphite is then estimated by titration with N/10 iodine solution. The method as at present worked out appears to present no advantages over the phloroglucide method.

In 1910, Flohil (Chem. Weekblad. 7, 1057) proposed to estimate furfural by measuring its

---

[1] To prepare aniline acetate paper equal volumes of aniline and water are mixed in a test tube and glacial acetic acid added drop by drop until the milky emulsion becomes a clear solution. Strips of filter paper are then moistened with this solution and allowed to dry.

reducing action on Fehling's solution under standard conditions. His results were revised by Eynon and Lane (Analyst, 37, 41), but even as these chemists left it, the method is inferior in accuracy to the phloroglucide method.

For the estimation of methyl pentoses or methyl pentosans, see Tollens and Ellet (Ber. 38, 492); Tollens and Mayer (*ibid.* 40, 2441); Jolles (Annalen, 351, 41).

Analysis of mixtures of sugars. I. Invert sugar. Commercial invert sugar is one of the most valuable and widely-used brewing sugars. It is prepared by hydrolysing raw cane sugars by an acid (usually sulphuric but occasionally hydrochloric)—raw beet sugars cannot be used for this purpose—neutralising with calcium carbonate filtering, and after passing through a column of animal charcoal concentrating the filtrate to such a degree that a 10 p.c. solution of the final product shows an extract of 70–72 Brewers' lb. per 2 cwt. The extract is determined by weighing out 10 grms. of the sample, dissolving in water, diluting to 100 c.c. and determining the specific gravity of the solution. The excess specific gravity over that of water (taken as 1000), multiplied by the factor 2·24, gives the extract of the sample in lb. per 2 cwt. This method is quite an arbitrary one, and if a solution of any other concentration than 10 p.c. is made use of, the factor directly proportional to 2·24 does not give the same result.

The estimation of the ash and water is conducted as described on p. 262 (see more especially under syrupy products). The sugars are estimated by a scheme devised by Morris (J. Inst. Brewing, 4, 162). Morris employed the gravimetric method of Brown, Morris and Millar (see p. 253), whilst the writer has always employed the volumetric method (see p. 247). The details of the scheme when the latter method is employed are as follows:—

Total reducing sugars. A convenient volume (usually 10 c.c.) of a 10 p.c. solution of the sample is made up to 1000 c.c. and titrated with 10 c.c. of Fehling's solution in the manner described on p. 248. Let the percentage of apparent invert sugar calculated on the sample be denoted by the symbol I.

Sucrose. The same volume of a 10 p.c. solution as that employed for the estimation of the total reducing sugars is diluted with 100 c.c. of water and 20 c.c. of N/2 hydrochloric acid. The mixture is raised to a boiling temperature and maintained in ebullition for one minute, after which it is cooled, neutralised by the addition of 20 c.c. of N/2 sodium hydroxide, and made up to 1000 c.c. The solution is then titrated against 10 c.c. of Fehling's solution. The percentage of apparent invert sugar calculated on the sample may then be denoted by the symbol I′. The percentage of sucrose is then calculated by the following formula: $S=\frac{95(I'-I)}{100}$. Commercial invert sugar contains unfermentable reducing substances, and it is therefore necessary to correct the results for these. The fermentation test is best carried out as follows: 25 grms. of the sample are dissolved in about 200 c.c. of water in an Erlenmeyer flask and the solution is sterilised by boiling. About 5 c.c. of yeast decoction (1–5) is now added, and about 3 grms. of washed pressed yeast. The flask is closed with a cotton wool plug and placed in a thermostat at 70°F. for 3–4 days, after which it is transferred to a 250 c.c. flask, a little alumina cream added and made up to 250 c.c. The reducing power of the filtrate is then determined and calculated on the sample. The value so obtained may be denoted as F. Then $I-F=K$, the reducing power due to dextrose and lævulose in the sample. The number of c.c.'s of Fehling's solution corresponding with 1 grm. of the sample is now calculated and denoted as G.

The rotation of a 10 p.c. solution of the sample in divisions Ventzke (2 dm. tube) is determined before and after fermentation. The direct rotation value corrected for that of the fermented solution and for that of the percentage of sucrose found (see above) is denoted by the symbol R.

From these data the percentages of dextrose and lævulose in the sample may be calculated by the following simultaneous equations:—

$$(a)\ 1{\cdot}966D+1{\cdot}838L=G.$$
$$(b)\ 0{\cdot}305D+(-0{\cdot}532L)=R.$$

The coefficients of D and L in equation are the gram Fehling equivalent of dextrose and lævulose respectively at a certain concentration. These coefficients may be obtained from the table of Ling and Jones (p. 248). If the gravimetric method is used, the constants worked out by Morris (J. Inst. Brewing, 4, 162) for the Brown, Morris and Millar method are applied.

Invert sugar is supplied to the brewer in three grades, and the following are typical analyses of each.

	No. 1	No. 2	No. 3
Dextrose	36·85	36·96	35·44
Lævulose	36·22	35·01	34·85
Sucrose	3·39	1·89	4·54
Albuminoids . . .	0·20	0·26	0·27
Ash	1·57	2·20	2·51
Other organic matter[1] .	4·25	5·23	3·60
Water	17·52	18·45	18·79
	100·00	100·00	100·00

	No. 1	No. 2	No. 3
[1] Containing unfermentable reducing carbohydrates expressed as invert sugar .	3·36	3·62	3·40 p.c.
Brewers' extract per 2 cwt.	72·8	72·6	72·6 lb.
Tint (Lovibond, 10 p.c. solution 1″ cell) . . .	3·5	8·5	13·0 N.
Specific rotary power $[\alpha]_D$	−11·6°	−11·4°	−10·4°.
Ferric Oxide (Fe_2O_3) .	0·002	0·003	0·003 p.c.

These results were obtained with samples of the three grades of invert sugar of exceptionally high quality. It sometimes happens that there is a shortage of raw cane sugar of low ash content on the market, and some considerable latitude has to be allowed with regard to the permissible limits of ash in the three grades of sugar. The percentages of ash should, however, never exceed the following limits, which will seldom be reached.

No. I, 2·00 p.c.; No. II, 2·75 p.c.; No. III, 3·50 p.c. The percentage of albuminoids should not exceed the following: No. I, 0·30 p.c.; No. II, 0·50 p.c.; No. III, 0·75 p.c. (compare below).

A widespread belief exists among brewers that invert sugar prepared from beet products gives rise to troubles when employed for brewing, and the writer from practical experience can confirm this in so far as invert sugars prepared from 'raw' beet products are concerned. On the other hand, no exception can be taken to invert sugars prepared from beet crystals and other high grade sugars derived from beet, except that they do not add to the palate fullness or lusciousness of the finished beers. In seeking an explanation of these facts, it has to be remembered that the substances other than the sugars present in 'raw' products derived from the sugar cane are helpful in producing that fullness of palate which—especially in the case of mild ales and stouts—is now demanded by the public. It is otherwise in the case of 'raw' beet products. Here the substances, other than the sugars, have a nauseous flavour which tends to impair the palate of beers. These substances appear also to cause certain secondary troubles in the finished beers.

When low grade beet sugars have been used for the manufacture of invert sugar, the product will possess a characteristic odour and flavour. If, however, higher grade (first runnings) raw beet sugars have been employed, it is difficult to arrive at a decision from the odour and flavour alone, more especially if the sample has been made from a mixture of first running beet sugars and raw cane sugars. The writer would point out in this connection that the percentage of albuminoids (*i.e.* nitrogen × 6·25) in beet products greatly exceeds that in cane products Thus he has found the following percentages in low grade cane products: Mauritius, 0·48 p.c.; Penang, 0·39 p.c.; Brazil, 0·63 p.c.; Panela, 0·61 p.c.; Jaggery, 0·59 p.c.; cane molasses, 4–5 p.c. On the other hand, he has found the following percentages in beet products: first runnings, 0·89 to 1·00 p.c.; second runnings, 1·77 to 2·00 p.c.; beet molasses, 6·23 to 9·50 p.c.[1]

II. *Honey*. Since the principal constituent of honey is invert sugar, the scheme just described for the analysis of commercial invert sugar may be used for its analysis. The following analyses of honey from various sources are reported by Campbell Brown (Analyst, 3, 267).

TABLE XXV.—*The Composition of Honey.—Percentages.*

Source	Water	Lævulose	Dextrose	Sucrose	Wax, pollen, and other insoluble matters	Ash	Other organic matter
England . . .	19·10	36·60	36·55	—	trace	0·15	7·60

Tibbles (Foods, their Origin, Composition and Manufacture, p. 729) gives the following analyses of authentic honeys:—

Seiber (Biedermann's Centralblatt 1885, 134) average of sixty analyses.

Dextrose	Lævulose	Sucrose	Water
34·71	39·24	1·08	19·28 per cent.

Hoitsema (Zeitsch. anal. Chem. 38, 429).

	Invert sugar	Sucrose	Wax, pollen,&c.	Ash	Water
Minimum	71·20	0·20	0·02	0·13	8·30 p.c.
Maximum	74·50	2·60	0·46	0·34	17·80 p.c.

Canadian Inland Revenue Bulletin, 47.

	Invert sugar	Sucrose	Ash	Water
Minimum	66·37	0·50	0·03	12·00 p.c.
Maximum	78·80	7·64	0·05	33·00 p.c.

Narbonne Honey (The Practical Grocer, ii. 161).

Invert sugar	Sucrose	Wax, pollen, &c.	Ash	Water
74·00	7·10	1·50	0·30	17·10 p.c.

The presence of sucrose in honey seems remarkable. The writer has found as much as 10 per cent. of sucrose in some samples of British honey. Such a high percentage is, however, exceptional.

Honeys in the United States have been found to contain dextrinous carbohydrates which are precipitable by alcohol from their aqueous solutions and are unfermentable by brewers' yeast. The specific rotatory power of honey dextrin, according to Browne, is $[\alpha]_D$ 115°–160°. Browne (Bull. 110, U.S. Bur. of Chem.) gives a number of analyses of dextrinous honeys of different kinds, and he shows that the quantity of dextrin varies from 0·34 to 12·95 p.c.

Honey is frequently adulterated with artificial invert sugar, and for the detection of the latter certain colorimetric tests have been devised. Furfural is said to be a constituent of artificial invert sugar and C. A. Browne (Bull. 110, U.S. Bur. of Chem.) suggests testing for this with aniline acetate. The reagent must be freshly prepared by the following method: 5 c.c. of aniline are shaken with 5 c.c. of water and 2 c.c. of gluceal acetic acid added. This amount of acid is just sufficient to produce a bright solution. One to two c.c. of the reagent are allowed to flow down the walls of a test tube into a solution of the honey in an equal weight of water. If, after shaking, a red ring forms below the aniline layer and gradually spreads to the whole solution, invert sugar is present.

Fiehe (Chem. Zeit. 32, 1045; Zeitsch. Nahr. Genussm. 1908, 75) points out that during the manufacture of invert sugar some of the lævulose is converted into β-hydroxy-δ-methylfurfural, which gives a red coloration with a solution of one part of resorcinol in 100 parts of hydrochloric acid (sp.gr. 1·19). This has been confirmed as a test for artificial invert sugar (see Witte, Zeitsch. Nahr. Genussm. 1909, 625; Reinhardt, *ibid.* 1910, 113; Muttelet, Ann. Falsif. 3, 206).

More recently, Litterscheid (Chem. Zeit. 37. 321) has stated that the following colorimetric method may be used for the detection of artificial invert sugar in honey: 10–20 grms. of the honey are successively triturated with two portions of 10 c.c. of ether in which one or two crystals of β-naphthol have been previously dissolved. The unfiltered extract is transferred to a shallow porcelain dish and left in a dark place until the ether has evaporated. Four or

---

[1] The molasses values are quoted from Stammer's analyses.

five c.c. of concentrated 88–90 p.c. sulphuric acid are added to the residue, the latter being completely moistened with the acid, and allowed to stand. A dirty yellowish or reddish-yellow colour, which in half an hour becomes dirty yellowish-green, is obtained with natural honey, whilst a Bordeaux red to bluish-violet colour appears in the course of half an hour in the case of honey containing commercial invert sugar. A positive result was obtained with mixtures of natural honey and 5 p.c. of commercial invert sugar, and sometimes also when the result obtained by Fiehe's method (*l.c.*) was inconclusive.

These tests are for the detection of artificial honey. For the detection of genuine honey, it has been suggested to apply a physiological (serum) test (Langer, Arch. Hygiene, 71, 308), and it has also been proposed to characterise natural honey by determining its catalytic and invertive powers (Auzinger, Zeitsch. Nahr. Genussm. 1911, 65).

Useful bibliographies of honey are published by the U.S. Department of Agriculture. Bull. 13 gives a list of papers from 1867 to 1892. Bull. 110 continues the bibliography to 1908, whilst it was brought to 1910 by Muttelet (Monit. Scient. 74, 152). The lists are published in the Journal of the Society of Chemical Industry (1892, 11, 761; 1911, 30, 702).

III. *Brewing glucose or glucose chips.* This description of sugar occupies a position next in importance to invert sugar as a brewing sugar. It is prepared by the hydrolysis of different kinds of starch with acids. This material consists for the most part of dextrose, but contains also maltose and dextrins or more probably malto-dextrins. The occurrence of maltose as an intermediate product in the hydrolysis of starch by acids was assumed by numerous observers on the sole evidence of the optical and reducing values obtained with them. Ost, however (Zeitsch. angew. Chem. 1904, 1663), succeeded in isolating maltose from the products of the hydrolysis of starch by acids. Chemists are therefore quite justified in interpreting these products from their constants in terms of dextrose, maltose and dextrins.

The analysis of these products is conducted on the same lines as that of invert sugar, but since the assumed proximate constituents are different, the results must be calculated by different equations. In the following equations D is the symbol for dextrose and M that for maltose. The same remarks apply in regard to the coefficient of D as in the case of the corresponding equation for invert sugar. The coefficient of M (which is the symbol for maltose) is a constant for the whole range of dilutions employed (see table of Ling and Jones, p. 248).

Inasmuch as these products contain dextrinous carbohydrates, the residue after fermentation is always dextro-rotatory, and in some cases a considerable correction has to be applied to the rotatory power to obtain the value denoted by the symbol G. Brewing glucoses, unlike invert sugars, however, do not contain sucrose.

The equations for calculating the percentage of dextrose and maltose in these products are as follows :—

$$(a)\ 1{\cdot}966\,D+1{\cdot}225\,M=G$$

$$(b)\ 0{\cdot}305\,D+0{\cdot}797\,M=R$$

The following is an analysis of a high grade sample of glucose chips :

Dextrose	66·76
Maltose	3·96
Albuminoids	0·53
Ash	1·75
Dextrinous carbohydrates and other organic matter	13·60
Water	13·40
	100·00
Brewers' extract per 2 cwt.	76·1 lb.
Tint (Lovibond, 10 p.c. solution 1′ cell)	10·0 N.
Specific rotatory power	$[\alpha]_D$ 50·8°

This analysis can scarcely be taken as typical, since these products vary enormously in composition. Thus, the percentage of total sugars ranges from 65 to 75 and the extract from 72 to 76 lbs. The percentage of maltose may also vary from 12 p.c. to *nil*. The specific rotatory power ranges from $[\alpha]_D$ 44° to 56°.

IV. *Glucose syrup or dextrin-maltose.* This product, which is semi-hydrolysed starch, is largely employed in confectionery and also, though to a lesser extent, in brewing. The analysis is conducted on the same lines as that of solid glucose. The percentage of dextrin is calculated from the rotatory power of a 10 p.c. solution after fermentation by dividing by the factor 11·66 (see p. 237). The factor to be employed really diminishes with the reducing power of the dextrin, but for practical purposes this may be ignored. A typical analysis of glucose syrup, the composition of which is remarkably constant, is the following :

Dextrose	23·10
Maltose	26·03
Dextrin	32·17
Albuminoids	0·22
Ash	0·48
Water	18·00
	100·00
Brewers' extract per 2 cwt.	70·7 lb.
Specific rotatory power	$[\alpha]_D$ 113·1°

Estimation of sugars as phenylosazones. Maquenne (Compt. rend. 112, 799) determined the yield of phenylosazones from dextrose, lævulose and sucrose,[1] and subsequently Lintner and Kröber (Zeit. ges. Brauw. 18, 153) made an attempt to estimate certain sugars as phenylosazones. The method would be chiefly of service in separating dextrose and lævulose which form phenylglucosazone sparingly soluble in hot water from maltose which yields a phenylosazone readily soluble in hot water. In their studies on the hydrolysis of starch by malt diastase, Ling and Davis (J. Inst. Brewing, 8, 475; Chem. Soc. Trans. 85, 16) used the osazone method to demonstrate the production of dextrose at the later stages of the reaction. They also used the osazone method for the approximate estimation of dextrose as phenylglucosazone in presence of the other starch conversion products (*cf.* also Ling, J. Inst. Brewing, 9, 448). The method is useful as a qualitative one for identifying dextrose in presence of maltose, but

---

[1] Sucrose gives a certain amount of phenylglucosazone when heated with phenyhydrazine and acetic acid in virtue of undergoing partial hydrolysis.

it can also be made approximately quantitative. For this purpose it is necessary to employ only the purest freshly distilled phenylhydrazine and also to establish the yield of glucosazone in presence of mixtures of the same sugars contained in the substance being investigated. Ling and Rendle (Analyst, 29, 243) were able to prove the presence and approximate percentage of dextrose in commercial malt extracts known to be unadulterated. Baker and Dick (*ibid.* 30, 79), repeating Grimbert's work on the detection and estimation of small quantities of maltose in presence of dextrose, by treating the mixed phenylosazones with dilute (20 p.c.) acetone, found that the method could not be relied upon for quantitative purposes.

Biochemical methods of estimating sugars. The only methods of this class which will be alluded to here are those depending on the selective fermentability of different sugars by different yeasts. The fermentation method has already been mentioned in connection with the estimation of dextrinous carbohydrates in presence of fermentable sugars (see pp. 259–261). The better known monohexoses, *d*-mannose, lævulose, dextrose and galactose, are fermentable by *Saccharomyces cerevisiæ*, *S. pastorianus* and *S. ellipsoideus* (not, however, the monopentoses, arabinose and xylose), as are also the bioses, sucrose and maltose. These latter, however, must in the first place be hydrolysed to dextrose and lævulose and dextrose respectively. Consequently, for a yeast to be able to ferment sucrose, it must contain invertase or sucrase, whilst to ferment maltose it must contain maltase. Lactose is unfermentable by the above-mentioned yeasts which do not contain lactase, but Fischer and Tierfelder (Ber. 27, 2031) describe a yeast which ferments milk sugar as well as the ordinary monohexoses, but does not ferment maltose.

S. Marxianus does not contain a maltase or a lactase. Consequently, whilst it ferments the ordinary monohexoses, the bihexoses, lactose and maltose are unfermentable by it. Baker and Dick (Analyst, 30, 79) found that maltose could be estimated in mixtures of that sugar and the ordinary monohexoses by fermenting the latter by *S. Marxianus.* Dextrins, if present, were found to vitiate the results. In this case, however, the writer would point out that the dextrin must be estimated in a separate experiment in which the maltose as well as the monohexoses is fermented by *S. cerevisiæ.*

Several observers have made use of the fact that lactose is unfermentable by ordinary yeasts, *e.g. S. cerevisiæ*, to estimate that sugar in admixture with the fermentable sugars. The writer finds this method to give fairly satisfactory results. It has been investigated by Baker and Hulton (Analyst, 35, 512).

In all these laboratory fermentations, it is necessary to add a certain quantity of yeast food, which may consist of Hayduck's solution: potassium phosphate (25 grms.), magnesium sulphate (8 grms.), and asparagine (20 grms.) dissolved in water and made up to one litre. One cubic centimetre of this solution to each 25 c.c. of liquid to be fermented is used. The writer usually employs, however, yeast decoction as a yeast food in these cases (see p. 259). The fermentations may be conveniently carried out in Erlenmeyer flasks plugged with cotton wool. The flasks must be of sufficient size that the liquid never reaches the cotton wool during the fermentation.

Estimation of mineral matter (*ash*) *in sugar products.* The estimation of the ash in sugars, molasses, &c., by direct incineration, is not only a lengthy and tedious operation, but it is very difficult and often impossible to obtain concordant results in repetition experiments. Thus the mineral residues obtained by burning commercial sugars consist largely of alkali carbonates, which are fusible and volatile at the temperature at which the incineration is sometimes conducted. When fusion occurs before all the carbon has been burnt, the latter is occluded in a fused mass of mineral matter and complete combustion is then impossible. The procedure recommended by the A. O. A. C. (Bull. 107 [revised] U.S. Bur. of Chem. 67–68) is as follows: 'Heat from 5 to 10 grms. of sugar molasses, &c., in a platinum dish of 50–100 c.c. capacity at 100°C. until the water has been expelled and then slowly over a flame until intumescence ceases. Then place the dish in a muffle and heat at low redness until a white ash is left.'

The method most frequently employed is that first proposed by Scheibler in which the sugar is burnt in the presence of sulphuric acid. When this method is employed it is not necessary to use platinum capsules, but these may be replaced by porcelain or silica capsules. Indeed, in one respect, the latter are superior to platinum for the purpose, for since porcelain and silica do not conduct heat as well as does platinum, there is not so much danger of the ash fusing should the temperature of the muffle suddenly rise. And here it may be pointed out that on no account should sugar be incinerated over a flame, but always in a muffle furnace which should be kept at a low red heat.

The plan of carrying out the estimation of sulphated ash, which the writer has adopted for many years, is as follows. A portion of the sample (5 or 3 grms.) is accurately weighed out in a recently ignited capsule, 2 c.c. of concentrated sulphuric acid, free from fixed mineral matter, are dropped over the surface and subsequently a little distilled water is added. The addition of water is to equalise the reaction; it is not necessary with syrups and molasses or with very moist solid sugars. The capsule is then heated over a flame until intumescence is complete, when it is transferred to a muffle and incinerated at a low red heat. The resulting ash should be feathery. When fusion occurs this is generally attended by low results unless carbon is present. Some chemists after determining the weight of the ash, dissolve it in water and test it with litmus paper for acidity, but if the above instructions are followed, there is no danger of the presence of sulphuric acid when combustion is complete. Obviously the sulphated ash weighs more than that obtained by direct incineration, and to correct for this, Scheibler's suggestion to deduct one-tenth from the weight of the sulphated ash is practically universally adopted. It is convenient to work on 3 grm. portions of sugars, for in this case multiplication of the weight of the resulting ash by 30 gives the percentage of ash on the sample with Scheibler's correction. In the case of some products, *e.g.* brewing sugars, the deduction of one-tenth from the weight of sulphated ash is undoubtedly too large a correction, but the method gives comparative rather than absolute accuracy, and the latter, as already observed, cannot be attained by the direct incineration method.

Sand. When sand is present and it is desired to estimate it, the ash is dissolved in the capsule in a little warm dilute hydrochloric acid, and, after allowing the sand to subside, the supernatant liquor is decanted off. The sand is now washed by decantation, dried, ignited and weighed. Any silica which existed in a soluble state in the sugar passes away mechanically with the washing water. In most books, instructions are given to collect the sand on a paper filter, and after washing out the soluble matter to burn the filter. Filtration is, however, quite unnecessary.

Soluble ash. This is the difference between the total ash and the sand. In case any silica, derived from soluble silicates in the sample, had been included in the latter, a slight error would be introduced. This, however, is quite negligible. On the other hand, low grade raw cane products frequently contain wood, fragments of sugar cane, and other insoluble extraneous matters, and the total ash taken as above includes the ash of these extraneous matters. The true soluble ash must be estimated on a known volume of a standard filtered solution of the sugar. Thus, 25 grms. of the sugar are dissolved in water, made up to 100 c.c., and an aliquot portion of the filtrate corresponding with 5 or 3 grms. evaporated and incinerated with sulphuric acid as already described.

Estimation of ash from the electrical conductivity of commercial sugar solutions. This method was first placed on a practical basis by Main (Seventh Inter. Cong. Appl. Chem. Section V., p. 66; Inter. Sugar J., 11, 334). The subject was investigated by Reichert (Zeitsch. anal. Chem. 28) more than twenty years ago. Main's observations are briefly as follows. For practical purposes, it may be accepted that sugar in solution is a non-electrolyte, and that the conductivity of impure sugar solutions is to be ascribed to the inorganic and organic salts present. If in a series of samples, solutions of the same concentration are made, the resistances of these solutions are inversely proportional to the amount of salts present. The resistances are measured by Kohlrausch's telephone method. Although the sugar in the solutions may be regarded as non-conducting, variations in the quantity of sugar present affect the conductivity of the salts present. The disturbing influence of differences in the quantity of sugar present can be removed by working with solutions of about the same specific gravity. Taking a series of sugars of about the same grade containing from 2 to 5 p.c. of ash, 5 grms. of each are dissolved in distilled water, made up to 100 c.c. and the resistance of the solutions determined at 20°C. Then it is found that the resistances expressed in ohms multiplied by the percentage of ash as determined gravimetrically in the usual manner give approximately a constant which serves for the determination of ash in other samples of similar sugars when the resistance of their solutions is determined in the same manner in the same cell. Thus $A = K/O$, where A is the percentage of ash in the sample, K the constant above referred to, and O the resistance of the solution expressed in ohms. When working with molasses, the samples are diluted to 33 Beaumé and 2 grms. weighed out, diluted to 100 c.c., and the constant determined as in the case of sugars.

The accuracy of which the method is capable may be judged from the following instances cited by Main. Column 1 in the tables gives the resistance in ohms=O. Column 2 gives the percentage of ash estimated gravimetrically=A. Column 3 gives the product $O \times A = K$. Column 4 gives the ash calculated from the mean value of K as already explained.

Sugars.

Lange (Zeits. Ver. Deut. Zuckerind. 1910, 359) finds that reliable results can be obtained by Main's method with products, the ash percentages of which do not differ by more than 0·5 p.c. In order to make the method of greater general applicability, the influence of sugar as a non-conductor on the conductivity of a salt solution was further investigated. Where C is the conductivity of the solution containing p grams in 100 c.c. of the non-conductor, c is the conductivity of the aqueous solution of the salt, and a an empirical coefficient, the relationship may be expressed by Arrhenius' formula $C=c(1-\frac{a}{2}p)^2$. The value of the coefficient a for the group of salts occurring in sugar products was found by Lange to be 0·0314. In the case of products containing more than 3 p.c. of ash, the conductivity of a series of solutions of different ash content has been determined, and the conductivity which the solutions would have if no sugar were present is calculated by the above formula. From the values thus obtained, a table has been constructed. When dealing with any product, it is simply necessary to determine the conductivity of its aqueous solution, and calculate from this and the known sugar content the conductivity of solution without sugar. The percentage of ash may then be ascertained by the aid of these data from a table. Lange has also constructed an empirical table for products containing less than 3 p.c. of ash, with which the influence of the sugar on the conductivity may be ignored. He has also calculated a table for correcting for the influence of temperature between 15° and 25°C. He gives a number of examples

[1] The mean value for K is 680.

[2] The mean value for K is 1672.

with various products illustrating the accuracy of the method.

Estimation of water and solid matter in saccharine products. The usual method of estimating water in solid commercial products is to heat from 3 to 5 grms. weighed out to the nearest half milligram in a drying oven at 100°C. for 3 to 5 hours, taking the loss in weight as due to water. In the case of small-grained, very moist sugars containing much molasses, this method gives low results. Better results are obtained if the drying be conducted at 105°–110°C.[1] This, however, applies more especially to beet products; in the case of cane products, which usually contain a large amount of reducing sugars, the use of such a temperature would be attended by error due to the decomposition of the latter. If the products be heated in a current of air or other gas, the moisture may usually be expelled from all solid sugar products at 100°C. A simple and convenient apparatus for this purpose has been devised by Siau (J. Soc. Chem. Ind. 30, 61). The official method of A. O. A. C. is to be found in Bull. 107 (revised), U.S. Bur. of Chem., p. 64.

The sugar is conveniently weighed out and dried in a shallow metal dish—a copper dish serves the purpose very well—or the drying may be conducted in a porcelain or quartz dish.

Estimation of water in syrups, molasses, and massecuites. The following directions are given for this purpose by the A. O. A. C. (Bull. 107, *l.c.*). The methods are not suitable, however, for those products which contain large percentages of reducing sugars, *e.g.* cane products.

Drying on pumice stone. 'Prepare pumice stone in two grades of fineness. One of these should pass through a 1 mm. sieve, whilst the other should be composed of particles too large for a millimeter sieve, but sufficiently small to pass through a sieve having meshes 6 mm. in diameter. Make the determination in flat metallic dishes or in shallow, flat-bottomed weighing bottles. Place a layer of the fine pumice stone, 3 mm. in thickness, over the bottom of the dish and upon this place a layer of the coarse pumice stone from 6 to 10 mm. in thickness. Dry the dish thus prepared and weigh. Dilute the sample with a weighed portion of water in such a manner that the diluted material shall contain from 20 to 30 p.c. of dry matter. Weigh into the dish, prepared as described above, such a quantity of the diluted sample as will yield, approximately, 1 grm. of dry matter. Use a weighing bottle provided with a cork through which a pipette passes if this weighing cannot be made with extreme rapidity. Place the dish in a water oven and dry to constant weight at the temperature of boiling water, making trial weighings at intervals of 2 hours. In case of materials containing much lævulose or other readily decomposable substances, conduct the drying *in vacuô* at about 70°C.'

Drying on quartz sand. 'In a flat-bottom dish place 6 to 7 grms. of pure quartz sand and a short stirring rod. Dry thoroughly, cool in a desiccator, and weigh. Then add 3 or 4 grms. of the molasses, mix with the sand, and dry at the temperature of boiling water for from 8 to 10 hours. Stir at intervals of an hour, then cool in a desiccator, and weigh. Stir, heat again in the water oven for an hour, cool, and weigh. Repeat heating and weighing until loss of water in one hour is not greater than 3 mgs.

'Before using, digest the pure quartz sand with strong hydrochloric acid, wash, dry, ignite and keep in a stoppered bottle.'

For the estimation of water in cane products, honey, &c., which contain a considerable amount of reducing sugars, methods of drying in a vacuum have to be resorted to for the reason above alluded to. The method of Carr and Sanborn (Bull. 47, U.S. Bur. of Chem., p. 134) is one of which the reliability has been proved. The method (*l.c.*) is as follows: Clean fine-grained pumice is divided into fragments of the size of No. 4 shot. The finer particles (dust) are separated from the coarser by passing through a 40-mesh sieve; the two grades are heated separately. They are digested with hot 2 p.c. sulphuric acid and washed until the washings are neutral. The washing may be carried out rapidly by decantation. The washed pumice is dried by heating to redness in a Hessian crucible, after which it is placed while hot in a desiccator. A thin layer of the dust is placed over the internal surface of the dish in which the estimation is to be conducted. Above this layer are placed sufficient of the larger particles that the dish is almost filled. The dish thus charged with pumice is ignited and weighed, after cooling in a desiccator. The substance to be dried is diluted (if necessary) to a specific gravity of about 1·08 by the addition of water or of alcohol, if no precipitation is caused by the latter. Two to three grms. are distributed uniformly by means of a pipette weighing bottle over the pumice in the dish, the area of which is about 3 sq. ins., *i.e.* 1 grm. for each square inch of area. The amount of the sample taken is determined by the loss in weight of the weighing bottle after distributing the sample over the pumice. The dish thus charged is placed in a vacuum oven in which a pressure not exceeding 5 ins. of mercury or a temperature not exceeding 70°C. is maintained. The vacuum oven devised by Carr (Browne's Handbook of Sugar Analysis, p. 20) is a convenient apparatus for this purpose.

For removal of the water from pure products, *e.g.* hydrated dextrose, raffinose, maltose, lactose, &c., the method devised by Lobry de Bruyn and Van Lænt (Rec. trav. chim. 38, 218) may be used. This method was employed by Brown, Morris and Millar (Chem. Soc. Trans. 71, 76) in their work on the products of starch hydrolysis by diastase. Briefly it is carried out as follows: Two small flasks are united by a tube furnished with a stop-cock and a side-tube leading to an air pump. The substance to be dehydrated is introduced into one of the flasks, the other being partially filled with phosphorus pentoxide. After exhausting the apparatus, the flask containing the substance is immersed in a water, salt water, or oil bath according to the final temperature required, and is slowly heated up to a point at which it ceases to lose weight.

Since in the estimation of water in the liquid or semi-liquid products above referred to,

---

[1] This temperature was prescribed by the International Commission on the Unification of Methods of Sugar Analysis (Paris, 1900).

comparative rather than absolute accuracy is required, and expedition being an essential, indirect methods of estimating the solid matter (the amount of which is complementary to the water content) are usually resorted to. Two principles are made use of in these indirect methods, one depending on the specific gravities and the other on the refractive indices of sugar solutions. The specific gravities and refractive indices of sugar solutions are both functions of the solid matter present. In most tables, however, the assumption is made that the effect of all sugars is identical on specific gravity and refractive index, which, as will be seen, is not strictly accurate. The two principles will now be discussed seriatim.

Specific gravity method of estimating water and solid matter. A vast amount of labour has been devoted to the determination of the specific gravity of sucrose solutions. In 1854, Balling (Zeits. Ver. Rubenzuckerind. 4, 304) published his well-known tables giving the specific gravities of sucrose solutions of different concentrations.[1] His tables, which have since been extended by Brix, are now almost universally used on the Continent for determining the density of sugar solutions by means of a spindle. Another table was published by Gerlach in 1863, and this was subsequently recalculated to another temperature by Scheibler. The condensed table (XXVI.) taken from Browne's Handbook, p. 29, shows the relation between the results obtained by different authorities.

Another table which forms the basis of a hydrometer scale very widely used in the sugar and other industries is that of Beaumé. This table is based on the specific gravity of solutions of common salt. Table XXVII., abridged from that given in Browne's Handbook, shows the relation between the various scales. It will be observed that two Beaumé scales are given, the new and the old. The latter, although known to be inaccurate, is still retained in many countries.

Table XXVIII. is for correcting readings of the Brix hydrometer, taken at different temperatures, to 17·5°C.

In his studies on the products of the hydrolysis of starch, O'Sullivan made use of a divisor for calculating the concentration (grms. per 100 c.c.) from the specific gravity of the solutions. This divisor was the excess specific gravity of a solution of maltose containing 10 grms. in 100 c.c. Brown and Heron subsequently suggested the divisor 3·86, which is the excess specific gravity (calling water 1000) of a solution containing 10 grms. of sucrose in 100 c.c. Comparative accuracy can be obtained with the use of this divisor with solutions containing up to 10 grms. per 100 c.c. of dissolved substance if the specific gravity is corrected for the influence of mineral matter (see below). If the specific gravities of the solutions are expressed in comparison with water as 1000, then obviously the values also express the weights in grams of 1 litre of the solution, or where the specific gravities are taken at 15·5°/15·5° or at any other temperature, the weight in grams of 1000 fluid grms. of the solution. It follows from this that the concentration (grams per 100 c.c.—100 fluid grms.) can be calculated by the aid of the

---

[1] It should be pointed out that the solutions used by Balling were standardised on their true percentage of sucrose by weight and not grams per 100 c.c.

formula $C = \frac{S-1000}{d}$, where C is the required concentration, S is the specific gravity of the solution, and *d* the excess specific gravity of a 1 p.c. solution of any given pure sugar.

Brown, Morris and Millar (Chem. Soc. Trans. 71, 72) have determined the divisors for sucrose, dextrose, fructose, invert sugar, maltose and certain mixed products of the hydrolysis of starch at various concentrations. Ling, Eynon and Lane (Seventh Inter. Cong. Appl. Chem., Section I., p. 137) have repeated this work for solutions of dextrose, lævulose and maltose. The following may be regarded as the accurate divisors for solutions for the undermentioned sugars containing 10 grms. in 100 c.c. Sucrose, 3·86 (Brown and Heron), dextrose, 3·82 (Ling, Eynon and Lane), lævulose, 3·92 (Ling, Eynon and Lane), invert sugar, 3·87 (mean of dextrose and lævulose values), maltose, 3·91 (Ling, Eynon and Lane). Mixed starch transformation products 3·93–4·01 (Brown, Morris and Millar). The divisor in all cases increases with a decrease of concentration. In the analysis of commercial products, however, solutions containing 10 grms. per 100 c.c. are usually employed. It has already been mentioned that in applying this method of estimating the concentration of a sugar solution, it is necessary to correct for the influence of the mineral matter. Solutions of most salts have much higher specific gravities for a given concentration than those of the sugars. Heron found that the mean specific gravity of a solution of the sulphated mineral matter containing 1 grm. per 100 c.c. is 1008, and this value in the writer's experience is not far from the truth. If, therefore, the percentage of soluble ash in a sample be multiplied by 0·8 and the product deducted from the specific gravity of the solution of c=10, the remainder divided by the appropriate number will give the grams of sugar per 100 c.c. with a fair degree of accuracy. Proteins have very little influence on this method, as the specific gravities of their solutions are so low. To calculate the carbohydrate concentration of beer worts, the writer, after diluting to a specific gravity of about 1040, determines the specific gravity at 15·5°/15·5°, corrects for ash as above and divides the corrected excess specific gravity by 4. This practice is also adopted by several other chemists.

Refractometric methods of estimating water and solid matter. The principle and construction of different forms of the refractometer is dealt with in a special article (vol. iv. p. 550). These instruments have been applied to a large number of products for several years, but the

first to suggest their application to commercial sugars and molasses was apparently Stromer in 1883 (Oest. Ung. Zeit. Zuckerind. 12, 925; 13, 185), who pointed out that the refractive indices and specific gravities of sugar solutions ran parallel to one another. In 1901, Stolle (Zeits. Ver. Deuts. Zuckerind. 51, 469) showed that solutions of sucrose, dextrose, lævulose, and lactose of the same concentration had substantially the same refractive indices. He used the Pulfrich instrument. The next work of importance in this connection is that of Tolmann and Smith (J. Amer. Chem. Soc. 28, 1476), who used an Abbe refractometer. The first to place the refractometric method on a sound practical basis, as regards its application to sugar analysis, was, however, Main (Inter. Sugar Journ. 9, 481). Main worked with the Abbe refractometer and constructed a table which has since been checked by Schönrock in the laboratories of the Physikalisch-Technische Reichanstalt, Berlin. Schönrock's [1] results, which are given in Table XXIX., show no greater deviation from those of Main than 4 in the fourth place of decimals.

Stanek (Zeits. Ver. Deutsch. Zuckerind. 61, 421) determined the corrections to be applied to Main's table, when the observations are made at temperatures other than 20°C. His results are embodied in Table XXX.

The immersion refractometer (*l.c.*, vol. iv. p. 553) has also been employed for sugar products. The range is, however, much less than that of the Abbe instrument, the scale being restricted to solutions containing 21·7 p.c. of sugar and less. The instrument is, however, capable of yielding

---

[1] Schönrock has modified the Abbe refractometer. Instead of glass of refractive index of 1·7 he uses the less refractive flint glass. This enables darker products and more concentrated solutions—up to 85 per cent. concentration—to be examined. The modified instrument is constructed by Messrs. Zeiss & Co.

more accurate results than the Abbe refractometer, since it gives a much sharper border line than the latter.

Comparison of densimetric and refractometric methods. When either of these methods is applied to commercial products, the assumption is made that the results are affected similarly by all the solid matters present, which is by no means the case. It has been shown above, for example, that the divisors to be applied to the specific gravities of solutions of sugars in order to calculate their concentration, differ according to the particular sugar dealt with, and that they also vary with the concentration of the solution of one and the same sugar. Further, weight for weight mineral matter produces, roughly speaking, twice the effect on specific gravity as do sugars themselves, whilst protein substances have a much lower specific gravity coefficient than have the sugars. Refractometric methods, on the other hand, can be applied over a much wider range of mixtures without impairing their accuracy for practical requirements, than can densimetric methods. Thus, Stanek, working with Main's table, has shown (Zeits. Zuckerind. Böhmen, 34, 5) that with solutions of betaine, sodium formate, potassium formate, sodium acetate, potassium acetate, sodium butyrate, sodium lactate and potassium lactate, a very fair approximation to the truth is obtained with refractometric methods, whilst with densimetric methods the divergencies from the truth are considerable. It should be pointed out, however, that whereas refractometric values can only be determined to four significant places, it is easy to measure specific gravities to five significant places.

The writer desires to thank his assistant, Mr. George McLaren, for help in collecting together some of the commercial analyses recorded in this article. A. R. L.

SUGAR CANE WAX *v.* WAXES.

SUGAR OF LEAD. *Lead acetate* (*v.* ACETIC ACID).

SUINE. A butter substitute made from pigs' fat (*v.* MARGARINE).

SULFAMINOL *v.* SYNTHETIC DRUGS.

SULFOSOT *v.* SYNTHETIC DRUGS.

SULPHAMMONIUM. The various forms of sulphur dissolve in liquid ammonia forming a purple solution, which, according to Moissan, contains a definite compound, stable up to 90°, which he terms *sulphammonium*. It gives a characteristic absorption spectrum and reacts with iodine and a number of metals and salts forming coloured substances decomposing at the ordinary temperature and pressure (Moissan, Bull. Soc. chim. 1902, [iii.] 27, 652).

SULPHANILIC ACID (p-*Aniline sulphonic acid*) $C_6H_4{\cdot}NH_2{\cdot}HSO_3$, or $C_6H_4<\genfrac{}{}{0pt}{}{SO_3}{NH_3}>$ is formed by heating aniline *p*-phenol sulphonate, or by heating aniline with concentrated sulphuric acid, or aniline ethyl sulphate to 200° (Limpricht, Annalen, 1875, 177, 80); the nitration products of benzene sulphonic acid, when reduced with ammonium hydroxide and hydrogen sulphide, yield the three aminosulphonic acids, which may be separated mechanically after recrystallisation. The light crystals of the *m*-acid rise to the surface, and may be removed from the others by washing. The residue is heated to 110°–120° when the *p*- acid becomes powdered and may be separated by passing through a sieve (Franklin, Amer. Chem. J. 1898, 20, 457).

Sulphanilic acid may be prepared by heating 28 parts of chlorobenzene-*p*-sulphonic acid with 370 of 25 p.c. ammonia solution, and 5 of cupric chloride for 12 hours to 170° in a closed vessel. The mass is then mixed with sodium carbonate, the ammonia is distilled off, the residue filtered and concentrated, when the sodium salt of sulphanilic acid separates (Bloxam, D. R. P. 205150; J. Soc. Chem. Ind. 1908, 1147). The acid may also be obtained by the action of hot strong acids or alkalis on acetylaniline-*p*-sulphonamide (Gelmo, J. pr. Chem. 1908, [ii.] 77, 369), and by other methods (Gerhardt, Annalen, 1846, 60, 310; Buckton and Hofmann, *ibid.* 1856, 100, 163; Pratesi, Ber. 1871, 4, 970; Kopp, *ibid.* 978; Bamberger and Kunz, *ibid.* 1897, 30, 2277; Wenghöffer, J. pr. Chem. 1877, [ii.] 16, 454; Wohlfahrt, *ibid.* 1902, 66, 551; Cohn and Springer, Monatsh. 1903, 24, 87; Bouchetal, Bull. Soc. chim. 1904, [iii.] 31, 24).

Sulphanilic acid forms a monohydrate and a dihydrate. The stable solid in contact with saturated solutions is dihydrate from 0° to 21°. monohydrate from 21° to 40°, and anhydrous acid from 40° upwards (Philip, Chem. Soc. Trans. 1913, 284). The dihydrate is strongly efflorescent, and on losing its water at the ordinary temperature, passes directly into the anhydrous acid. The latter may be obtained by crystallisation not only from hot water, but also from fuming sulphuric acid (Laar, Ber. 1881, 14, 1933). It chars when heated to 280°–300°. It acts as a monobasic acid (Astruc, Compt. rend. 1900, 130, 1563), yields aniline when fused with caustic potash, and when the barium salt is treated with bromine water, it forms tribromaniline and barium dibromoanilinesulphonate. When oxidised with chromic acid it yields quinone (Schrader, Ber. 1875, 8, 759; Limpricht, *ibid.* 1885, 18, 1419; Laar, J. pr. Chem. 1879, [ii.] 20, 242).

Sulphanilic acid forms salts with the alkali metals, also with barium copper, silver, and cerium (Gerhardt, *l.c.*; Laar, *l.c.*; Morgan and Cahen, Chem. Soc. Trans. 1907, 477). On pouring a mixture of sodium sulphanilate and sodium nitrite in aqueous solution into dilute sulphuric acid, it forms *benzene-diazonium sulphonic acid* $C_6H_4<\genfrac{}{}{0pt}{}{N_2}{SO_3}>$, which is important in the preparation of azo dyes, such as helianthine. Finely powdered dry sodium sulphanilate reacts with acetic anhydride forming *sodium acetylaniline*-p-*sulphonate*, which, with concentrated sulphuric acid, yields the free acid $NHAc{\cdot}C_6H_4{,}SO_3H$. The sodium acetyl salt treated with phosphorus pentachloride and then with cold water yields the corresponding *sulphonyl chloride* $NHAc{\cdot}C_6H_4{,}SO_2Cl$, m.p. 149° (Schroeter, Ber. 1906, 39, 1559).

When 46·2 grms. of sodium -*p*-sulphanilate is heated with 1 litre of water, 18 c.c. hydrochloric acid, and 54 grms. of tetramethyldiaminodiphenylcarbinol, on a water-bath for 6 hours to 80°–90°, equal quantities of the following substances are obtained: (1) a yellow crystalline compound dyeing tannin-mordanted cotton yellow, similar to auramine; (2) a sulphonated leuco base, converted by lead peroxide into a green dyestuff for wool, decolorised by alkalis; (3) a substance soluble in water, which does not yield a dyestuff on oxidation; (4) hexamethyltriaminotriphenylmethane (crystal violet). With *m*-sulphanilic acid treated similarly (but in different proportions), yields as chief product a sulphonated leuco base, which, on oxidation, yields a violet dyestuff turned green by caustic soda. If the leuco base is diazotised, boiled with water, and then oxidised, it yields a green dyestuff, reddened by alkalis; but if the diazo compound is boiled with alcohol and the product oxidised with lead peroxide, it forms a dyestuff which colours wool bluish-green shades remarkably fast to caustic soda (Suais, Bull. Soc. chim. 1897, [iii.] 17, 517).

Sulphanilic acid yields a number of nitro, halogen, and other derivatives.

SULPHAZIDES may be prepared by the action of sulphurous acid upon the acid solution of diazo salts, or by passing nitrous acid into or adding potassium nitrite to, an ice-cooled solution of the diazo salt in alcohol saturated with sulphurous acid (Limpricht, Ber. 1887, 20, 1238). According to Eng. Pat. 12872, 1900, a much better yield is obtained by diazotising an aromatic amine in hydrochloric acid solution, mixing this with sodium bisulphite and adding the diazo sulphite thus formed to an alcoholic solution of sulphurous acid (J. Soc. Chem. Ind. 1900, 893).

Phenylbenzenesulphazide

$$C_6H_5NH{\cdot}NHSO_2C_6H_5$$

forms white leaflets, m.p. 148°–150°.

***o*-Tolyltoluenesulphazide**

$$C_7H_7NH{\cdot}NHSO_2C_7H_7$$

forms white lustrous needles, m.p. 140°–142° (decomp.); the *p*-tolyl- derivative has m.p. 140°.

Nitro derivatives of these compounds are described by Limpricht (*l.c.*).

When the sulphazides are heated with baryta, or with soda solution, or with alcoholic soda, they are decomposed, yielding the corresponding sulphinic acid, nitrogen, and an aromatic hydrocarbon.

Similarly, nitrosulphinic acids and nitrohydrocarbons are formed from the nitrosulphazides.

SULPHIDE DYES.

Historical summary. Sulphur enters into the composition of many important organic colouring matters of widely different properties and mode of application (*v.* METHYLENE BLUE, PRIMULINE, &c.), but the group of dyes comprised under the above heading is distinguished by the dyeing process employed in fixing these compounds on the textile fibres, usually cotton. The sulphide dyes are soluble with reduction in aqueous solutions of the alkali sulphides giving rise to leuco derivatives which have a considerable affinity for the cotton fibre. After absorption by the cotton these leuco compounds are oxidised *in situ* to the insoluble dye, either by air or by chemical agents. In this behaviour the sulphide colours somewhat resemble indigotin, thioindigo, and other vat dyes (*v.* VAT DYES, &c.), and proposals have been made for employing these colours in the vat-dyeing processes (D. R. PP. 146797, 200391).

The earliest experiments in this field of tinctorial chemistry were made by Troost in 1861, who reduced a crude mixture of 1 : 5- and 1 : 8-dinitronaphthalenes with sodium sulphide and other reducing agents, and obtained coloured products giving red, violet, and blue shades on the textile fibres (J. 1861, 958; *cf.* Fr. Pat. 244885). But although these experiments indicated the influence of sulphur in the conversion of organic compounds into colouring matters, the substances produced met with no success as dyes. The first discovery of technical importance was embodied in a patent taken out by Croissant and Bretonnière (Eng. Pat. 1489, 1873; Fr. Pat. 98915; *cf.* Bull. Soc. Ind. Mulhouse, 1874, 468), in which these chemists showed that a very heterogeneous collection of organic materials were capable of yielding dyes when heated with alkali sulphides and polysulphides. The materials enumerated in the patent are in most cases products of the vital activities of animal and vegetable life, together with certain waste products of manufacture, among which the following may be mentioned: wood, sawdust, humus, vegetable detritus, lichens, mosses, bran, farina, glutin, starch, sucrose, glucose, cellulose, paper and cotton waste, tannin, gallic acid, gelatin, casein, albumin, blood, horn, feathers, animal excrement, the organic acids and their salts, aloes, resins, gums, gum-resins, and soot.

Two modes of interaction are distinguishable in the patent. In one process aloes are warmed with an aqueous solution of sodium polysulphide when a dye is produced, dyeing cotton in lilac and grey shades. The patentees state that this dye is an additive product, the sulphur being introduced into the molecule without replacement of hydrogen in the form of hydrogen sulphide.

In the second process, which is by far the more widely applicable, the organic matter is heated with alkali polysulphides at temperatures above 100° and approaching 300°. Substitution occurs, sulphur being introduced into the molecule while hydrogen sulphide is evolved. The products dye in various shades of brown, and the patentees' experiments indicated that the higher the temperature of heating the darker was the shade of colour produced.

In spite of the wide scope of the patent only one useful colour was obtained under it for about 20 years. This product was **Cachou de Laval**, a brown dye which was generally prepared by heating together sawdust, sodium sulphide, and sulphur (*v. infra*).

The next development in the sulphide dye industry occurred 20 years later, when Vidal found that certain aromatic nitro compounds were capable of yielding green, blue, brown, and even black dyes (**Vidal black**) when heated with alkali polysulphides. This discovery was the turning-point in the manufacture of sulphide colours, for from this time onward the attention of inventors was directed towards the production of these colours from definite coal-tar derivatives rather than from the ill-defined materials indicated in Croissant and Bretonnière's patent.

The compounds first utilised by Vidal for the production of brown and black sulphur dyes were the nitrated products of phenol and its homologues. Acyl derivatives of aromatic nitro-amines and diamines were then employed (D. R. P. 82748), and in 1897 the nitro derivatives of hydroxydiphenylamine were made use of in the production of **Immedial black.** Improvements in the manufacture of sulphide blues speedily followed, culminating in the discovery in 1900 of **Immedial pure blue** and its homologues from dialkyl-*p*-amino-*p*-hydroxydiphenylamines (D. R. P. 134947).

The addition of copper salts, or even finely-divided copper to the alkali sulphide fusions of diamino- and dialkylamino-hydroxydiphenylamines led in 1901 to the production of green sulphide dyes (D. R. PP. 135410, 148024).

Yellow, orange, and brown sulphide dyes resulted in 1902 from the thionation of tolylene-2:4-diamine and its acyl derivatives with sulphur alone, the products being rendered soluble by subsequent treatment with aqueous sodium sulphide (D. R. PP. 139430, 144762 152595). These dyes resemble the thiazole colouring matters in the fact that they are formed from aromatic compounds containing methyl and other non-aromatic groups. These side chains play an essential part in the production of the colouring matter, just as they do in the case of dehydrothiotoluidine and primuline, for diamines, such as *m*-phenylenediamine, without side chains do not furnish these yellow and orange dyes.

Although the problem of producing scarlet and bright-red sulphide dyes has not hitherto been solved, it has been shown that colouring matters of distinctly reddish shade can be obtained by thionating certain of the red dyestuffs, such as the azines, rosindulines, and safranines, in some cases in the presence of copper salts (D. R. PP. 126175, 152373, 161462, 177709, 181125).

These red sulphide dyes, however, are less fast to light than the brown and black dyes of this series, and the yellow sulphide colours also suffer to some extent from this drawback. On this account the greatest development of the sulphide dye industry has taken place in the production of brown, blue, and particularly black dyes, the last of which are now manufactured on an enormous scale owing to their cheapness, fastness, and ease of application.

As the exact chemical constitution of the various commercial sulphide dyes is not in general known with certainty, it will be convenient to group these substances together in accordance with their tinctorial properties.

The firms engaged in the manufacture of sulphide dyes designate their respective products by generic names which are set forth in the following table; the abbreviations in brackets are used throughout this article to indicate the makers or patentees of the various products described.

Manufacturers.	*Sulphide dyes.*
Aktiengesellschaft für Anilin Fabrikation, Berlin (*A.*)	Sulphur colours.
Badische Anilin-Soda-Fabrik, Ludwigshafen a/Rhein (*B.*)	Kryogen „

BLACK SULPHIDE DYES.

Vidal black (*P.* Eng. Pats. 23578, 1893; 9943, 1894; D. R. PP. 85330, 90369) is produced by heating with alkali polysulphides either *p*-aminophenol or substances capable of yielding this compound. *p*-Nitrophenol (100 parts) is slowly added to 400 parts of crystallised sodium sulphide, $Na_2S,9H_2O$, melted in its water of crystallisation; the temperature is raised to 130°, and, when reduction is complete, 75 parts of sulphur are introduced and the mixture heated to 150°–175°. A vigorous reaction takes place, hydrogen sulphide being evolved freely; finally the mixture becomes too solid to be stirred, and is dried at 180° until quite hard and crisp. The dried mass can then be used directly in dyeing, or the dye may be purified by precipitation from aqueous sodium sulphide with dilute hydrochloric acid. Its solution in alkali sulphide is green, and cotton is dyed in green shades which change to black when the fabric is subsequently chromed, the black shades thus produced are extremely fast to light and scouring agents.

Vidal black is a black mass with bronzy reflex, and its green leuco derivative, produced by aqueous sodium sulphide, can be further changed by powerful reducing agents (zinc and sodium hydroxide) to a reduction product having no affinity for cotton.

The purified dye is obtained by dissolving the crude fusion product in water and precipitating with dilute acetic or hydrochloric acid. The precipitate when washed free from inorganic salts is dried at 110°, extracted with carbon disulphide till free from uncombined sulphur, washed with dry ether and light petroleum, and dried at 90°–100°. The product is thus obtained in small amorphous black nodules with dark bronzy lustre; it contains about 32 p.c. of combined sulphur.

Vidal black S (D. R. P. 88392) is the soluble sulphite compound of the preceding dye produced by adding 100 kilos. of 15 p.c. Vidal black paste to an aqueous solution containing 50 kilos. of sodium sulphite or bisulphite.

A modified Vidal black is obtained by heating with sulphur at 240° *p*-aminophenol and its homologues with acetanilide, the acetotoluidides, &c. (*G.* D. R. P. 128361).

Clayton black D (*Cl. Co.* D. R. P. 106030;

Eng. Pat. 21832, 1898). Nitrosophenol (95 parts), is dissolved in 92 parts of sodium hydroxide (38°Be.), diluted with 500 parts of water and mixed successively with 500 parts of sodium thiosulphate in 300 parts of water and 750 parts of 30–40 p.c. sulphuric acid below 22°. The filtered solution mixed with an alkaline solution of 57 parts of nitrosophenol is heated for 4–6 hours until sulphur dioxide is all evolved, and then cooled, when the precipitated dyestuff is collected.

Clayton black D. is soluble in aqueous sodium hydroxide or carbonate to a coal-black solution turned violet by sodium sulphite; it dissolves in concentrated sulphuric acid to a blue solution and when dyed on cotton in sodium sulphide bath, 10 p.c. of colour gives an intense pure black, which is deepened by chromic acid or copper sulphate, and is fast to acids, alkalis, and soap.

Dinitrophenol black; immedial black N; sulphur black T extra; thiophenol black T extra; thionol black; cross dye black B X (D. R. PP. 127835, 136016, 218517; Eng. Pats. 19831, 1896; 13035, 17805, 1903; Fr. Pats. 259509, 267343, 333096). Thirty parts of 2:4-dinitrophenol are slowly added to a solution of 125 parts of sodium sulphide $Na_2S,9H_2O$, and 45 parts of sulphur in 150 parts of water, and the mixture boiled under a reflux apparatus (103°–106°) for 25–40 hours. The boiling mass, which assumes a green colour changing to bluish-black, is then poured into water, and the filtered solution is either acidified or oxidised by a current of air. The bluish-black colouring matter is collected and washed free from inorganic salts. The dye is further purified by dissolving in aqueous sodium sulphide, reprecipitating by filtered air and washing the precipitate until free from sodium salts. The product is then dried at 100°–110°, and extracted with boiling carbon disulphide until free from uncombined sulphur. Dinitrophenol black is thus obtained as a bluish-black bronzy mass devoid of crystalline structure. It dissolves in aqueous alkali sulphides to a dark greenish-blue solution, and is practically insoluble in cold concentrated sulphuric acid.

A specimen of cross dye black BX (*H.*), purified in the foregoing manner, contained 29·0 p.c. of sulphur and 12·5 p.c. of nitrogen. Thionol black O extra (*Lev.*) when similarly isolated, contained 28·0 p.c. of sulphur and 10·4 p.c. of nitrogen. Thionol black OO extra (*Lev.*) contained 36·0 p.c. of sulphur.

The great commercial importance of this colouring matter lies in the fact that it dyes unmordanted cotton in intense black shades which are fully developed by aerial oxidation without subsequent treatment with chromic acid or any other oxidising agent. Moreover, the colour is not affected in tint by after-chroming, and it is remarkably fast to light, acids, alkalis, and scouring and milling agents.

Immedial black NN. The above-described method for making dinitrophenol black is a boiling process carried out at comparatively low temperatures (103°–106°) in aqueous solution, and in this respect the result is an exception to the general tendency, noticed by Croissant and Bretonnière (*v. supra*), for darker shades to be produced at higher temperatures. Vidal, who first suggested the use of dinitrophenol for making sulphur blacks, devised a melting process which leads to products totally different from the black obtained by the boiling process and dyeing cotton in worthless dark-brown shades (Eng. Pat. 16449, 1896; D. R. P. 98437). When, however, the reagents are mixed in the following proportions, dinitrophenol (25 parts), sodium sulphide (125 parts), and sulphur (50 parts), and heated gradually to 160° and maintained at this temperature until the fusion becomes solid (2–3 hours), then a black is obtained, but a departure from these proportions, which correspond with Na_2S_5, leads to brown products (*C.* Eng. Pat. 19831, 1896). The product of fusion is dissolved in water and the dye precipitated by acid or air and made into a paste or dried.

Thion black (*K.*) is a similar product obtained by a melting process at 140°–160° for 2–3 hours, using 35 parts of sodium tetrasulphide and 20·6 parts of sodium dinitrophenoxide (Eng. Pat. 26379, 1903).

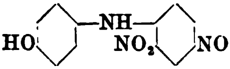
Thional black (*K. S.* Eng. Pat. 26465, 1901) is produced in aqueous solution under pressure at 160°–165° from dinitrophenol (92 parts) sodium thiosulphate (400 parts), 33 p.c. sodium hydroxide (61 parts), and water (800 parts).

Thiophenol black T extra (*Bl.* Eng. Pat. 13035, 1903) is obtained from dinitrophenol and polysulphide either at 115°–140° under the ordinary pressure, or at 110°–115° under a pressure of 2½ atmospheres, and a greener shade of black is produced either by adding copper salts or 5 p.c. of chloro-2:4-dinitrobenzene (*cf.* D. R. P. 208377; Eng. Pat. 27213, 1906).

The dinitrophenol employed in these operations is prepared by the action of boiling aqueous sodium hydroxide on chloro-2:4-dinitrobenzene, and the latter substance has itself been employed in the boiling process with sodium hydroxide and polysulphide when hydrolysis and thionation occur in one operation (Eng. Pat. 26345, 1904).

Cross dye black R X (*H.*) is produced from a mixture of 2:4-dinitrophenol and picric or picramic acid in the boiling process; it gives a redder shade of black than cross dye black B X, and dissolves slightly in cold concentrated sulphuric acid to a purple-blue solution. Picramic acid (14 parts), sodium sulphide (60 parts), and sulphur (25 parts) in 50 parts of water give after 24 hours' boiling under a reflux condenser a violet-black dye (*A.* Eng. Pat. 7332, 1900; D. R. P. 116791). The dinitrated products of the cresols and chlorophenols also yield various shades of sulphide blacks by the boiling process (*A.* Eng. Pats. 7076, 1900; 15625, 1909; D. R. P. 129564).

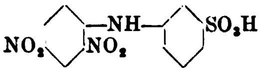
Immedial black V extra (*C.*). *p*-Aminophenol and chloro-2:4-dinitrobenzene, when boiled in alcoholic solution in the presence of sodium acetate, yield 2:4-dinitro-4′-hydroxydiphenylamine



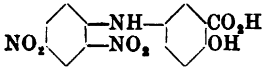
Fifteen parts of this substance are heated for 5 hours in a reflux apparatus with sodium sulphide crystals (75 parts), sulphur (30 parts), and a small amount of water to 140°–160°, the dye being precipitated from an aqueous solution of the fused product by acid, carbon dioxide, or air. Cotton is dyed in bluish-black shades, and when oxidised on the fibre with hydrogen peroxide the colour changes to blue (**Immedial blue,** *C.* D. R. P. 103861; Eng. Pat. 25234, 1907; Fr. Pat. 271909). The immedial black fusion may be carried out under pressure; the 2 : 4-dinitro-4′-hydroxydiphenylamine (10 parts) and dry sodium tetrasulphide (18 parts) are heated in an autoclave with 50–60 parts of alcohol, and the product, suspended in water, is converted into immedial blue by the addition of hydrogen peroxide (*C.* D. R. PP. 132424, 137784; Eng. Pat. 5385, 1900). The colour on cotton is fast to chlorine, light, and scouring agents.

When immedial black, eclipse black, or kryogen black is heated up to 200° with 1 : 8-dinitronaphthalene and sodium polysulphide, a black is produced which is more stable to oxidising agents than that from either of its generators (*v. Fast black, B.* Fr. Pat. 319790).

Cotton black (*D.* Eng. Pat. 13167, 1898; D. R. PP. 101862, 105058). Chloro-2 : 4-dinitrobenzene is condensed with 3-aminobenzenesulphonic acid and the resulting 2 : 4-dinitrodiphenylamine-3′-sulphonic acid (12 parts) is thionated with sodium sulphide (60 parts), sulphur (8 parts), and water (5 parts), the temperature being raised to 200°–220°. The colouring matter dyes in greenish-black shades which are not affected by oxidising agents. 2 : 4-Dinitrodiphenylamine-4′-sulphonic acid gives a coal-black sulphide dye absolutely fast to milling.

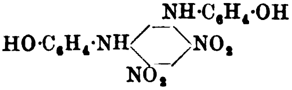


Sulphanil black C (*K.*). Chloro-2 : 4-dinitrobenzene is condensed with 4-aminosalicylic acid, the product, 2 : 4-dinitro-4′-hydroxydiphenylamine-3′-carboxylic acid is thionated at 150° with an equal weight of sulphur and 2·5 parts of sodium sulphide (D. R. P. 129885).



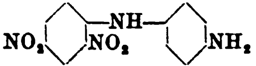
Katigen black (*By.*) is produced in a similar way by the thionation of 2 : 4-dinitro-2′-hydroxydiphenylamine-3′-carboxylic acid (D. R. P. 112182).

Kryogen blacks G, BG, B, N, result from the condensation of dinitro-*m*-dichlorobenzene with *p*-aminophenol (2 mols.), and its sulphonic and carboxylic acids, these three reagents on thionation giving respectively deep black, greenish-black, and bluish-black shades (*B.* Eng. Pat. 20232, 1899; D. R. P. 112298).



Indocarbon black S, SF (*C.*). The indophenol obtained by condensing carbazole (40 parts), nitrosophenol (30 parts) in 1100 parts of concentrated sulphuric acid at 15°, is heated with sodium sulphide, sulphur, aqueous sodium hydroxide, and copper sulphate in a reflux apparatus at 125° for 18 hours. The product, which is precipitated by air from sodium sulphide solution, gives full bluish-black shades very fast to chlorine (D. R. P. 221215). Similar dyes are produced from halogenated carbazoles and the homologues and substitution products of nitrosophenols (*v.* D. R. PP. 222640, 224590, 224591, 227323, 235364, 235836, 238857).

Auronal black (*T. M.*) is prepared from 2 : 4-dinitro-4′-aminodiphenylamine (36 parts) derived from chloro-2 : 4-dinitrobenzene and *p*-phenylenediamine by heating with sodium sulphide (180), sulphur (60), water (60), and glycerol (15 parts), the last substance serving to regulate the temperature of the boiling solution. At 165° a colour is produced, dyeing in dark-blue shades rendered faster by afterchroming. This product gives reddish-blue and violet solutions in concentrated sulphuric acid and aqueous sodium hydroxide respectively. At 170°–180° the fusion gives a bluish- or greenish-black, the colours in concentrated sulphuric acid being greenish-blue and black respectively. At 180° a spontaneous generation of heat occurs and an olive sulphide dye is produced (D. R. P. 144119; Eng. Pat. 11733, 1901).



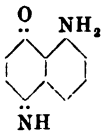
The above diphenylamine derivative is converted into a greenish-black compound by heating up to 150° with sodium polysulphide and hydroxide (*K.* D. R. P. 134704); in the absence of caustic alkali an insoluble product is obtained.

Pyrol black (*L.*). *p*-Aminophenol (11 kilos.) is heated with its hydrochloride (15 kilos.) for 10 hours at 170°, or for 5–6 hours at 180°–220°; 12 kilos. of the condensation product insoluble in dilute acids are heated at 180°–220° with 30 kilos. of sodium sulphide and 4 kilos. of sulphur. The fusion dissolves in water to a dark blue solution from which acids precipitate the black dye. The leuco compound with zinc dust and alkali is red; the dyed black is fast to light and scouring agents.

Melanogen blue B, BG, D. When 1 : 5-dinitronaphthalene, dissolved in warm concentrated sulphuric acid, is treated with hydrogen sulphide or a metallic sulphide, a compound is produced which is precipitated as its insoluble zinc chloride compound from the diluted solution. This substance (1 kilo.), which is an intermediate product in the preparation of naphthazarin, is heated with sodium sulphide (5 kilos.) and sulphur (1 kilo.) at 150°–180° for several hours, when the fusion is poured into water and the filtered solution evaporated to dryness. This soluble colouring matter dyes cotton in fast greyish-blue shades which are not altered during dyeing by aerial oxidation, but subsequent treatment with copper sulphate develops a fast bluish-black shade. Subsequent treatment with chromium, nickel, or cobalt salts give bluish-blacks, whilst zinc, cadmium, or aluminium salts develop bright blue shades (*M.* D. R. PP. 114266, 114267, 116417, 119248, 120899, 124507). The non-sensitiveness of these dyes to aerial oxidation distinguishes them from the typical sulphide dyes which furnish oxidisable leuco derivatives.

Kryogen blue B, G, R, are similar dyestuffs produced by heating the reduction products of 1 : 5- and 1 : 8-dinitronaphthalene (*B.* D. R. PP. 88236, 92471, 92472) with sodium sulphide and sulphur; violet and blue shades are produced at 100°, whilst blacks are obtained at 150°–200°

(*B.* D. R. PP. 103987; *M. ibid.*, 128118). The intermediate naphthazarin product



is converted into a wool dye by alkali thiosulphate and then by the action of sulphites or bisulphites into soluble compounds, which dye chrome mordanted cotton in greenish-black shades (*B.* D. R. P. 147945).

Fast black B and BS. The former of these colouring matters consists of a mixture of two dyes produced by boiling 1 : 8-dinitronaphthalene with 3-5 molecules of aqueous sodium sulphide (1 : 120), then acidifying and boiling for 2 hours longer.

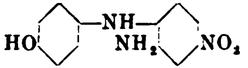
Fast black BS is produced by heating at 93° for 1 hour 200 parts of **fast black B** (30 p.c. paste) with 98 parts of sodium hydroxide (30°Be.) or the equivalent amount of sodium sulphide. The soluble product gives intense black shades on cotton (*B.* D. R. PP. 84989, 88847; Eng. Pat. 10996, 1893; 22603, 1894).

Anthraquinone black. 1 : 4′-Dinitro-anthraquinone (50 parts), sodium sulphide (250 parts), and sulphur (75 parts) are heated together until the product is soluble in water to a bluish-green solution.

Cotton is dyed with aqueous sodium sulphide in intense black shades. The colour is slightly soluble in alcohol to a green solution; with concentrated sulphuric acid the colour is greyish-black (*B.* D. R. PP. 91508, 95484; Eng. Pat. 15242, 1895).

Sulphide Blues.

Pyrogen direct blue (*Bl.*), the first blue sulphide dye discovered, is prepared from 2 : 4-dinitro-4′-hydroxydiphenylamine (m.p. 187°–188°) or its reduction product (m.p. 196°–197°)



Ten parts of either of these substances are heated with 18 parts of anhydrous sodium tetrasulphide and 60 parts of alcohol in an iron or enamelled autoclave at 135°–145°. The reaction proceeds smoothly in alcoholic solution, colour formation begins at 110°, and after 3–4 hours the pressure reaches 8–10 atmospheres. Cotton is dyed in dark violet-blue shades with 2 p.c., and in black bluish-violet shades with 5 p.c. of the dye (Eng. Pat. 5385, 1900; D. R. P. 132424). The violet tint of the dye is increased by suspending it in water and adding hydrogen peroxide; ozonised air or steam produces a similar effect which is probably due to elimination of NH_2 groups. The violet product is fast to chlorine, light and scouring agents (D. R. P. 137784). When the temperature of the autoclave in the foregoing process is raised to 160°–170° **pyrogen grey** is produced, the shade of which is not affected by oxidising agents.

Pyrogen indigo (*Bl.*). Phenyl-4-amino-4′-hydroxydiphenylamine

$$C_6H_5{\cdot}NH{\cdot}C_6H_4{\cdot}NH{\cdot}C_6H_4{\cdot}OH$$

(27·6 kilos.), is heated with dry sodium pentasulphide (55 parts) in 150 litres of alcohol under reflux for 24 hours. The solvent is distilled off, the residue dissolved in water, and the dye precipitated by air as a dark blue powder, dissolving in aqueous sodium sulphide to a blue solution and dyeing cotton in indigo blue shades (D. R. P. 150553).

Immedial pure blue (*Immedial sky blue*) (*C.*). Nitrosodimethylaniline is reduced with iron powder in dilute acetic acid solution. After removing the iron the filtrate is mixed with the calculated amount of phenol in aqueous solution, and the mixture oxidised with air in the presence of copper salts. The resulting indophenol

is then reduced to 4-dimethylamino-4′-hydroxydiphenylamine

(m.p. 161°–162°) a base which is also obtained by heating *as*-dimethyl-*p*-phenylenediamine with *p*-aminophenol hydrochloride at 150°.

Twenty-five kilos. of this base are added gradually to 50 kilos. of crystallised sodium sulphide, 12·5 kilos. of sulphur, and 10 litres of water heated to 90°. The mixture is then heated under a reflux apparatus at 110°–115°, a green pitch separates and gradually redissolves. After 24 hours the product is dissolved in 500 litres of water, and the colour precipitated with 50 kilos. of salt. Cotton is dyed in shades resembling methylene blue which are superior to indigo blue in brilliancy of tint and in fastness to light, chlorine, acids, and milling (Eng. Pat. 16247, 1900; D. R. PP. 134947, 141752; Fr. Pats. 303524, 308669).

The *Bisulphite compound*

$$C_{14}H_{12}O_4N_2S_3,NaHSO_3,2H_2O$$

is the first crystallisable derivative obtained from sulphide dyes, and is used in purifying the foregoing colouring matter. The melt is dissolved in 700 litres of water and treated with sodium hydrogen sulphite until the additive compound is precipitated. The solution is then heated to 90°, when this substance dissolves, leaving the impurities. The bisulphite compound separates on cooling in yellowish needles, and is washed with brine solution; it dyes wool in acid baths, and with the aid of oxidising agents (chromates, copper salts, &c.) gives indigo blue shades. The colouring matter is regenerated by digesting the additive compound with dilute sodium hydroxide solution. The lower homologues of immedial pure blue have been described (D. R. P. Anm. K. 13405, 1900; D. R. P. 133481).

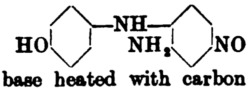
Eclipse blue (*G.*). The indophenol from dimethyl-*p*-phenylenediamine and phenol when treated with alkali sulphites gives a sulphonic acid with its sulphur in the nucleus containing the tertiary amino groups

$$N(CH_3)_2C_6H_3(SO_3H)NH{\cdot}C_6H_4{\cdot}OH.$$

The sodium salt of this acid heated at 120°–140° with an equal weight of sulphur and 2½ parts of crystallised sodium sulphide, gives a blue solution from which the colouring matter is precipitated by air, hydrogen peroxide, or alkali hypochlorite; cotton is dyed in very fast pure blue shades (Eng. Pat. 12578, 1901; D. R. P. 129325).

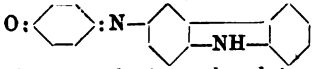
Immedial indone (*C.* D. R. P. 199963; Eng. Pat. 58, 1902; Fr. Pat. 317219; U.S. Pat. 709151). The indophenol from *p*-aminophenol and *o*-toluidine is heated with sodium polysulphide in alcoholic or aqueous solution (120°). The blue dye has a remarkable affinity for the cotton fibre, being much superior in this respect to its lower homologue from phenol and aniline. A brighter blue of redder shade has been obtained by heating the foregoing indophenol with sulphur alone at 190°–200° for 2 hours in the presence of hydrated chromic oxide. The product is directly applicable in sulphide solution as a cotton dye (*K. S.* Eng. Pat. 12879, 1903).

Thion blue B (*K.*). 2 : 4-Dinitro-4′-hydroxydiphenylamine, the condensation product of chloro-2 : 4-dinitrobenzene and *p*-aminophenol, is partially reduced to 4-nitro-2-amino-4′-hydroxydiphenylamine



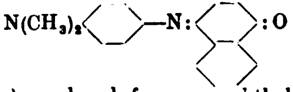
and this base heated with carbon disulphide, whereby the thiocarbamide derivative is produced. Five parts of this compound are heated for 10 hours at 145° with sodium sulphide (40 parts) and sulphur (24 parts). The fusion product is dissolved in water and the dye precipitated by the continued passage of air in the presence of sodium chloride. The shade on cotton is bluish-green, changed to pure blue by hydrogen peroxide, subsequent treatment with stannic chloride increasing the fastness of the dye (Eng. Pat. 19332, 1901; D. R. P. 139099).

Hydron blue. The indophenol

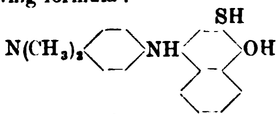


from carbazole and nitrosophenol is warmed with sodium sulphide (1·5 parts) until the colour disappears and then heated with sulphur (1–1·5 parts); the dye gives intense dark blue shades which are remarkably fast to light and chlorine (*C.* D. R. P. 218371).

Thiophor indigo (*C. J.*). The indophenol



(25 parts) produced from *a*-naphthol and *p*-aminodimethylaniline is heated in a reflux apparatus at 115° with 40 parts of crystallised sodium sulphide and 15 parts of sulphur. The leuco-indophenol which separates as an oil slowly reacts with the thionating mixture during 8–10 hours with evolution of hydrogen sulphide. The colouring matter, which crystallises from benzene in small prisms with a coppery lustre, still possesses the indophenol character of being hydrolysed by acids. On this account the leuco derivative of the dye is represented by the following formula :—



The solution of the dye in aqueous sodium sulphide is pale greenish-yellow, and, unlike the great majority of sulphide colouring matters, this product is soluble in the organic media, including ether.

Various shades of blue and violet are produced by changing the base employed in producing the indophenol; *p*-phenylenediamine and 2 : 4-tolylenediamine give rise to dark violet tints. The temperature is generally kept below 160°, and alterations in tinctorial properties are effected by introducing alcohol or glycerol into the thionating mixture. The dyed colours are fast to light, alkalis and scouring agents, but are destroyed by acids (D. R. P. 179839; Eng. Pat. 17540, 1905; Fr. Pat. 357587; U.S. Pat. 821378).

A series of sulphide blues having the property of dyeing weak blue shades from sodium sulphide baths, and remarkably fast blue shades when employed as vat dyes, are produced by heating with sodium polysulphide (Na_2S_5—Na_2S_8) in alcoholic solution, the indophenols from dialkyl-*p*-phenylenediamines and phenol and its ortho- and diortho-chloro derivatives (*B.* D. R. PP. Anmeldung, 60985 and 62302, 1911). Similar sulphide blues capable of employment as vat dyes are obtained in a similar manner from the indophenolthiosulphonic acids (prepared from alkyl-*p*-diaminethiosulphonic acids and phenol), or from the corresponding thiazines (*B.* D. R. PP. 153361; Anmeldung, *B.* 60984, 1911).

Other commercial brands of sulphide blues :— **Immedial direct blue, B, JB, R, OD; Immedial indogene B, GCl; Thiogene blue, B, R, 2R; Thiogene cyanine B, O, G; Thiogene deep blue RL, 2RL; Thiogene new blue JL, Bl, 2RL; Thionol blue 2B, RB, 2RF.**

SULPHIDE GREENS.

Italian green, *Verde Italiano* (Lepetit, Dollfus, and Gansser, D. R. P. 101577). *p*-Nitrophenol (12·5 kilos.), copper sulphate (4·5 kilos.) in 30 litres of water, are mixed with sodium hydroxide (19 kilos.), sulphur (17·5 kilos.), in 17 litres of hot water, and the mixture gradually heated to 210°, ammonia being evolved. Cotton is dyed in dull grass-green shades which appear pure green by artificial light. Hydrogen peroxide, chromic acid, or copper sulphate change the colour to blue-black, and concentrated oxidising agents discharge the colour, this reaction being made use of in printing with the dye.

Pyrogen green B, FB, FF, 2G, 3G, (*Bl.* D. R. P. 148024), **pyrogen dark green B.** *p*-Aminophenol (8 parts), sodium sulphide (50 parts), sulphur (20 parts), copper bronze (1 part), and water (100 parts) are heated to 170° in 3 hours. Cotton is dyed in olive-green shades; copper is present in the ash of the dyed fibre.

The greater the amount of copper bronze the more olive is the shade of colour produced. Other variations in the tint are brought about by using the homologues and substitution products of *p*-aminophenol.

Pyrogen olive N (*G.* D. R. P. 135335). *p*-Hydroxybenzylidine-*p*-nitroaniline, *p*-nitrobenzylidene-*p*-aminophenol and similar methylene and benzylidene derivatives of *m*- and *p*-diamines, and aminophenols are heated to 180°–200° with sodium polysulphide with or without metallic salts.

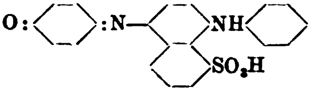
Eclipse green G (*G.* D. R. P. 135410; Eng. Pat. 26448, 1901). The indophenol from *p*-aminodimethylaniline and phenol is treated with sodium sulphite, and the resulting sulphonic acid (40 parts, Na salt) heated with sodium sulphide (100 parts), sulphur (40 parts), and copper sulphate (10 parts) in a reflux apparatus at 125°–130°. The dye is precipitated by air from its solution in aqueous sodium sulphide; it dyes in yellowish-green shades fast to light and soap.

Thion green B (*K.* D. R. P. 138104; Eng. Pats. 9619, 16931, 1902; Fr. Pats. 320701, 323489). Hydroxyphenylthiocarbamide and hydroxythiocarbanilide are heated respectively with sodium polysulphide at 140°–180°, the former gives a blue-green and the latter a mignonette-green, both dyes are turned bluer by chromic acid, and are insoluble in strong sulphuric acid. The dye is purified by dissolving the fused mass in water, acidifying slightly, filtering off the precipitated sulphur, and salting out the colour in the filtrate.

Immedial green. 4-Dimethylamino-4′-hydroxydiphenylamine (50 kilos.) is added to a solution of sulphur (31 kilos.) in crystallised sodium sulphide (124 kilos.). When the base has dissolved, copper sulphate (10 kilos.) is added, and the temperature raised to 120° and maintained for 24 hours. The dye is precipitated by salt or calcium chloride from the resulting solution; it dissolves in strong sulphuric acid to a green solution, and in aqueous sodium sulphide or hydroxide to a reddish-violet solution. The bluish-green shade on cotton is very fast (*C.* D. R. P. 129540).

An olive-green (*O.* D. R. P. 146064) is obtained by heating diformyl-*m*-phenylenediamine with sodium polysulphide at 110°, and then with the further addition of zinc chloride at 230°.

The 1 : 8- derivatives of naphthalene are employed in producing sulphide greens. Phenyl-α-naphthylamine-8-sulphonic acid and *p*-aminophenol yield an indophenol



which gives a green on heating with sodium polysulphide in the presence of copper sulphate. The perimidines produced by condensing 1 : 8-naphthylenediamine with aldehydes, ketones, and aliphatic acids (Annalen, 1909, 365, 53; Ber. 1909, 42, 3674) yield indophenols with *p*-aminophenol, and its chloro derivatives (*e.g.* 2 : 6-dichloro-*p*-aminophenol). These indophenols, when heated for 60 hours in a reflux apparatus with alcoholic sodium polysulphide, give rise to very fast dark green colouring matters (*A.* D. R. P. Anmeldung, 20316. 1911).

Other commercial brands of sulphide greens :— **Immedial deep green G; Thionol green 3G; Thionol brilliant green GX, 3GX, 4GX; Thionol dark green; Thiogene green G, GG, GL; Thiogene olive green GG, GGN.**

Sulphide Browns.

Cachou de laval (*P.*) is usually prepared from sawdust and other waste products allied to cellulose by heating these materials with sodium polysulphide at 250°–300°, the higher the temperature the darker the shade of brown produced (*cf.* Richardson and Akroyd, J. Soc. Chem. Ind. 1896, 328).

In all probability the final products of this reaction are phenolic in character, inasmuch as cellulose yields phenol on distillation, and the latter on oxidation passes into phenoquinone, a substance containing three benzene nuclei, which on heating with alkali polysulphide under pressure gives a dye resembling cachou (Wichelhaus, Ber. 1872, 5, 248; 1907, 40, 126; 1910, 43, 2926). A similar brown sulphide dye is produced by heating crude cresol with sodium polysulphide at 170°–250° (*By.* D. R. P. 102897; Eng. Pat. 22417, 1895).

Cachou de laval S is the soluble product formed by digesting the precipitated colouring matter of cachou with alkali sulphites or bisulphites; it is used in printing (D. R. P. 88392).

Thiocatechin (*P.* D. R. P. 82748; Eng. Pat. 3414, 1895; Fr. Pat. 239714; U.S. Pat. 561276; Ber. 1880, 13, 1226). The acetyl derivatives of aromatic diamines and nitro-amines are heated either with sulphur alone or with sulphur and sodium sulphide at 200°–250° for 3 hours.

The dye dissolves in aqueous sodium sulphide to a yellowish-brown solution, and when dyed on cotton requires to be fixed by subsequent oxidation. Various shades of yellow and brownish-yellow are produced by heating with 2 parts of sulphur, the following aromatic substances: acetyl-*p*-phenylenediamine, aceto-α-naphthalide, acetyl-*p*-nitroaniline, diacetyl-di-*o*-nitrobenzidine, and the acetyl derivatives of nitro-, *o*-, and *p*-toluidine

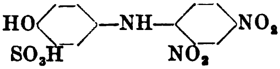
$[CH_3 : NH_2 : NO_2 = 1 : 2 : 4 \text{ and } 1 : 4 : 2]$

Thiocatechin S is the soluble product obtained by digesting thiocatechin with aqueous sulphites or bisulphites.

Cattu Italiano, sulphine brown (Lepetit, Dollfus, and Gansser, D. R. P. 118701; Eng. Pat. 18900, 1899; Fr. Pat. 290714). Turkey-red oil (5 parts), the higher fatty acids, and especially the unsaturated acids and their esters and alkali salts, when heated with sodium carbonate (12 parts) and sulphur (10 parts) at 320°–330°, evolve carbon dioxide, hydrogen sulphide, and volatile organic matter. The product is a black porous mass readily soluble in water. In spite of the different starting materials which are utilisable in this process, the colouring matter is very constant in properties; it dyes cotton brown from a bath containing sodium chloride in shades which are brighter than the cachous, but less fast to light and chlorine. The dye dissolves in water or aqueous sodium sulphide to solutions which are green to blue in colour, depending on the temperature at which the colouring matter was originally produced.

Thion brown (*K.* D. R. P. 137540; Eng. Pat. 18489, 1896; Fr. Pat. 315648; U.S. Pat. 723448). Chrysoidine base R (*H.*) (*v.* Azo-colouring matters), benzeneazotolylene-2 : 4-diamine (30 parts) are added to crystallised sodium sulphide (80 parts) and sulphur (30 parts) at 110°–120°, and the temperature raised to 160°, when the azo compound is decomposed with elimination of aniline. The viscid mixture is then baked for 1–2 hours at 160°–170°, and finally for 3–4 hours at 200°–220°, when a brownish-black powdery mass is produced which dyes cotton in intense yellowish-brown shades very fast to light. The dye is precipitated by acids from its alkaline solutions, dissolving as a dark brown mass in alcohol or concentrated sulphuric acid to brown solutions.

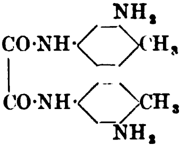
Sulphanil brown (*K.* D. R. P. 125584). 2 : 4-Dinitro-4′-aminodiphenylamine, prepared from chloro-2 : 4-dinitrobenzene and *p*-phenylenediamine is converted by means of aqueous alkali sulphite at 150° (46 p.c.) into the sulphonic acid.



This compound (40 parts), dissolved in twice its weight of water, is heated at 140°–160° with sodium sulphide (80 parts), sulphur (30 parts), and water (100 parts) until the mass is dry. The aqueous solution of the dye is violet-black changed to brown by caustic alkali.

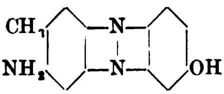
Cotton brown (*D.* D. R. PP. 102821, 106039). The higher nitrated derivatives of diphenylamine obtained by treating the base with concentrated sulphuric and nitric acids at 25°–60° yield a brown dye when cautiously reduced with sodium sulphide or polysulphide, and the reduction product dried at 200°. The colour is soluble in water, and dyes in cold or hot baths (*cf.* Eng. Pat. 18924, 1903).

Eclipse brown, N, R, B, G, 3G, V (*G.* D. R. PP. 125586, 125587, 126964, 128659; Eng. Pat. 1644, 1901; Fr. Pat. 306655). Tolylene-2 : 4-diamine (34 parts), oxalic acid (17 parts), sodium sulphide (120 parts), and sulphur (40 parts) are heated to 225°–250°, and then to 300°. The process may be varied by taking molecular proportions of the diamine and of tolylene-2-amino-4-oxamide



and the polysulphide may be replaced by a solution of sulphur in aqueous sodium hydroxide. The dye dissolves in water to a chestnut-brown solution, being precipitated therefrom by boiling with dilute mineral acid. Hydrogen sulphide is evolved on reducing the compound with zinc dust. In these condensations the oxalic acid may be replaced by succinic and phthalic acids, the latter giving rise to brown colouring matters dyeing very fast catechu shades.

A brown colouring matter of the immedial series, dyeing cotton in very fast shades closely resembling natural catechu, is produced by oxidising a mixture of *p*-aminophenol and tolylene-2 : 4-diamine to 2-methyl-3-amino-6-hydroxyphenazine



and by heating the azine obtained from 15·8 parts of *p*-aminophenol with 100 p.c. sodium sulphide (42 parts) and sulphur (80 parts) for 20 hours at 135° (*C.* D. R. P. 208109; Fr. Pat. 382412; *cf. By.* Eng. Pat. 19548, 1907; *B.* D. R. P. 147990). Similar fast catechu shades are produced by heating at 250° tolylene-2 : 4-diamine (2 parts), acetyltolylene-2 : 4-diamine (1 part), and sulphur (8 parts), the product being ground with 3 parts of sodium hydroxide and warmed at 130° (*A.* D. R. PP. 221493, 229154; Eng. Pat. 24703, 1909; Fr. Pat. 419665).

A mixture of methyleneresorcinol or its polymerides (Ber. 1892, 25, 947; 1894, 27, 2888), *p*-phenylenediamine, sodium sulphide, and sulphur when heated gradually to 200°–220° gives very fast yellowish catechu shades (*O.* D. R. P. 167429; Eng. Pat. 13950, 1905; Fr. Pat. 355783).

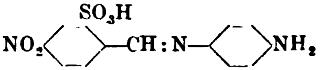
Immedial brown B, dark brown A (*C.* D. R. P. 112484; Eng. Pat. 25754, 1899; Fr. Pat. 295593). 4-Hydroxy-4′-aminodiphenylamine is boiled with aqueous sodium hydroxide and the product heated to 160° with sodium polysulphide. The two changes may be effected in one operation. This colouring matter gives on cotton intense yellow-brown shades, rendered yellower and faster by after-chroming.

Among other sulphide browns of similar origin to the foregoing colouring matters may be mentioned the following:—

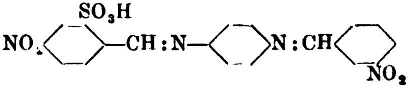
Katigen brown (*By.*); **Sulphur brown G** (*A.*); **Sulphur cutch** (*A.*); **Kryogen brown** (*B.*); produced from 1:8-dinitronaphthalene; **Immedial cutch, immedial khaki, immedial catechu** O.G. and O.R. (*C.*).

SULPHIDE YELLOWS.

Pyrogene yellow M, O, OR, 3R (*Bl.* D. R. P. 135335; Eng. Pat. 1007, 1900; Fr. Pat. 295712). These colouring matters were the first sulphide yellows discovered, and are produced by heating with sodium sulphide and sulphur (either with or without metallic salts), various condensation products of aromatic *p*-diamines, and amino- and diamino-phenols with formaldehyde, benzaldehyde, the nitrobenzaldehydes, and nitrobenzyl chlorides. The compounds with these aldehydes are of the nature of anhydro bases (Schiff bases). The two following derivatives, which may be regarded as typical of the members of the series, give respectively in the polysulphide fusion colours dyeing in greenish-yellow (I.) and orange-yellow (II.) shades.



I.



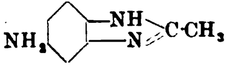
II.

Other derivatives give rise to different shades, methylene-*p*-aminophenol

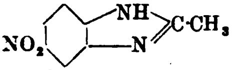
gives a brown, whereas *p*-nitrobenzylidene-*p*-aminophenol

furnishes an olive dye.

Kryogen yellow R (*B.* D. R. P. 142155). 2 : 4-Dinitroacetanilide when reduced with iron filings and dilute acetic acid yields the anhydro-base, 5-amino-2-methylbenziminazole



This base is heated at 200°–230° for 2–3 hours with 2 parts of sulphur, the product ground with an equal weight of sodium sulphide, dissolved in water, the mixture dried and baked at 200°–230° for 1–2 hours. This colouring matter is diazotisable on the cotton fibre. A similar dye giving greener shades is produced by heating the nitro-anhydro base



with sulphur and an equal weight of benzidine at 200°–240° until hydrogen sulphide is no longer evolved (*TM.* D. R. P. 157862; Eng. Pat. 5449, 1905; *cf.* *A.* D. R. PP.121463, 146916, 147403, 147729, 150915, 152717, 154108).

Immedial yellow D (*C.* D. R. PP. 139430, 141576; Eng. Pat. 11771, 1902; Fr. Pat. 321122). Tolylene-2:4-diamine (50 kilos.) and sulphur (100 kilos.) are heated gradually during 2 hours up to 190°. The amorphous sulphur compound produced is brownish or orange-yellow, insoluble in all ordinary media, dilute acids, or aqueous alkalis, but dissolving slightly in concentrated sulphuric acid to a brown solution. This substance (100 kilos.) is powdered and gradually added to crystallised sodium sulphide (90 kilos.) in water (60 kilos.) at 110°.

The mixture is heated at 120° until the organic compound becomes soluble. The solution is diluted, acidified with hydrochloric acid, and the yellow precipitate collected. The final product, which is soluble in aqueous alkali hydroxides or sulphides, gives on cotton yellow shades which are fast to scouring agents and acids; it is almost insoluble in concentrated sulphuric acid.

Thion yellow G, GG, GN (*K.* D. R. P. 139429; D. R. P. Anm. K. 24649; Eng. Pat. 16932, 1902; Fr. Pat. 323490). Tolylene-2:4-diamine and sulphur interact, forming a thio derivative (m.p. 145°), which when dissolved in hot aqueous sodium sulphide furnishes a yellow colouring matter precipitated by carbon dioxide from the alkaline solution.

The aromatic *m*-diamines yield complex thiocarbamides when heated with carbon disulphide (Ber. 1885, 18, 3293), and these thio derivatives when heated with sulphur at 150°–170° give rise to similar yellow dyes which are dissolved in aqueous sodium sulphide. Benzidine is sometimes added during fusion (*M.* D. R. PP. 152027, 153916, 166864; *A.* *ibid.* 171871). Tolylene-2:4-diamine itself yields a yellow dye when fused with benzidine and sulphur at 190°–280°, the product being rendered soluble by sodium sulphide (*M.* D. R. P. 163143; *TM.* D. R. P. 163001).

Immedial orange C, N (*C.* D. R. P. 152595; Eng. Pat. 11898, 1902; Fr. Pat. 321183). Tolylene-2:4-diamine (50 kilos.) and sulphur (125 kilos.) are heated in an iron pan with stirrers until hydrogen sulphide is no longer evolved, and the product baked at 250° until a hard brittle mass is produced, which is then added to sodium sulphide (150 kilos.) at 110°–120°. The mixture is dissolved in water, and the colouring matter precipitated by acid. Cotton is dyed in orange-brown shades which are brightened by hydrogen peroxide, but scarcely affected by chromic acid. This colouring matter is insoluble in concentrated sulphuric acid.

Eclipse yellow G, 3G (*G.* D. R. PP. 138839, 145762, 145763). When heated with commercial formic acid in a reflux apparatus, tolylene-2:4-diamine gives rise to formyltolylene-2:4-diamine, very sparingly soluble pyramids, m.p. 113°–114°, and diformyltolylene-2:4-diamine, acicular aggregates, m.p. 176°–177°. These products, which are separated by fractional crystallisation from water, the latter being the more soluble, are both used in the preparation of sulphide dyes. The formyl derivative is added to a solution of an equal weight of sulphur in 3 parts by weight of crystallised sodium sulphide fused in its water of crystallisation and the temperature raised to 240°. The dye, which is obtained as a light brown precipitate on acidifying a solution of the fusion, gives bright yellowish-orange shades, those from the monoformyl derivative having the browner tint. The thionation may also be effected by sulphur, either alone or with the addition of benzidine or other analogous bases. The formyl derivatives may be replaced by the condensation products of tolylene-2:4-diamine and oxalic acid (*M.* D. R. PP. 156177, 157103).

Similar sulphide yellows are produced by fusing with sulphur at 200°–220° mixtures of tolylene-2:4-diamine and its diformyl derivative or diformylbenzidine (*G.* D. R. PP. 146917; *A.* 159097, 170746), and various shades of yellow, yellowish-brown, and orange are obtained by employing mixtures of tolylene-2:4-diamine and various aromatic nitro derivatives, such as the nitranilines and their homologues, and the dinitro-benzenes and -naphthalenes (*By.* D. R. PP. 201834, 201835, 102836).

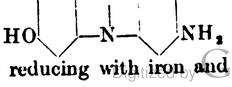
Immedial yellow GG (*C.* D. R. P. 180162; Eng. Pat. 4097, 1906; Fr. Pat. 372137; U.S. Pat. 892455). The relationship between sulphide yellows and thiazole dyes is illustrated by the employment of dehydrothiotoluidine (*v.* PRIMULINE) in the sulphur fusion. Benzidine (19 parts), dehydrothiotoluidine (16 parts), and sulphur (70 parts) are heated together for 1 hour at 210°, and the fusion digested with fused sodium sulphide at 120° until rendered soluble. The dye is then precipitated by mineral acid. Cotton is dyed in greenish-yellow shades very fast to scouring agents (*cf.* *B.* Rassow, D. R. P. 234638).

Among the numerous other yellow sulphide dyes are **Thioxine yellow** and **Thioxine orange,** yellowish powders slightly soluble in concentrated sulphuric acid and insoluble in sodium hydroxide; **Thionol yellow G, R; Thionol orange; Thiogene yellow G, GG, 5G.**

REDDISH SULPHIDE DYES.

Although bright red sulphide dyes have not yet been obtained, it has been found possible to produce various shades of purple, violet, and maroon by thionating certain red colouring matters. In these reactions sulphur is probably introduced into the molecule without destroying the complex to the presence of which the red colour is due.

Immedial maroon, bordeaux, and violet (*C.* D. R. P. 126175; Eng. Pat. 14836, 1900; Fr. Pat. 303107; U.S. Pat. 701435). The simplest starting material for the production of the bordeaux-red sulphide dyes is 6-amino-3-hydroxyphenazine



prepared by reducing with iron and acetic acid

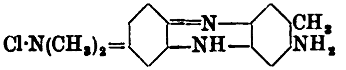
2 : 4-dinitro-4′-hydroxydiphenylamine (from *p*-aminophenol and chloro-2 : 4-dinitrobenzene) and oxidising the resulting hydroxytriamine

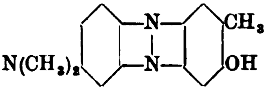
$$HO{\cdot}C_6H_3(NH_2)NH{\cdot}C_6H_4{\cdot}NH_2$$

in alkaline solution with manganese dioxide.

The sulphonic and carboxylic acids of this phenazine, which are obtained in a similar manner, are also employed in the sulphide fusion.

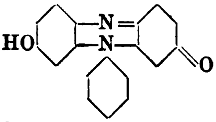
Tolylene red (neutral red), 6-dimethylamino-3-amino-2-methylphenazine obtained by oxidising a mixture of dimethyl-*p*-phenylenediamine and tolylene-2 : 4-diamine, is too insoluble for employment in the sulphide fusion, and is converted either into its sulphonic acid by fuming sulphuric acid (23 p.c. SO_3) or into the corresponding hydroxy-azine by hydrolysis with water under pressure.





These products being soluble in aqueous alkali hydroxides or sulphides are utilisable in the production of reddish sulphide dyes.

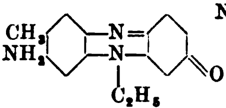
Safranol, 3-hydroxy-6-oxy-N-phenylphenazine produced either by condensing nitrosophenol with *m*-hydroxydiphenylamine, by oxidising this base mixed with *p*-aminophenol or by the alkaline hydrolysis of phenosafranine or phenosafraninone, is employed in the sulphide fusion, as is also phenosafranine and its carboxylic and sulphonic acids.



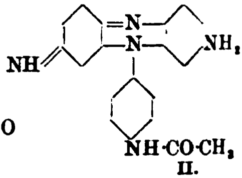
One of the foregoing azines (10 parts) is added to a solution of sulphur (20 parts) in sodium sulphide (50 parts) and water (10 parts), and the mixture heated to 140°–150° until the product dissolves in water to a dark violet solution. This operation may also be carried out either in a reflux apparatus or in an autoclave. The sulphide dyes from 6-amino-3-hydroxyphenazine and its carboxylic and sulphonic acids, and from the alkali soluble tolylene red derivatives give brownish-violet shades, the safranol condensation product dyes in bluish-violet tints, whereas reddish-violet shades are obtained from the dyes derived from N-ethylsafranol and from phenosafraninone and its carboxylic and sulphonic acids.

The fusion of these phenazine derivatives is also carried out in the presence of metallic salts ($CuSO_4$, $CoSO_4$, or $NiSO_4$, *cf. Lev.* Eng. Pats. 24008, 1906; 17749, 1907), the resulting dyes being redder and faster than those produced in the absence of these adjuvants.

3-Amino-6-hydroxyphenazine and its C-methyl homologue when heated to 120°–140° with aqueous sodium polysulphide and copper sulphate or metallic copper give dark red sulphide dyes. Safranol and safraninone when similarly treated yield violet-red colours and N-ethyl-2-methylsafraninone (I.) gives rise to a bordeaux-red dye. *p*-Acetylaminosafranine (II.) (N-acetylaminophenyl-3 : 6-diaminophenazine) and its homologues when heated at 120° for 20 hours with aqueous sodium polysulphide containing copper sulphate give rise to bluish-violet dyes precipitated by acid, which are faster and brighter than those prepared from the simpler safranines (*M.* D. R. PP. 171177, 177709, 179021, 222418; Fr. Pat. 361608; U.S. Pat. 818980).



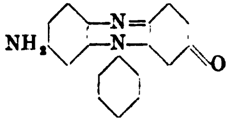
I.



II.

Azines without hydroxyl groups, such as tolylene red, being insoluble in alkali sulphides, are first fused with sulphur at 180°–230°, the product being then treated with sodium sulphide at 180°. Cotton is dyed in reddish-brown shades (*B.* D. R. P. 147990).

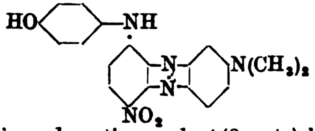
Thiogen purple (*M.* D. R. P. 181125; Eng. Pat. 2797, 1906; Fr. Pat. 372277; U. S. Pat. 829740). The N-alkylated aminohydroxyphenylphenazines and their tolyl homologues, the chloro derivatives of the azines (produced from chloroaminophenols) when heated at 110°–135° in a reflux apparatus or under pressure with aqueous or alcoholic sodium polysulphide give sulphide colouring matters dyeing cotton in clear bordeaux-red shades, the higher the temperature of the fusion the bluer the tint produced. Reddish-violet and dark red sulphide dyes are obtained by heating in a reflux apparatus at 110°, the chloro- and bromo-phenazines and the corresponding halogenated toluazines with aqueous sodium polysulphide in the presence of copper sulphate (*M.* D. R. P. 174331; *A. ibid.* 207096). In these condensations the halogen radicle of the chloro- or bromo- azine is readily replaced by a SH group, and accordingly the organic base is first heated with sodium sulphide alone at 110°–140°, and subsequently treated with polysulphide at a high temperature. When the latter operation is omitted intermediate mercaptan derivatives of the hydroxyphenazines are produced which have only a slight affinity for the cotton fibre and are converted into sulphur dyes by fusion with alkali polysulphide (*M.* D. R. PP. 181327, 187868; Fr. Pat. 360437).



Thiogen violet V, B (*M.* D. R. PP. 168516, 177493, 179960, 179961). Phenosafraninone, 3-oxy-6-amino-N-phenylphenazine (10 parts) warmed at 115°–120° with sulphur (30 parts), alone or with a diluent, then heated further to 200°, and mixed with sodium sulphide. The violet dye produced, which contains sulphur, is converted into a colouring matter, dyeing bluer and faster shades by heating for 20 hours in a reflux apparatus at 135° with twice its weight of aqueous sodium polysulphide. The addition of copper sulphate or copper to the foregoing polysulphide fusion leads to the production of redder and faster shades of violet, the redness increasing with the amount of copper employed in the condensation.

Violet to violet-blue shades of sulphide dyes are produced by heating at 170° for 3 hours safranol (10 parts), sulphur (30 parts), and aniline (10 parts), or some other organic solvent of high boiling-point (*e.g.* dimethylaniline, benzidine). Bluer and more sombre tints are obtained either by prolonging the heating or by raising the temperature to 240° (*M.* D. R. P. 178982; Fr. Pat. 360437).

Thion violets (*K.* D. R. PP. 144157, 152373, 160790, 160816, 165007). 4-Nitro-2-amino-4′-hydroxydiphenylamine and nitrosodimethylaniline hydrochloride condense to form the complex azine 1-nitro-4′-*p*-hydroxyphenylamino-6-dimethylaminophenazine.



This condensation product (8 parts), heated at 130°–140° for 2–3 hours with sodium sulphide (40 parts) and sulphur (16 parts), yields a violet sulphide dye dissolving in water to a dark green solution, and in concentrated sulphuric acid with a bluish-green coloration.

Trihydroxyphenylrosinduline is obtained by the condensation of *p*-aminophenol and benzene-azo-*a*-naphthylamine hydrochloride, or from the former compound and *a*-nitronaphthalene (*K.* D. R. PP. 158077, 158100, 158101, 160789 160815, 163239). This rosinduline (52 parts), heated for 5 hours at 160°–170° with sodium sulphide (160 parts), sulphur (40–60 parts), sodium hydroxide (40°Be, 24 parts), and water (200 parts), gives rise to a reddish-violet dye dissolving in concentrated sulphuric acid to a blue solution.

The indophenol from *p*-aminophenol and *p*-xylenol when heated with aqueous sodium polysulphide in a reflux apparatus for 16 hours or under pressure (125° for 12 hours), or in alcoholic solution for 2–3 days, gives rise to a sulphide violet which separates from solution in small brown crystals having a metallic lustre. This colouring matter dissolves in aqueous sodium sulphide to a blue solution, and dyes in deep violet shades which are very fast and, hitherto, unsurpassed in intensity (*C.* D. R. PP. 191863; Eng. Pat. 4653, 1902; Fr. Pat. 318577).

MANUFACTURE OF SULPHIDE DYES.

The apparatus most generally employed in the polysulphide fusion is a cylindrical cast-iron jacketed pan about 3 ft. deep by 2 ft. in diameter, and having a capacity of about 100 gallons. The jacket serves for the introduction of superheated steam, a pressure of 4–6 atmospheres sufficing to raise the temperature of the fusion to 125°–135°. The pan is fitted with a mechanical stirrer and its domed lid contains a man-hole for introducing the reagents, a thermometer tube dipping into the fusion, an opening leading to the reflux condenser, and an inlet tube for air under increased or decreased pressure. The jacket is fitted with a manometer, and if the pan is to be used for fusions under pressure, it is also fitted with a pressure gauge. This plant serves for the majority of modern sulphide fusions (*e.g.* dinitrophenol black), which are carried out at temperatures only slightly above the boiling-point of water (105°–120°). In fusions requiring higher temperatures (*e.g.* 200°–300°, cachou de laval, eclipse brown, &c.) smaller cast-iron pans are employed, heated either by direct fire or in an oil bath, the fittings of the melting-pan being similar to those of the jacketed pan. Vaseline or a high-boiling liquid (*e.g.* aniline, b.p. 182°) may be employed in the oil bath, which is preferable to heating by direct fire, as local overheating is avoided. This mode of heating is employed both in sulphide melts and in fusions with sulphur alone in the production of yellow.

Sulphur fusion. This fusion is restricted chiefly to the production of sulphide yellows, oranges, and browns, which, being allied to the thiazole dyes (*v.* PRIMULINE), are prepared in a similar way. A few bases give blue and black sulphide dyes with sulphur alone at comparatively low temperatures, 2 : 4-diaminophenol, for instance, with sulphur at 80°–120°, gives a colour dissolving in sodium sulphide to a blue solution, and dyeing cotton in bronzy black shades, which, however, are not fast to chroming (Vidal, Eng. Pat. 16449, 1896). The products of the sulphur fusion for yellows are insoluble substances, which are ground up and rendered soluble by boiling with concentrated aqueous sodium sulphide.

Sulphide fusion. The heating of nitro compounds and sulphur is avoided, so far as possible, owing to the risk of explosion, and in general the sulphide fusion is carried out with a mixture of sodium sulphide and sulphur (sodium polysulphide Na_2S_2 . . . Na_2S_5) generally in the presence of water either added or derived from the commercial crystallised sulphide $Na_2S,9H_2O$.

In the case of nitro compounds yielding easily decomposable polyamines on reduction, it is preferable to add the organic substance to the fused polysulphide rather than to reduce the nitro compound with sodium monosulphide before introducing the sulphur.

In the Vidal black process the *p*-aminophenol produced by reduction from *p*-nitrophenol is comparatively stable, and consequently the sulphur can be added after reduction. With dinitrophenol, however, the best result is obtained by adding the nitro compound to the polysulphide in aqueous solution when reduction and thionation occur concurrently. The black obtained by reducing dinitrophenol with aqueous monosulphide, and then adding sulphur, is distinctly inferior in tinctorial properties to Cross dye black BX (*H.*).

At high temperatures sodium monosulphide will act as a thionating agent, for, on reducing nitro compounds, it becomes itself converted into a complex mixture of sulphites, polysulphides, and thiosulphates. A sulphide brown is produced by fusing dinitrophenol at 160°–180° for 6–8 hours with crystallised sodium sulphide.

The fusion under reflux condenser, which is employed when the formation of colour occurs at temperatures near 100°, is of great utility in the manufacture of blacks from dinitrophenol, picric, and picramic acids, 2 : 4-dinitro-4′-hydroxydiphenylamine and its chloro derivatives and especially in the production of blues from indophenols, and of violets from hydroxy and amino derivatives of the azines.

Alcoholic condensation. The thionation is often carried out in alcoholic solution, the sulphide employed being either anhydrous or crystalline. In this medium sulphur dissolves readily to an extent corresponding with the tetrasulphide Na_2S_4. Although on account of the low temperature (80°) the condensation takes a long time, yet the products are obtained in a very pure condition, the dyes derived from certain indophenols separating in a crystalline form. The alcoholic or aqueous fusions are sometimes effected under pressure. Immedial black, when prepared in this way from 2 : 4-dinitro-4′-hydroxydiphenylamine or its reduction products, separates as a crystalline dark blue lustrous powder dyeing in very intense black shades.

Additions to the sulphide fusion. Sometimes the temperature of the condensation is raised either by substituting amyl alcohol for water or ethyl alcohol, or by adding to the fusion such inert substances as glycerol, naphthalene, or β-naphthol. Aromatic amines have also been added to sulphide fusions, but in some cases they take part in the condensation. Benzidine, for example, is frequently added to sulphur fusions for yellow. Dehydrothiotoluidine, when melted with sulphur alone, gives no colouring matter, but when benzidine is introduced into the melted mixture immedial yellow GG is produced (*C.* D. R. P. 180162).

Copper is added to many sulphide fusions, most frequently in the form of sulphate, but also as copper bronze; it imparts greenish shades to black, reddish shades to browns and violets and yellowish shades to red. In some cases this metal alters the chemical properties of the dye without greatly modifying its shade of colour. The immedial black fusion in presence of copper gives a greenish instead of a bluish-black, which, unlike ordinary immedial black, is not oxidised on the fibre by hydrogen peroxide to immedial blue. It is often immaterial whether the copper is added during thionation or afterwards. Zinc salts are added to fusions of 1 : 8-naphthalene derivatives to prevent the formation of brown impurities during the preparation of certain blue sulphide dyes (*By.* D. R. P. 116655).

The condensation of the indophenol

$$p\text{-}NH_2\cdot C_6H_4\cdot N : C_6H_4 : O$$

with aqueous polysulphide does not give a satisfactory colour unless manganous sulphate is added to the fusion when an indigo blue dye is produced (*P.* D. R. P. 22406; Fr. Pat. 406225).

The course of the sulphur and polysulphide fusions may be ascertained by dissolving samples in water or sodium sulphide, and precipitating the sulphide dye and excess of sulphur with dilute acid. The acid filtrate contains the unthionated amines which may be recognised in one of three ways: (1) By diazotisation and coupling with alkaline β-naphthol; (2) oxidation to indophenols; (3) production of coloured solutions: this occurs in the case of the azines and other coloured bases. The fusion product is dissolved in water, or if necessary, aqueous sodium sulphide, and in some cases (*e.g.* dinitrophenol black) the colour is precipitated from the filtered solution of its leuco derivative by passing in a current of air. This precipitation by air sometimes takes place, however, with considerable difficulty, and then the colouring matter is precipitated by dilute acid in a wooden vat surmounted with an efficient draught hood for carrying off the torrent of hydrogen sulphide set free when the alkali sulphide solution is acidified. In other cases the dye is salted out with sodium, ammonium, or calcium chloride, or other soluble salts. The precipitated dye is collected either in a filter press or on a vacuum filter, the latter being employed only when the precipitate is not too slimy.

Immedial pure blue is purified either through the soluble bisulphite compound or by dissolving the leuco derivative of the colouring matter in hydrochloric acid, filtering from insoluble impurities and precipitating the hydrochloride of leuco immedial pure blue by the addition of brine solution.

The Dyeing of Sulphide Colours.

The sulphide dyes are best dissolved in wooden vessels by pouring over them boiling water containing sufficient sodium sulphide to bring the colours into solution. Copper or brass vessels are to be avoided, and the metallic parts of the dyeing apparatus should consist of iron or lead. The dyeing operation is carried out in wooden or iron vats heated by steam coils. In addition to sodium sulphide, the bath is generally prepared with sodium carbonate and either sodium chloride or sulphate. In the following dyeing recipes the percentage of ingredients is always reckoned on the weight of dry cotton, which is generally dyed in about 20 times its weight of water.

Sulphide blacks. For dyeing 100 grms. of cotton yarn in a full shade of cross dye black BX (*H.*), 10 grms. of this colour are dissolved in 500 c.c. of hot water containing 20 grms. of crystallised sodium sulphide and 5 grms. of sodium carbonate. This mixture is boiled for 5 mins., the solution made up to 2 litres, the yarn, which has been previously well boiled out with water, is then introduced, and the bath kept boiling for 15 mins. This temperature is maintained for 30 mins. longer, during which period 75 grms. of salt are gradually added, the bath being kept up to constant volume by the addition from time to time of hot water. The dyed yarn is then lifted and rinsed in cold water.

Although after-chroming does not materially alter the shade of black which is fully developed as the result of aerial oxidation, nevertheless this treatment is sometimes used to increase the fastness of the dye, and is effected by immersing the rinsed yarn for 30 mins. at 60° in 2 litres of water containing 2 p.c. of sodium or potassium bichromate, and 2 p.c. of sulphuric acid. Any bronziness due to oxidation or excess of colour is removed and the tone of the black improved by heating the dyed yarn for 30 mins. at 60° with the following emulsion: 5 p.c. of soap, 1·5 p.c. of olive oil, and 1·0 p.c. of ammonia in 2 litres of water. The finished yarn is then squeezed out and dried without washing.

The dyeing process for Vidal black (*P.*) from p-nitrophenol is carried out as above with 10–15 p.c. of the colour, but in this case, after-chroming is essential in order to develop the full shade of black from the dark green tints produced by aerial oxidation. The above-described finishing process enhances the tone of black obtained by chroming.

Immedial black V extra (*C.*) is dyed in full shades with 15–25 p.c. of colour, 10–18 p.c. of crystallised sodium sulphide, and for each 10 gallons of liquor are added 4·5–8 oz. of sodium carbonate and 1–3 lbs. of common salt or anhydrous sodium sulphate. The yarn is dyed at a boiling temperature for 1–1½ hours and rinsed in water, containing 4·5–8 oz. of sodium formate or acetate per 10 gallons of liquor. For grey shades only 1–8 p.c. of this black is required, with 2–6 p.c. of sulphide crystals, one-third the amount of salt or sodium sulphate, and the same proportion of sodium carbonate as for full black shades.

Thiogene black conc. (*M.*) and thioxine black RNO (*O.*) are dyed in full shades with 10 p.c. of colour, 30 p.c. of crystallised sodium sulphide, 8–10 p.c. of dry sodium carbonate, and 50 p.c. of common salt or anhydrous sodium sulphate. The bath should have at 15° a sp.gr. of 6·7°Be. Cotton yarn is dyed at the boil for 1 hour, and mercerised yarn at 90° for a somewhat longer period.

An increase in fastness and depth of the sulphide blacks is produced by an after-treatment with 1–2 p.c. of chrome alum or copper sulphate, 1·5–2 p.c. of potassium bichromate, and 5 p.c. of acetic acid.

Sulphide blues. Immedial indone 3B is dyed on cotton yarn in pale and medium shades by using 2–10 p.c. of colour, 5–20 p.c. of sulphide crystals, and 2–10 p.c. of glucose with 4·5–8 oz. of soda ash and 1 lb. of common salt or dry sodium sulphate to each 10 gallons of water. Deeper shades are obtained with 10–16 p.c. of colour, and correspondingly greater amounts of sodium sulphide and glucose. The lighter shades are dyed at 30°–40°, and the darker at 60°–80°, a brighter tone being thus obtained than at the boiling temperature.

Thiogene deep blue and thiogene cyanine B are dyed in full shades with 6–10 p.c. of colour, 10–15 p.c. of sulphide crystals, 5 p.c. of sodium carbonate, and 30 p.c. of sodium chloride at a boiling temperature for 1 hour.

Sulphide greens. Immedial green is dyed on cotton in full shades with 14 p.c. of colour, the same proportion of sulphide, 0·5 p.c. of soda ash, and 5 p.c. of common salt or dry sodium sulphate. The tint is brightened by exposure to air after rinsing, or by warming the dyed yarn with soap solution containing sodium carbonate.

Sulphide yellows. Thiogene yellow 5G and thioxine yellow G require for the dyeing solution from 2 to 4 times their weight of sulphide crystals; the bath is prepared with 4–5 p.c. sodium carbonate, 25–35 p.c. of sodium chloride, or 15–20 p.c. of dry sodium sulphate, the dyeing being effected just below the boiling-point. Immedial yellow GG is dyed at 70°–80° without sodium chloride or sulphate.

Sulphide browns. These colouring matters dissolve with 0·4–1·0 part by weight of sulphide crystals, and are dyed for 1 hour at the boil with sodium carbonate and sodium chloride, full shades being obtained with 8–10 p.c. of colour. The fastness of sulphide browns to light, washing, milling, and alkalis is very satisfactory, but they are appreciably affected by chlorine or hypochlorites.

Sulphide violets and purples. The maroons, violets, purples, and bordeaux of this series are best dyed at 60°–80°, and not at boiling temperatures. In some cases sodium chloride or sulphate is not added to the bath, but a little glue (one-fifth of the weight of dye) is introduced with the object of brightening the shade.

Sulphide colouring matter as vat dyes. Immedial blue is reduced with alkaline hydrosulphite until the solution assumes a brownish-yellow colour, the cotton is then introduced, and the colour developed on the fibre by oxidising agents. Indigo can be dyed from the same bath. The sulphide dyes cannot be employed in the zinc-dust or alkaline ferrous sulphate vat, because they yield insoluble lakes with the metallic radicles present (*M.* D. R. P. 146797; Eng. Pat. 24455, 1899; Fr. Pats. 295589, 301740; U. S. Pat. 680472; *cf.* Fr. Pats. 299733, 385087).

Various brands of sulphide black (*e.g.* kryogen black and thiophenol black) have been dyed on cotton from a fermentation vat, although the process is unserviceable for the animal fibres (*B.* D. R. P. 200391; Eng. Pat. 12219, 1907; Fr. Pat. 379584).

Dyeing of sulphide dyes on wool, silk, and fibres other than cotton. The destructive action of the alkali sulphide on wool and silk is mitigated by adding to the dye-bath an amount of dextrose equal to twice the weight of sodium sulphide present. Silk is dyed for 1 hour at 80° in 20 times its weight of liquor, each litre of which contains 20–30 grms. of sulphide black, or 5–10 grms. of some other sulphide colour, 1 grm. of sodium carbonate, 5–10 grms. of Glauber salt, 3 c.c. of turkey-red oil, and the minimum amount of sodium sulphide with twice its weight of dextrose (*C.* D. R. P. 161190).

Wool is dyed at 60° in a similar bath, but without the turkey-red oil. Tannin may be employed as the protective agent instead of dextrose. A preliminary treatment of wool with warm 4 p.c. formaldehyde solution protects the fibre from the action of alkali sulphides (Kann, D. R. PP. 144485, 146845; Eng. Pat. 25971, 1906); but wool thus treated, although taking up sulphide dyes (*e.g.* cachou de laval) in moderately alkaline baths at 90°, is not dyed by sulphide colours in colder baths of moderate alkalinity (Levinstein, J. Soc. Dyers. 1907, 296; Eng. Pats. 25971, 1906; 19840, 1907). The addition of ammonium chloride or alkali bisulphite lessens the destructive action of alkali sulphides on wool and silk (*Bl.* D. R. P. 130848).

Artificial silk is readily dyed by sulphide colours even at comparatively low temperatures, 30°–40°, for light shades, and 60° for heavy shades, in the latter case the bath being prepared with sodium sulphate and sodium carbonate. Ramie and hemp fibres are readily dyed by sulphide colours, jute absorbs these dyes less easily than the cotton fibre.

CONSTITUTION OF SULPHIDE DYES.

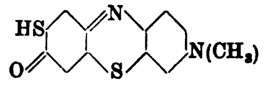
The problem of ascertaining the constitution of the sulphide dyes is greatly complicated by the uncrystallisable nature of these products, and by the circumstance that these dyes, like many other substantive colours, tend to form colloidal solutions which render impossible the determination of their molecular weight.

Only in the case of the simplest members of the series, the sulphide blues, has it been found possible to obtain crystalline derivatives, and through these compounds to establish a relationship between the sulphide blues and the colours of the methylene blue series.

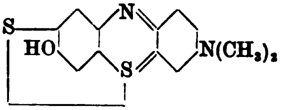
Immedial pure blue (*C.* D. R. P. 134947) gives a bisulphite compound

$$C_{14}H_{12}O_4N_2S_3,NaHSO_3,2H_2O,$$

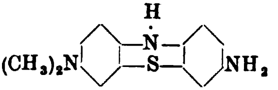
crystallising in yellow needles (D. R. P. 135952). The colouring matter contained in this additive compound has been given the following constitution, but probably immedial pure blue is the disulphide corresponding with the mercaptan represented by the first of these formulæ



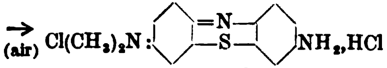
or



Gnehm and Bots (J. pr. Chem. 1904, [ii.] 69, 169) find, however, that the bisulphite compound is more correctly represented by the formula $C_{14}H_{12}O_2N_2S_3,NaHSO_3,2H_2O$, a result which would indicate a somewhat different constitution for immedial pure blue. On heating methylene blue with alcoholic ammonia at 140° Gnehm and Kaufler (Ber. 1906, 39, 1016) obtained dimethylleucothionoline I.

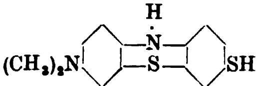


I.

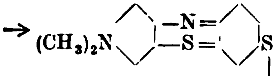


II.

which became oxidised to dimethylthionoline (II.). The diazo compound of the latter was converted into the corresponding xanthate, and this substance hydrolysed with 80 p.c. sulphuric acid. The final product was an amorphous bluish-black powder, dissolving in aqueous sodium sulphide to a colourless leuco compound, and dyeing cotton from this solution in greyish-blue shades. These results indicate that the replacement of NH_2 in dimethylleucothionoline by SH furnishes a leuco compound, having the constitution III., and accordingly the bluish-black substance, which has the properties of a sulphide dye, would probably be represented by the formula IV.

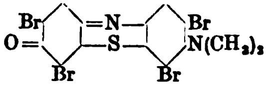


III.



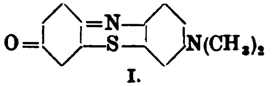
IV.

Moreover, immedial pure blue, when heated in sealed tubes with potassium chromate and hydrobromic acid, gives a 42 p.c. yield of etrabromomethylene violet

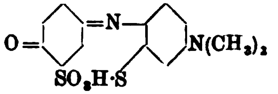


a substance which has also been produced synthetically from methylene blue (Gnehm and Kaufler, Ber. 1904, 37, 2618, 3032).

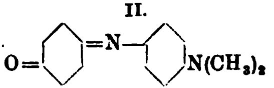
Methylene violet (I.) and the indophenolthiosulphonic acid (II.), when treated below 140° with sodium tetrasulphide in aqueous or alcoholic solution, yield a blue closely analogous to immedial pure blue which is prepared from the indophenol (III.)



I.



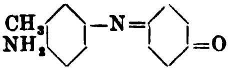
II.



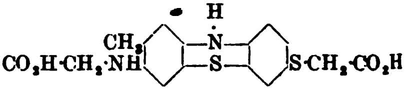
III.

The similarity in the products of these two condensations points to the existence in the sulphide blues of the thiazine ring, which is present in methylene blue, but in addition the leuco derivatives of sulphide blues contain SH groups, which undergo oxidation to insoluble sulphide blues, which are to be regarded as complex disulphides.

Immedial indone, produced from the indophenol

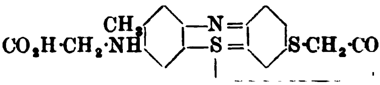


has been found by Frank to undergo condensation with chloroacetic acid, so that its leuco derivative gives rise to a readily purified compound containing two $CH_2{\cdot}CO_2H$ groups

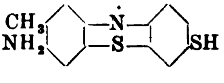


(Chem. Soc. Trans. 1910, 97, 2047).

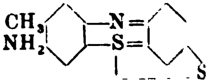
This product is readily oxidised to a blue colouring matter, which, unlike the original immedial indone, has no affinity for cotton in a sodium sulphide bath, but dyes wool bright blue from an acid bath. This wool dye has very probably the following constitution—



These results, therefore, indicate that the constitutions of leuco-immedial indone (I.) and of immedial-indone (II.) are most probably to be represented respectively by the following formulæ—



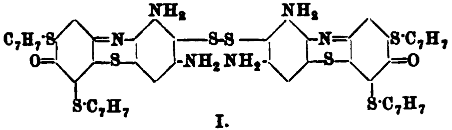
I.



II.

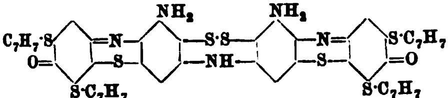
The alkylation of immedial black with benzyl chloride in the presence of aqueous sodium sulphide leads to the production of several substances which are separated by successive extraction with carbon disulphide, chloroform, and phenol and chloroform (D. R. P. 131758).

The substance soluble in carbon disulphide has the empirical formula $C_{52}H_{40}O_2N_6S_8$, and is regarded as having the following constitution (I.)—



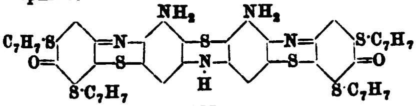
I.

A second product (II.), sparingly soluble in carbon disulphide, and extracted by chloroform, results from the foregoing by the elimination of ammonia.



II.

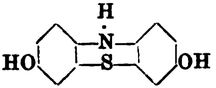
A third substance, insoluble in carbon disulphide and chloroform, is produced by eliminating ammonia from 2 molecules of the first product; and a fourth compound (III.), differing from the first in containing less sulphur and less nitrogen, has also been isolated, being sparingly soluble in chloroform, although insoluble in carbon disulphide.



III.

These results serve to indicate the relationship between the more complex sulphide blacks and the less condensed sulphide blues. They show, moreover, that in all probability the blacks are not homogeneous compounds, but mixtures of highly-condensed molecules (*cf.* Ris, Ber. 1900, 33, 796; D. R. P. 122850).

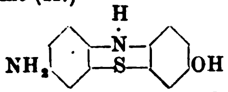
Vidal's earlier researches also point to the existence of thiazine rings in sulphide blacks (Mon. Scient. 11, 2, 655; 17, 427; D. R. P. 99039). On heating together quinol, sulphur, and ammonia, water and hydrogen sulphide were eliminated and leucothionol (I.) was produced



I.

which is also formed together with a large proportion of black colouring matter by heating *p*-aminophenol and sulphur, and is obtained in quantitative yield by heating molecular proportions of *p*-aminophenol and quinol with sulphur.

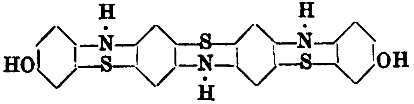
Quinol and *p*-phenylenediamine, when heated with sulphur, give water, hydrogen sulphide, and leucothionoline (II.)



II.

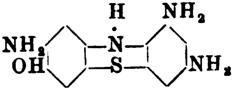
which on further heating with sulphur gives a black colouring matter.

Since leucothionol, on heating with sulphur and ammonia, also gives rise to a black dye, Vidal supposes that the black arises from a further condensation of leucothionol and leucothionoline to form dihydroxytetraphentrithiazine



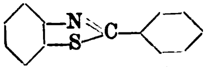
which he regards as being the essential constituent of Vidal black. This assumption does not, however, explain the characteristic mercaptan properties of the sulphide colours. It is evident that these colours must, in addition to the thiazine rings, contain mercaptan sulphur SH, or even polysulphide sulphur S_xSH in side chains.

2 : 4-Diaminophenol is readily converted by aqueous sodium polysulphide at 100° into diaminoleucothionoline



which is easily oxidised to the corresponding diaminothionoline, but without exhibiting any dyeing properties. When, however diaminophenol is heated with aqueous thiosulphate, it passes into complex thiosulphonic derivatives, dissolving in aqueous alkalis to blue solutions, and dyeing cotton in blue shades. In the second thionation of diaminophenol, sulphur is introduced into the side chain as well as into the thiazine ring. The processes for preparing Clayton black are further examples of this type of condensation (D. R. PP. 106036, 120504, 120560, 136016; Eng. Pats. 21832, 22460, 1898; Fr. Pat. 288465).

The yellow and brown sulphide dyes resemble dehydrothiotoluidine and primuline in containing the thiazole group



characteristic of the latter substances, and for this reason they are largely produced from tolylene-2 : 4-diamine, tolidine, and similar compounds containing carbon in side chains.

The sulphur of the thiazole ring is introduced by direct interaction of this element and the organic substance, giving rise to an insoluble coloured product which is rendered soluble by subsequent treatment with hot concentrated aqueous sodium sulphide. In the latter operation, mercaptan (hydrosulphide) groups are introduced into the molecule of the coloured substance, with the result that a true sulphide dye soluble in alkali sulphide solution is produced.

SULPHINE *v.* Primuline and its derivatives.

SULPHOCYANIDES or **THIOCYANATES** *v.* Cyanides.

SULPHONAL *diethylsulphonedimethylmethane* $(CH_3)_2C(SO_2C_2H_5)_2$ was first prepared by Baumann by treating dithioethyldimethyl methane or acetone mercaptol

$(CH_3)_2C(SC_2H_5)_2$

with 5 p.c. potassium permanganate solution (Ber. 1886, 19, 2808).

It may also be prepared by heating diethyl sulphone methylene methane $MeCH(SO_2C_2H_5)_2$ or diethylsulphonemethane $CH_2(SO_2C_2H_5)_2$ with alcoholic potash and methyl iodide (Fromm, Annalen, 1889, 253, 147).

Some difficulty is experienced in preparing an odourless product. According to Kobbe, it is easy to determine whether a preparation is odourless or not by boiling 1 grm. with about 10 c.c. of water in a test tube, when any remaining odour is easily detected (Kobbe, Pharm. Zeit. 1888, 730).

To isolate sulphonal from mixtures containing it, the mixture is evaporated to dryness, extracted 3 times with its own volume of 90 p.c. hot alcohol, the extract on cooling is filtered and the alcohol distilled off. The residue is filtered while still hot, a few drops of potash added to the filtrate and treated 3 times with 3 times its volume of ether. The ether is then evaporated, the residue is dissolved in water and again treated with ether; on evaporation pure sulphonal is left (Vitali, Boll. Chim. Farm. 39, 461, 497).

Sulphonal forms colourless, odourless, almost tasteless prismatic or elegant foliated crystals. It may be identified as follows: it melts at 125·5°, volatilises at 300°, dissolves in 15 parts of boiling water, and 500 parts of water at 15°; in 133 parts of ether at 15°; 2 parts of boiling alcohol, 65 parts of alcohol at 15°; and in 110 parts of 50 p.c. alcohol at 15°. 100 c.c. of benzene dissolve 8·01 grms., 100 c.c. of petroleum spirit 0·06 grms., and 100 c.c. of chloroform 32·5 grms. Toluene and acetone also dissolve considerable quantities of sulphonal. The sample should also be tested for sulphuric acid, potassium, and manganese. It is exceedingly inert towards all reagents, a characteristic property of the substance. Fused with potassium cyanide, it gives a smell of mercaptan. Mercaptan, according to Ritsert, may be formed by heating sulphonal with sodium-amalgam or pyrogallol. Fused with dry potash, a smell of mustard oil is evolved. Mercaptan is also formed by heating the substance with zinc chloride, sodium acetate, manganese dioxide, sodium amalgam, or with a fragment of charcoal; the white fumes which are at the same time given off turn litmus-paper red, and decolorise blue iodide of starch paper (J. Soc. Chem. Ind. 1888, 772; Kippenberger, Zeitsch. Nahr. Genussm. 1899, 2, 75). These tests, however, are said to be given by other compounds containing sulphur.

By the following method 0·001 grm. may be detected. When sulphonal is heated moderately with 3 times its weight of powdered potash, an unpleasant smell is developed, the liquid becoming first yellow, then red, it becomes scarlet on cooling and changes to blue on addition of water, the liquid becoming turbid. On filtering and adding hydrochloric acid to the filtrate, the latter becomes violet, sulphur dioxide is evolved and sulphur is precipitated. In the residue obtained by evaporating the acid solution to dryness, sulphate, hyposulphite and polysulphide may be detected in the usual way.

If the original mixture of sulphonal and potash be heated very strongly the red coloration changes to blue (Vitali, *l.c.*).

Sulphonal may be detected in trional and tetronal by treating the sample with ether in which sulphonal is much less soluble than the other two substances. The undissolved residue, if it contains sulphonal, can be detected by its m.p. 125·5°, its characteristic crystalline form and other reactions (Gabutti, J. Pharm. Chim. 1907, 25, 183).

Sulphonal is employed as a hypnotic, being intermediate in its action between chloral and paraldehyde and much safer than most drugs of its class as it does not depress the heart (Fischer, Pharm. Zeit. 33, 235).

Chlorsulphonal $CH_3(CH_2Cl)C(SO_2C_2H_5)_2$ forms white pearly crystals, m.p. 78°–79° (Autenrieth, Ber. 1891, 24, 171).

Nitrososulphonal $CH_3(CH_2{\cdot}NO)C(SO_2C_2H_5)_2$, rhombic tablets, has m.p. 104°–105° (Posner, *ibid.* 1899, 32, 1246).

Trimethylpiperidinediethylsulphonal

$$(C_2H_5SO_2)_2C{<}\begin{matrix}CH_2{\cdot}CH(CH_3)\\CH_2{\cdot}C(CH_3)_2\text{-}\end{matrix}{>}NH$$

is obtained by oxidising the corresponding mercaptol with potassium permanganate in dilute sulphuric acid (Pauly, *ibid.* 1898, 31, 3149). It forms lustrous feathery crystals, m.p. 135°.

Sulphonal carboxylic acids are described by Posner (Chem. Zeit. 1905, 29, 1107).

Compounds in which the C_2H_5 group is replaced by some other radicle are formed from the corresponding mercaptan by similar methods to those used for preparing sulphonal (Stuffer, Ber. 1890, 23, 3228) (*v.* KETONES, also SYNTHETIC DRUGS).

SULPHONATED OILS (Turkey-red Oils), *v.* OILS, FIXED, AND FATS.

SULPHONES $\begin{matrix}R\\R_1\end{matrix}{>}SO_2$ may be obtained by oxidising vigorously the thioethers, or the sulphoxides, or the sulphides (Beckmann, J. pr. Chem. [ii.] 17, 439; Baumann and Walter, Ber. 1893, 26, 1124); by washing an alcoholic solution of sodium sulphinate or sodium alkylsulphinate with alkyl or alkylene halides (Otto, Ber. 1880, 13, 1272; *ibid.* 1888, 21, 652, 658; Annalen, 1894, 283, 181; *ibid.* 1895, 284, 300; Michael and Palmer, Amer. Chem. J. 6, 253) by the action of sodium alkyl sulphinate or mercaptide on chloracetone thus:

$$CH_2Cl{\cdot}CO{\cdot}CH_3+SO_2PhNa$$
$$=NaCl+SO_2Ph{\cdot}CH_2{\cdot}CO{\cdot}CH_3$$

(Otto and Rössing, Ber. 1890, 23, 752); by the action of phosphoric anhydride at a high temperature on a mixture of an aromatic sulphonic acid and a hydrocarbon (Michael and Adair, *ibid.* 1877, 10, 583; *ibid.* 1878, 11, 116); by the interaction of an aromatic sulphochloride and a hydrocarbon in the presence of aluminium chloride $RSO_2Cl+R'H=HCl+RR'SO_2$ (Beckurts and Otto, *ibid.* 2066); by the interaction of aromatic sulphinic acids and halogen derivatives of aromatic nitro compounds (Ullmann and Pasdermadjian, Ber. 1901, 34, 1150); a sulphone of formula $C_6H_5SO_2C_{10}O_7$, m.p. 121°, has been obtained by heating benzene sulphonic chloride with naphthalene and zinc dust (Chrustschoff, Ber. 1874, 7, 1167) and di-*p*- and di-*o*-xylyl sulphones have been prepared by subjecting the well-cooled xylene to the action of sulphuric anhydride (Zorn and Brunnel, Compt. rend. 1894, 119, 1224).

For other methods, *see* Otto, Ber. 1885, 18, 154, 246; *ibid.* 1891, 24, 1832; Stuffer, *ibid.* 1890, 23, 3226; Damköhler, J. pr. Chem. [ii.] 30, 321; Genvresse, Bull. Soc. chim. 1894, [iii.] 11, 501; Eng. Pat. 16333; J. Soc. Chem. Ind. 1899, 980; Blanksma, Pr. K. Akad. Wetensch. Amsterdam, 1901, 4, 264; Posner, Ber. 1905, 38, 646.

The sulphones are isomeric with the organic alkyl sulphinates $R{\cdot}SO{\cdot}OR$, and form stable, neutral solid bodies not attacked by nascent hydrogen, hydrogen iodide, or by phosphorus pentachloride.

The sulphones of general formula $R_2C(SO_2R)_2$ are stable towards alkalis, but when one of the groups SO_2Ph, SO_2Et, or Cl is introduced, they are decomposed by alkalis, the three sulphone groups being eliminated as sulphinic acid (Autenrieth, Ber. 1891, 24, 1512; Stuffer, *ibid.* 1890, 23, 1408). Diphenyl sulphone, when heated with sulphur at 250°–275° in a current of carbon dioxide, yields diphenyl sulphide, but many other sulphones do not react thus (Böeseken, Rec. trav. chim. 1911, 30, 137).

Sulphones containing one benzyl and another aromatic residue react with formaldehyde yielding diformal derivatives, but the presence of two aromatic residues without a benzyl group, or a benzyl group without a second aromatic residue, hinder this reaction (Fromm and Erfurt, Ber. 1909, 42, 3823).

Some of the disulphones $R_2C(SO_2R)_2$ are employed in medicine (*v.* SULPHONAL, TRIONAL, TETRONAL). According to Baumann and Kast (Zeitsch. physiol. Chem. 14, 52; *ibid.* 1889, 15, 32; *see* also Laves, Arch. Pharm. 229, 448), the SO_2 group as such has no hypnotic effect and the sulphones containing the ethyl group are the most powerful, the methyl group having little or no effect.

But in the case of dimethyl sulphone dimethyl methane $Me_2C(SO_2Me)_2$, the replacement of the methyl by the ethyl group produces no alteration in physiological properties, whilst the propyl, and to a less extent the *iso*-propyl, increases the activity. On the other hand, the introduction of a carbonyl group as in 2:2-diethyl sulphone pentane-3-one

$$CMe(SO_2Et)_2COEt$$

destroys the hypnotic and all noxious properties (Hildebrandt, Chem. Zentr. 1905, ii. 502). The influence of other groups has also been studied by Hildebrandt.

SULPHONIC ACIDS $R{\cdot}SO_3H$. These acids may be conveniently described under two headings: (*a*) aliphatic sulphonic acids, (*b*) aromatic sulphonic acids.

Aliphatic sulphonic acids. These acids are not of much importance.

General methods of preparation. (i.) By the oxidation of mercaptans, alkyl disulphides, or alkyl thiocyanates with nitric acid.

(ii.) Their salts and esters are formed by the interaction of alkyl iodides with alkali sulphite and silver sulphite and the required alcohol respectively.

(iii.) By the oxidation of sulphinic acids.

Properties. They are mostly viscous liquids, readily soluble in water, and usually can be obtained crystalline. On heating they undergo decomposition; by fusion with caustic alkalis they are decomposed into alcohols and alkali sulphites, but they remain unchanged when boiled with aqueous alkali hydroxides. Phosphorus pentachloride converts them into sulphonic chlorides.

Aromatic sulphonic acids. These acids are easily obtained by digesting the substance to be sulphonated with sulphuric acid. The number of hydrogen atoms replaced depends on the strength of the acid and on the temperature. These acids are important as the source of many dyes; many dyes which are insoluble in water are converted into their sulphonic acids which are readily soluble. The aromatic sulphonic acids are also manufactured to be converted into phenols by fusion with caustic alkali. Many are also valuable as synthetic drugs (*q.v.*).

General methods of preparation. (i.) By digesting the substance with sulphuric or anhydrosulphuric acid; or with chlorosulphonic acid when the sulphonic chloride is produced.

(ii.) By the oxidation of thiophenols or of sulphinic acids.

(iii.) By heating diazoamino compounds with sulphurous acid.

Of these methods the first is the most important. It is often somewhat difficult to isolate the acids, as they are readily soluble in water, are non-volatile, cannot be extracted from aqueous solutions with organic solvents or separated from other substances by steam distillation. The following method is usually employed: excess of sulphuric acid is removed from the sulphonation product by boiling with excess of barium carbonate; the precipitated barium sulphate is filtered off, and to the filtrate which contains the barium salt of the sulphonic acid, sulphuric acid is added until precipitation no longer occurs. After filtering, the solution is evaporated to dryness when the acid is obtained either crystalline or as a syrup. Calcium carbonate may be used instead of barium carbonate, in which case, as the acid will contain a little calcium sulphate, alcohol is added to the final product, the calcium sulphate filtered off, and the alcohol removed by evaporation. Sometimes lead carbonate is employed, when the lead salt of the sulphonic acid is decomposed with hydrogen sulphide. These methods only apply when the barium, calcium, or lead salts are soluble in water.

When two or more sulphonic acids are present, separation is usually effected by fractional crystallisation of their salts. If this is not effectual, they are converted into sulphonic chlorides by means of phosphorus pentachloride. The sulphonic chlorides are well-defined crystalline substances, which can easily be obtained in a pure state.

Properties. The aromatic sulphonic acids are usually very soluble in water, and when obtained crystalline, are often very hygroscopic. They can be salted out from aqueous solutions as sodium salts by the addition of sodium chloride. They gradually decompose when heated, so seldom have a definite melting-point. They are strongly acid substances, decomposing carbonates and dissolving certain metals with evolution of hydrogen. The following are the principal reactions in which they take part:—

(i.) Phosphorus pentachloride or oxychloride converts their alkali salts into *sulphonic chlorides.*

(ii.) Fusion with caustic alkalis yields *phenols.*

(iii.) Distillation with potassium cyanide yields *nitriles.*

(iv.) *Hydrocarbons,* together with *phenyl sulphones,* are formed by distillation of the acids alone or with hydrochloric acid.

(v.) The sulphonic group may be replaced by the *nitro group* by the action of nitric acid.

(vi.) The sulphonic group may be replaced by the *amino group* by the action of sodamide.

(vii.) The sulphonic chlorides are converted into *thiophenols* on reduction.

SULPHUR. Sym. S. At.wt. 32·07. This substance has been known from the earliest times. Its ancient and familiar name of brimstone (A.S. *byrnan,* to burn, and *stane,* a stone, probably corrupted from *brinstone* or *brenstone,* *i.e.* fiery stone) is based upon the circumstance that it is combustible and that, when ignited, it will continue to burn in presence of air with a characteristic blue flame until it is entirely consumed. To the alchemists the term sulphur was practically synonymous with the principle of inflammability, and hence was not necessarily restricted, as now, to the element.

Sulphur occurs in the free state in the neighbourhood of volcanos, active and extinct, and is a characteristic product of volcanic action. Volcanic sulphur is found largely in Italy, Sicily, Iceland, Mexico, North and South America, Japan, Asia, New Zealand, and other parts of the world, and some of these places constitute valuable sources of supply.

Deposits of free sulphur occur in sedimentary rocks as a product of bacterial action, certain bacteria having the property of reducing sulphates and of assimilating sulphur to a relatively large extent. In union with a great variety of metals sulphur occurs as *sulphides,* and some of these compounds constitute important metalliferous ores. Combined with oxygen and bases, sulphur is found in nature as *gypsum, selenite* and *anhydrite* (calcium sulphate); as *heavy spar* (barium sulphate); as *celestine* (strontium sulphate); as *Epsom salts* and *kieserite* (magnesium sulphate), etc.

Sulphur is also found in nature combined with hydrogen, as *hydrogen sulphide* or *sulphuretted hydrogen,* and occasionally with carbon and oxygen as *carbon oxysulphide* in a number of mineral waters which are supposed to owe their therapeutic value to such sulphur compounds.

Sulphur is found unoxidised, but combined, in vegetable and animal tissues, in a variety of proteid substances; in the hair, nails and horn; in the taurin of the bile, in the cystine in urine, &c. Many volatile oils, *e.g.* oil of mustard, oil of garlic, &c., are composed of organic sulphur compounds to which their characteristic smell and other properties are due.

For many years past, and until the year 1903, about 95 p.c. of the world's supply of sulphur was mined and prepared for use in Sicily, the greater portion of the remainder being obtained from Romagna, in Italy, and from Japan. But the successful application of the Frasch process, a description of which follows, to the winning of pure sulphur at a low cost from deposits at Calcasieu Parish in Louisiana, U.S.A., long known but unworkable by ordinary mining methods, has resulted in a reduction at the end of 1912 of sales of Sicilian sulphur from the 95 p.c. per annum of the world's consumption above mentioned to about 50 p.c.

In the year 1900 the production in the United States was about 2000 tons. After the Frasch process was developed upon a practical scale during the year 1902 the production increased to 30,000 tons; in 1903, to 137,292 tons; and the production in 1913 is upwards of 300,000 tons per annum. All the requirements of the United States are met by Frasch sulphur with the exception of Japanese sulphur supplied to the western coast, and the imports from Sicily have fallen until they may now be regarded as negligible. The exports from the United States of Frasch sulphur have thus far not been developed to any great extent, but since 1905 about 30,000 tons have been sent annually from Louisiana to France. Having regard to the stocks now accumulated, to the vast tonnage of obtainable sulphur stated to be in sight, and to the extremely low cost of winning sulphur of great purity as compared with the methods employed in Sicily, it would appear that should it be considered desirable to extend the export trade of Frasch sulphur there is no reason why it should not be done upon a very large scale.

The Frasch process has proved to be applicable to the extraction of sulphur from the deposits in the dome formations of the Gulf Coastal-Plain regions, of which the deposits at Calcasieu in Louisiana constitute a portion. Other deposits have been located in this formation, and it is stated that a very important one in Texas at Bryan Hill, about forty miles from Galveston, is about to be worked upon a large scale by the Freeport Sulphur Company, and that a modification of the Frasch superheated steam process is to be employed.

Sulphur deposits in other parts of the world are now well known, and in addition to those already named may be mentioned those in the Caucasus, in Jebels Kabrit and Jemsah in Upper Egypt, and on White Island in New Zealand.

Japanese sulphur is of high purity and has a market to the extent of about 30,000 tons per annum. Of the total output, about 90 p.c. is obtained from the deposits which have been worked for many years in the volcanic district of Central Hokkaiedo. It is mainly shipped to the Pacific ports of the United States and to Australia. The sulphur is of what is known as the soltafara type and is deposited in cracks in the lava and in the tuffs owing to the interaction of sulphuretted hydrogen and sulphurous acid gases which have their origin in active or expiring volcanos.

Italian sulphur. Between 30,000 and 40,000 tons of sulphur are obtained per annum from deposits in Romagna which have long been worked. The sulphur thus obtained is almost exclusively employed in Italy for agricultural and viticultural purposes.

Sicilian sulphur is stated to have been employed in industry during the past 300 years. It is estimated that about 16,000,000 tons have been mined and extracted up to date, and until the introduction of Louisiana sulphur, extracted by the Frasch process, Sicily controlled the sulphur industry of the world.

The sulphur occurs in Miocene strata and constitutes what is known as the 'gypsum' type as distinct from the 'soltafara' type. Marls, shale and gypsum are prominent constituents of the sedimentary rocks in which the sulphur is produced. The reducing action of the bituminous matter under efficient conditions of temperature and pressure upon gypsum results in the formation of calcium sulphide, which in turn is acted upon by oxygen, carbonic acid and moisture, producing calcium carbonate, sulphuretted hydrogen and polysulphide of lime. The latter in turn yields calcium carbonate, sulphur and sulphuretted hydrogen. It is stated by Fuchs and De Launay (Traité des Gites Mineraux, p. 274) that 24 p.c. of sulphur would represent about the average that would be deposited as the result of these reactions, and inasmuch as this percentage may be taken as representing the average amount of crude sulphur found in Sicilian sulphur rock, it is regarded as a strong argument in favour of the sulphur being deposited in the manner suggested.

The mines are distributed throughout the provinces of Caltanisetta and Girgenti. They cover an area of about 100 miles by about 55 miles. The deposits of sulphur (*solfare*) vary in depth from 150 ft. to about 650 ft., and in the deep mines the ore is now all brought to the surface by mechanical means: in the past it was practically all dealt with by manual labour.

The ore varies very considerably in its total sulphur contents. The rich ore contains from 30 p.c. to 40 p.c. of crude sulphur, which, depending upon the method of extraction employed, yields from 20 p.c. to 25 p.c. of commercial sulphur. But the average ordinary ore contains from 20 p.c. to 25 p.c. and yields from 10 p.c. to 15 p.c. of commercial sulphur. In some ores the sulphur is as low as 8 p.c., but unless they contain about 15 p.c. they do not pay for working by the method adopted in Sicily.

In addition to the 16,000,000 tons which have been stated to have been mined, prepared and sold, it has been officially reported by a highly qualified engineer that the quantity of commercial sulphur still in sight in the Sicilian deposits amounts to about 34,000,000 tons.

The effect of the Louisiana sulphur competition upon Sicilian production may be strikingly illustrated by the fact that in the year 1903 there were 757 active sulphur mines in Sicily and that nearly 40,000 operatives were employed. To-day the number of mines being worked is about 400 and the number of operatives about 20,000.

It must be admitted that the methods of extracting sulphur employed in Sicily were not adapted to meet competition of a serious character, although it should be equally admitted that substantial progress has been made since the regenerative furnace has been brought to its present stage of development. Since 1850 the method mainly employed was to submit the ore containing not less than 15 p.c. of sulphur to combustion, the necessary fuel being mainly provided by the sulphur itself, about one-quarter of which was thus consumed. When this process is employed the ore is massed in large quantity in circular heaps of about 60 ft. diameter and about 9 ft. deep. The heaps are coated externally with moistened ash obtained from the burnt ore. Each heap is provided internally with a sloping floor fitted with compartments in which the fused sulphur produced by the heating collects and from which it is subsequently recovered in the form of loaves weighing about one hundredweight each. The heaps thus prepared are known as *calcaroni*. The process is started by charging in wood fuel from the top of the heap and setting fire to it, and this heat is maintained by means of lighted wood. By this process the loss of sulphur by combustion is so considerable that the yield of sulphur obtainable as loaves is only about 60 p.c. of the total sulphur contained in the ore. In addition to the large loss of sulphur thus occasioned, the pollution of the atmosphere is very great, and where the *calcaroni* system has been worked upon a continuous large scale, much damage has been caused to the trees and plants in the surrounding country.

In 1880 Robert Gill introduced his regenerative furnace into Sicily, and it has since been improved and developed very considerably. The object of its construction was to effect the easy regulation of the combustion and to provide a continuous process. In order to effect this, two large square brick furnace chambers, provided with double floors on which the molten sulphur collects and subsequently cools and solidifies, are independently connected with a chimney stack, and the heating of the chambers is so regulated that when the ore has been treated in one chamber the heating of the other chamber is at once started, and therefore the process becomes continuous. But still greater improvements have been effected by the provision of as many as six large circular chambers connected with the chimney instead of the two square chambers above-mentioned, and these have been still further improved by combustion air regulating devices which are found in the Sanfilippo furnaces now mainly employed in Sicily. By this method the extraction of sulphur from the ore can be effected up to about 80 p.c., a very great advance upon the yield obtainable from the *calcaroni*, which have now been substantially superseded.

Serious attempts have also been made in Sicily to extract sulphur by means of superheated steam under pressure, and in this way it has been found possible to obtain a yield of sulphur as high as 90 p.c. of that present in the ore. But steam extraction, although successfully applied in Romagna, would not appear to be practicable upon a large industrial scale in Sicily owing to the cost of fuel and the losses occasioned when much gypsum is present, as is often the case.

It is difficult to arrive at an absolutely accurate figure as regards the present cost of sulphur production in Sicily, but it would appear that the position may be fairly summed up by stating it at 40*s*. per long ton, and this is probably placing the figure too low. This price of Sicilian sulphur production must undoubtedly be carefully taken into consideration when making a comparison between the future industrial possibilities of Sicilian sulphur and those of other deposits which have been referred to.

The commercial crude Sicilian sulphur, which constitutes a very large proportion of the island sulphur trade, contains impurity ranging in amount from about 2 p.c. to about

11 p.c. It is known as *Greggio*, and its price varies according to the amount of impurity. Thus it is graded as 'Best Unmixed Seconds,' 'Best Unmixed Thirds,' and 'Current Thirds.' These three qualities practically represent the entire Sicilian brimstone trade. The difference in price between the best and worst qualities is about 5*s.* per ton, and if pure sulphur be required it is prepared by refining and as a result the impurity of the commercial refined product is reduced to about one-half p.c. It is then sold as *Raffinate*.

In its preparation the crude sulphur is subjected to sublimation and one of two different kinds of product may be prepared. If the temperature of the condensing chamber is kept well above 100°C. then the molten sulphur is allowed to flow into moulds and when solidified is sold as refined sulphur. If the temperature is kept below 100°C. then flowers of sulphur are formed, for which there is a very considerable industrial demand. When sulphur is used for application to vines, the crude sulphur is ground so as to pass through fine mesh sieves, or it may be preferably winnowed by means of compressed air. When thus treated the sulphur is found to adhere to the foliage of the vine, whereas if it be sublimated and condensed it will not satisfactorily adhere.

The history of the Sicilian sulphur industry is characterised by the remarkable changes to which it has been subjected. Previous to the year 1838, sulphuric acid, wherever manufactured, was made from brimstone, and the supply came practically from Sicily only. It is thus apparent that the alkali industry was, to a great extent, dependent upon the price charged for brimstone and that the fixing of that price was in the hands of those who controlled the Sicilian industry. This having been duly recognised in Great Britain, attempts were made to employ pyrites as the source of sulphur instead of brimstone, and in 1813 a patent was granted to Hill, of Deptford, in connection with this application. But Sicily continued to hold the sulphuric acid raw material trade until the year 1838, when a monopoly was granted by the King of Naples for the export of Sicilian sulphur to M. M. Taix & Cie., of Marseilles. The result of this monopoly grant was to raise the price of brimstone from £5 to about £14 per ton. The immediate answer of Great Britain was that much work was done and many patents were taken out in connection with the application of pyrites to the manufacture of sulphuric acid, and shortly afterwards a large industrial plant was successfully installed by Thomas Farmer of London. As a result, brimstone was speedily replaced by pyrites, and Sicily lost nearly the whole of this trade. A certain proportion of the world's supply of sulphuric acid is, however, still made from brimstone, owing to the fact that brimstone made acid is free from arsenic, and as such is suitable for the preparation of sulphuric acid used in the preparation of products connected with food and pharmacy. Notwithstanding that the arsenic can be efficiently removed from sulphuric acid made from pyrites, brimstone is still preferably employed in this connection.

In order to meet the competition occasioned by the successful application of the Frasch process to the winning of sulphur in Louisiana, Professor G. Oddo proposed the employment of 'smalls' (*sterro*), which constitute about 20 p.c. of the Sicilian sulphur ore, for the production of sulphuric acid by means of the Herreshoff furnace. A large-scale plant was erected and worked, and it is claimed that successful results were achieved. Owing, however, to the very small percentage of sulphur contained in the 'smalls,' as compared with that contained in pyrites employed in industry, it was found that the cost of carriage would render the export of *sterro* to other countries impossible, and that the only chance of success was to start a sulphuric acid industry upon a very large scale in Sicily. This, however, has not yet been attempted.

The industry was not only damaged as regards the sulphuric acid industry by the rise in price of sulphur to £14 per ton as abovementioned, but as might have been expected, great harm was done in other directions. As a result, the monopoly was in due course withdrawn and the price of £5 per ton re-established. Excepting the use of sulphur in the manufacture of sulphuric acid, all went smoothly as regards the world's supply until the Chance-Claus process for the recovery of sulphur from alkali waste became a success. From about 1891 to 1896, it was stated and believed that this process could not only be applied to the waste then being produced in the alkali industry, but also to the recovery of sulphur from the waste upon tip heaps which had been accumulating for many years past. Had this been possible, the vast quantity of sulphur recoverable would undoubtedly have revolutionised the sulphur industry of the world. Advantage was taken of the possibility to cause internal competition amongst the producers in Sicily, with the result that the market was completely disorganised and wages were reduced almost to starvation rates. This depression of prices reacted in turn upon the price of the Chance-Claus sulphur produced in England. In due course it was ascertained that it was not possible to extract the sulphur from the tip heaps waste, owing to the change it had undergone through oxidation, and it being known that the amount produced from fresh waste would not exceed 50,000 tons per annum, and therefore could not affect the Sicilian market, the price was fixed by speculators at about £5 10*s.* per ton. This action was resented by the consumers, who took the necessary steps to start a keen fight, not only between the producers in Sicily but also in Great Britain, with the result that the selling price of brimstone was reduced to 45*s.* per ton, out of which had to be paid the export tax of 8*s.* per ton. This state of affairs continued for some time, until 1896, when Sicily was on the verge of revolution as well as ruin.

It was then that efforts, initiated in England, were made to combine the Sicilian and British interests and to regulate the trade of the world, so that the price could no longer be dictated by speculators. At the same time, steps were taken to remedy the serious grievances of the Sicilian workmen and owners of mines. The movement, which resulted in the formation of the Anglo-Sicilian Sulphur Company, was heartily supported by the Italian Government and notably by the Marquis di Rudini, then Prime

Minister in Italy, with the result that the capital for the organisation of the business having been obtained mainly in England, a Royal Decree was then issued, and subsequently confirmed by a special Act of Parliament by which the heavy export tax was abolished, wages of the workmen increased, child labour, previously employed to a very large extent, was abolished, income tax and other heavy charges were withdrawn, and a tax of one lire per ton on sulphur exported was substituted. The bulk of the stock both in Sicily and England was taken over at an agreed and reasonable price, and an agreement was also made whereby about 65*s.* per ton would be paid to the producer in Sicily, and the production should be regulated so as to keep in touch with the quantity exported. The capital of the company was one million sterling, of which £735,000 was fully subscribed.

The formation of this company resulted in the maintenance of fair and satisfactory prices for sulphur, and of peace and prosperity for Sicily for a period of about ten years. Both buyers and sellers were satisfied with the conditions under which the company's business was carried on, and the variations of selling price during the ten years did not amount to more than 5*s.* per ton.

The contracts which the company made with the producers and the stock of sulphur which it acquired when it was formed gave it a control over about 75 p.c. of the total production of Sicily, and this led to the complete control of the market. The company also had the right under its contracts to call for a reduction of 18 p.c. of the output in any year in which the output should exceed the sale. But the producers were also entitled to be paid 1 p.c. extra for each 3 p.c. reduction in the price of sale. The company was only interested in the sale of sulphur and was in no way financially interested in the mining or in the process of production. It may be stated that the operations of the company were quite successful to all interested, and it would undoubtedly have continued to exist and to prosper but for the unexpected competition caused by the successful development of the Frasch process. It succeeded in obtaining a fair but not excessive market price for sulphur all over the world. For instance, in May, 1896, just previous to the formation of the company, the price of 'seconds' in New York was about 63*s.* per ton. In October of the same year, after the company had started operations, the selling price of the same quality was 104*s.* per ton.

The stock acquired by the company was about 60,000 tons, which, as representing about 70 p.c. of the industry of Sicily, was to be regarded as quite a satisfactory quantity. During the first eight years of the company's existence, no complications of any kind were experienced, but during the year 1904, the Frasch process was proved to be an industrial success, and the United States sulphur sales were from that time gradually taken away from the Anglo-Sicilian Sulphur Company. As a result, the company in July, 1906, exercised its option of terminating its agreement with the producers and was in due course liquidated with results which were completely satisfactory to the shareholders. The effect of competition with Louisiana sulphur will be appreciated when it is stated that the stock of the Anglo-Sicilian Sulphur Company, when it terminated its contracts, amounted to no less than 360,000 tons, and at the end of June, 1912, the stock of sulphur in Sicily amounted to no less than 546,902 tons. This had been reduced by the end of January, 1913, by limiting production, to 441,775 tons.

The Italian Government found it necessary again to support the sulphur industry when the Anglo-Sicilian Company was about to be liquidated, and with its assistance the stock of the company, amounting to 360,000 tons, was purchased at 49*s.* 2*d.* per ton, and was paid in Government debentures yielding 3·65 p.c. interest per annum redeemable in twelve years. The industry was placed, as from the 1st August, 1906, under the direction of the 'Consorzio obligatorio per l'Industria Solfifera Siciliana,' which was charged with the sale and regulation of the production of Sicilian sulphur for a period of twelve years. The Consorzio was assisted by the Government so as to be provided with sufficient capital to permit of its paying four-fifths of the selling value in advance to the producer for delivered crude sulphur, and also had full power to limit production. Sulphur was exempted from all taxation.

Considering the difficulties that have had to be faced as a result of the displacement of Sicilian output by Frasch sulphur, it may be stated that the Consorzio has constituted a successful organisation. Some modifications of the law relating to it were passed in Parliament in the years 1907, 1908, and 1909, by means of which the number of directors was reduced and full powers were given to restrict the output from the mines to the quantity sold for export. The result has been a very great reduction in the stocks now held in Sicily as above mentioned.

Louisiana sulphur. The deposits from which this sulphur is obtained are geologically associated with 'Dome Formations,' which constitute a striking feature of the coastal plains which extend through the States of Louisiana and Texas and the Gulf States of Mexico. Petroleum and rock salt of remarkable purity (98–99 p.c.) are also found in these formations in abundant quantity. The oil was first exploited, and it was when oil drilling was being carried out by the Louisiana Oil Company, in the year 1865, at the head of Bayou Choupique, about fifteen miles west of Lake Charles, that the first sulphur bed was found at a depth of 443 ft. It was proved that this sulphur bed had a depth of about 100 ft. Further detailed examination showed that the sulphur deposits have an average overburden of about 464 ft., consisting of about 376 ft. of clay and sands (pleistocene), quicksand and gravels (Port Hudson and Orange sand groups), and about 88 ft. of soft rock, mainly grey limestone. The average depth of the sulphur bed is 125 ft. Beneath the sulphur is gypsum with occasional layers of sulphur.

Between the years 1868 and 1895 many attempts were made to win the sulphur by ordinary shaft mining and by modifications of the same. They all resulted in hopeless failure, loss of many lives and great loss of capital. Among the companies formed for the purpose of mining the sulphur may be mentioned the

Calcasieu Sulphur and Mining Company, the Louisiana Sulphur Mining Company, the American Sulphur Company, a French company which spent £300,000 upon a scheme for the employment of machinery specially devised for overcoming the difficulties, and an Austrian company. These difficulties were mainly twofold: to resist the lateral pressure upon the shaft due to the enormous amount of moving water contained in the quicksands, and to prevent the inrush of the sand waters into the sulphur bed, when it had been penetrated, owing to the fact that there was no roof over the sulphur bed. These waters were found to be permeated with sulphuretted hydrogen and sulphurous acid gas which proved fatal to the miners. In 1893, E. P. Rothwell, acting as manager to a New York company, sought to overcome the difficulty by lining the shaft with two cast-iron tubes cemented together. The lateral pressure was thus withstood and the sulphur bed was reached, but the inrush of gases again proved fatal to the workmen and the scheme had to be abandoned.

It will be seen that during no less than thirty years, successive attempts were made to win sulphur from what were proved by borings to be vast deposits, but ordinary mining operations were found to be absolutely impracticable.

The Frasch process. This may fairly be described as one of the triumphs of modern technology, and the result of its successful development has been to provide a great industry for the United States, which it did not previously possess, and to remove from Sicily to that country the domination of the conditions regulating the world's supply of sulphur.

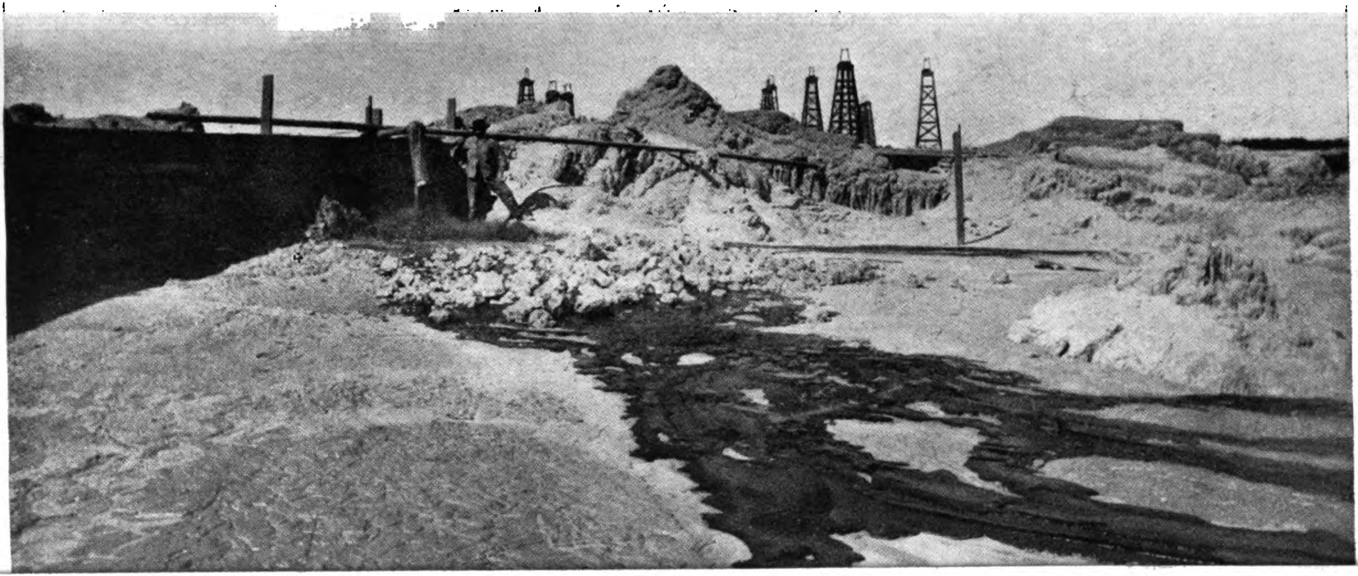
Herman Frasch, who had long been engaged in industrial research work in the United States in connection with petroleum drilling and refining, heard in 1891 of the difficulties connected with the mining of Louisiana sulphur, as above described. As a result of prolonged study, he arrived at the conclusion that the ordinary mining methods were inapplicable, but that the problem could be solved provided he could introduce superheated water into the sulphur bed through a tube passing through the quicksands at a temperature at or above the melting-point of sulphur and then raise the molten sulphur through another tube to the surface. The molten sulphur would then solidify on cooling at the surface, and the sulphur thus obtained would necessarily be of high purity. To succeed with this scheme meant not only to overcome the difficulties in connection with lateral pressure upon the tubes already alluded to, not only to introduce the superheated water to the sulphur about 500 ft. below the surface at the required temperature, but, recognising that a pool or well of melted sulphur would be formed below the bottom of the tube by this superheated water, it would be necessary to raise this molten sulphur from the pool or well to the surface before it could be cooled below melting-point by the incoming water from the quicksands.

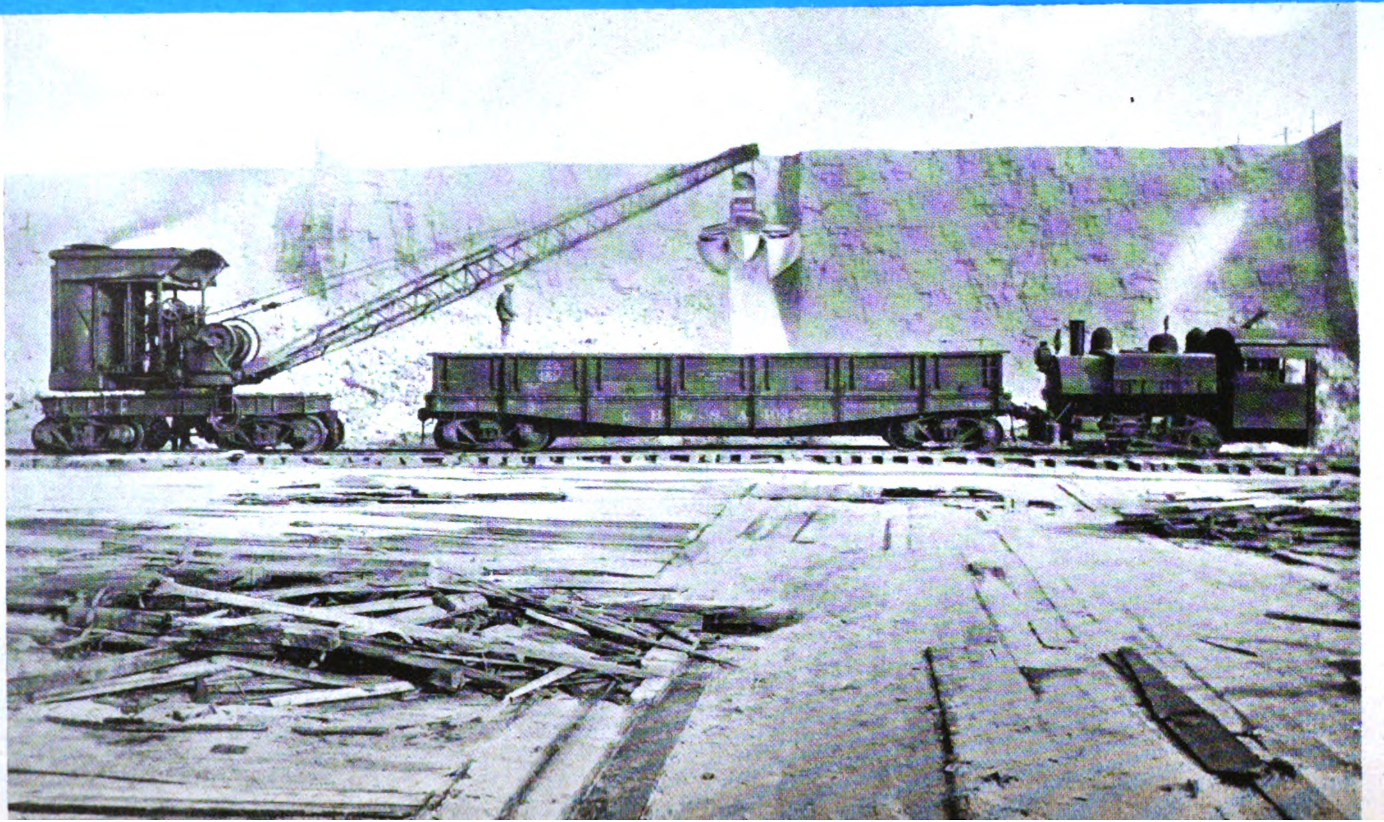
He and his associates purchased land within a short distance of the sulphur mine then being worked by the New York Company. He drilled four wells to a depth of 2000 ft. each and found no sulphur. He concluded that the New York company's property was located where the sulphur was concentrated in bulk, and in conjunction with his associates he acquired this property in the name of the Union Sulphur Company of Cleveland, Ohio. It consisted of a flat lying area of 5000 acres, situated near the parish of Calcasieu, Louisiana, 80 miles from Port Arthur, Texas, on the Gulf of Mexico, and 228 miles from New Orleans. The property is about 50 miles east of the great Texas oil field at Beaumont and is geologically the eastern extension of that field. As a result of many trial drills it is estimated that the Louisiana deposits contain not less than 40 million tons of sulphur, and that it would be a conservative estimate to conclude that not less than half this quantity can be brought to the surface by the Frasch process.

As may be imagined, many difficulties were encountered in working out the process, and it was not until the year 1903, when 35,000 tons of sulphur were brought to the surface, that success may be said to have been achieved. The chief trouble arose in connection with the pumping up of the molten sulphur, mainly due to the breaking down of the valves owing to corrosion. Zinc and aluminium valves were respectively tried, but were found incapable of standing the strain. Ultimately, pumping was replaced by an 'air lift,' by means of which the molten sulphur is forced through a tube to the surface. An additional advantage resulting from the use of the compressed air is that the specific gravity of the mixture of air and sulphur which is raised is lower than that of molten sulphur by itself, and hence the strain upon the great length of piping is reduced. The mixture employed is two parts by volume of air to one part of molten sulphur.

The following may be regarded as a substantial description of the process as worked: A well, 17 ins. in diameter, is bored to a depth of some 50 ft. This is not provided with a casing, but a mixture of clay and water is pumped down with a view to fill up the interstices in the sand, whereby caving is greatly reduced. Within this well a wrought-iron pipe, 13 ins. in diameter, is sunk to a variable depth, dependent upon outside pressure, and sometimes it can be arranged to reach the bottom of the quicksands at about 250 ft. A mixture of clay and water is also employed in connection with this pipe, and in addition to helping to support the walls it materially facilitates the withdrawal of the pipe when the well is exhausted, thereby effecting a considerable economy in the working of the process.

Inside this 13-inch diameter pipe, an 8-inch diameter pipe is driven to the bottom of the sulphur bed. Water and clay are also used. Those sections of this pipe which are intended to be in the sulphur bed are perforated with holes of half an inch diameter, arranged in spiral form, the holes being six inches apart. This arrangement has for its object to prevent gypsum, &c., getting to the bottom of the pipe. The superheated water, which is conveyed through this pipe to the sulphur bed, has free access to the sulphur throughout the entire thickness of the deposit, and any substance which should by chance get into the bottom of the pipe causes no trouble. Inside the 8-inch diameter pipe, an unperforated 6-inch diameter





pipe is sunk to the bottom of the sulphur bed. Superheated water is also pumped down this pipe. Enclosed in this 6-inch pipe is an unperforated 3-inch diameter pipe, through which the molten sulphur is raised to the surface. Inside this 3-inch pipe is driven to the bottom of the bed a 1-inch diameter unperforated pipe through which the compressed air is forced.

Superheated water is pumped down the 8-inch and 6-inch pipes. The water from the 8-inch pipe melts the sulphur which (sp.gr. 2·06) sinks down alongside the pipe to the bottom of the sulphur bed. The water in the 6-inch pipe mainly serves to keep the sulphur hot in the enclosed 3-inch pipe, thereby preventing crystallisation on its way to the surface. Compressed air, at a pressure of 250 lbs. per square inch, is forced down the 1-inch pipe to raise the sulphur by the 'air lift.' This pressure is found sufficient in practice to raise the sulphur to the surface, as the air is helped by the head of water in the 6-inch and 8-inch pipes to overcome the weight of sulphur in the 3-inch pipe.

One of the most important features of the process—indeed, that upon which successful working mainly depends—is the maintenance of a proper adjustment between the pressure of the superheated water and the air pressure so as to allow of the uninterrupted flow of sulphur through the 3-inch pipe. If the air pressure be too great, the liquid sulphur is kept away from the 3-inch pipe and superheated water gains entrance to it. When the water and the molten sulphur come into contact, the sulphur granulates, subsequently causing clogging in its upward path. As a result there is irregular discharge of the sulphur, and this means such great local pressure in the pipe that serious breakage is apt to occur. It has been found advisable, in this connection, to so adjust the respective lengths of the pipes that the 8-inch and 6-inch pipes are a few inches shorter than the 3-inch and 1-inch pipes as they stand in the well. What is aimed at is to have a constant pool of sulphur surrounding the bottom of the 3-inch pipe.

It has been found advisable to introduce sawdust with the superheated water once the pool of liquid sulphur has been formed. It is found that this prevents to a very great extent the flow of quicksand water into the pool with consequent lowering of temperature. When the well is exhausted, before the withdrawal of the 8-inch pipe, it is now usual to replace with earth the space of the extracted sulphur and thus prevent subsequent subsidence of the earth as much as possible. In order to obtain the sandy earth necessary for this purpose, the Union Sulphur Company have provided a dredging plant in the vicinity of their works with a capacity of 4000 cubic yards per day. Notwithstanding this precaution, considerable subsidence is stated to have taken place.

It is obvious that in working this process so as to produce a yield of, say, 250,000 tons of sulphur per annum, an enormous supply of water is necessary. It is stated that the average daily consumption is about 7,000,000 gallons. To provide for this, the Union Sulphur Company have constructed a pumping station on a river about six miles from the works, to which the water is conveyed by means of a canal; as a standby there is also provided at the works a reservoir covering 150 acres.

To supply the necessary heat and power, the latter constituting only a fractional percentage, it is found that each well requires a battery of 15 or 20 boilers of 50 h.p. each. Steam pressure runs at about 100 lbs. The total boiler capacity at present installed is stated to be about 25,000 h.p. Crude oil is used as fuel and its local availability and cheapness have undoubtedly largely contributed to the successful working of the Frasch process. There are two oil burners to each boiler. It is stated that the present daily consumption of crude oil is about 700 barrels at each battery, and that the average annual consumption is upwards of 1,000,000 barrels.

The boilers supply steam to six heaters, each 15 ft. high and 3 ft. in diameter. Two direct acting horizontal pumps, working under a stroke of 38 to 40 per minute, supply each heater with the necessary water at a temperature of 140°F. (C. = 60°). The steam enters the heaters at the top and the water at the bottom, and the superheated water leaves the heater at a temperature varying from 340°F. (C. = 171·1°) to 360°F. (C. = 182·2°) under an absolute pressure of 104 lbs. to 140 lbs. The water is conducted to the well by means of insulated pipes. The melting-point of sulphur is 239°F. (C. = 115°), and at a temperature slightly below this it will granulate.

It has been estimated that of the total heat units employed, 0·5 p.c. only are utilised in melting the sulphur. The temperature of the quicksand water, of which there is a great influx to the sulphur bed during the operation of the process, is low and has to be raised before the sulphur can be melted. The well gives out when the cavity from which the sulphur has been extracted becomes too large to permit of the necessary temperature being maintained.

Each well is driven by the ordinary oil-well driller mounted on a derrick from 75 ft. to 100 ft. high; five men generally constitute the drill gang. The average time required for drilling the well may be said to be between three and four weeks. The speed of drilling naturally varies with the nature of the material to be passed through, but it is stated to average 80 ft. per day through the quicksand, from 5 ft. to 8 ft. per day through the limestone rock, and 20 ft. to 30 ft. per day through the sulphur.

The average cost of sinking each well, exclusive of pipes, is stated to be about £400, and the expense of working the well during its life, including oil, labour, depreciation, &c., will average about £2000 more. The wells are sunk in groups, the wells being placed from 50 to 100 ft. apart. The output from a well is obviously liable to considerable variation. It is stated that as much as 73,000 tons of sulphur were obtained from one well. This is undoubtedly exceptional, but a good idea of the output may be obtained from the statement that as much as between 400 tons and 500 tons have been produced per well per day during some months. The total annual production is restricted to meet the world's demand, in conjunction with other sources of supply, but the average is now not less than 250,000 tons per annum.

On reaching the surface the sulphur is

conducted through a pipe supported on a light framework to a bin roughly constructed of beams in which it quickly solidifies. At the early stages of working these bins were divided into compartments into which the sulphur was allowed to flow until it had acquired a depth of 9 ins., when the flow was diverted to another compartment, so as to permit of the cooling of the collected 9 ins. After solidification, another 9 ins. of sulphur was allowed to flow in, and the bin was by this method finally filled up. The bins as now used are about 150 ft. by 250 ft. and about 65 ft. high. The sulphur is delivered into the centre of these bins and caused to spread in layers about 1 in. thick. By this method of working, the cooling is sufficiently rapid to permit of continuous operation. As much as 150,000 tons of sulphur have thus been accumulated in one series of bins.

From 600 to 700 men are employed in winning and despatching the sulphur, and, having regard to the quantity dealt with, this is a notable proof of the up-to-date character of the labour-saving methods adopted. A comparison of these figures with the labour employed for the Sicilian output is vastly in favour of the Frasch process. Further, if the total cost of obtaining the sulphur be considered, it is obvious that commercial competition by Sicily with Louisiana would be impossible, but the supply of the world's consumption from the respective sulphur-producing countries is now said to be regulated by arrangement, so that Sicilian sulphur is able to realise a reasonable profit.

In order to remove the sulphur from the bins to the railway trucks, the wooden hoarding is removed and blasting applied to the bottom of the sulphur. In this way the sulphur on being shot down by the blasting is so broken up that it can be picked up by grab buckets, which, by means of cranes, discharge it into wagons at such a speed that a 35-ton wagon can be filled in about 14 minutes. It is stated that as much as 1000 tons per day have thus been loaded for periods of 20 to 30 consecutive days.

For some considerable time after the process was started, the sulphur was conveyed by rail to New Orleans, about 228 miles distant. This was superseded by the construction of a special line, 68 miles in length, to Port Sabine, Texas. The cost of transport to New York has, in this way, been reduced to about one-third of what it previously was. The loading on to ships at Sabine is effected by mechanical arrangements, thereby reducing the cost to one-tenth of what it used to be at New Orleans, and it is stated that the sulphur can be evenly loaded on to the ships at the rate of 600 to 800 tons per hour. The company owns ships specially constructed for sulphur transport, and one of them will carry 5500 tons.

The stocks of Louisiana sulphur in the United States, France, and Hamburg may be said to amount to fully 400,000 tons.

The sulphur obtained by the Frasch process is of a very high degree of purity, from 99·93 p.c. to 99·98 p.c., and in addition only contains a trace of water. The process is only applicable when the deposit is especially rich in sulphur—say, between 60 p.c. and 70 p.c.—and for this reason, amongst others, it is not available for use in Sicily.

Up to the present, the Louisiana deposit owned by the Union Sulphur Company practically supplies all the sulphur obtained in the United States. Endeavours have been made, and are still being made, to locate other deposits in the same geological formations and to organise their development.

In recognition of the work involved in devising and industrially working out this process, Herman Frasch was, in December, 1911, awarded the Perkin medal of the Society of Chemical Industry.

F. Lucas, p. 140; Sulphur Mines of the Union Sulphur Company in Louisiana, by F. H. Pough, p. 143.

From alkali waste. The recovery of sulphur, as such, from the calcium sulphide contained in alkali waste, a by-product of the Leblanc process, and the conversion of the calcium, with which it was previously combined, into an industrially available product, was taken in hand by several recognised leaders of the alkali industry. But it required about fifty years of almost continuous work before commercial success was achieved.

In 1837 Gossage devised a process at the development of which he worked for many years. It was based upon the decomposition of the calcium sulphide by means of carbon dioxide obtained from lime-kiln working, and the subsequent recovery of the sulphur from the sulphuretted hydrogen gas thereby generated. But although his labours undoubtedly contributed largely to the ultimate solution of the problem, he was unable himself economically to produce either sulphur or sulphuric acid, due to his failing to overcome the difficulties connected with the state of extreme dilution, and also the very variable strength of the sulphuretted hydrogen generated.

Ludwig Mond in England and Mactear in Scotland worked upon similar lines, but their respective processes, though ingenious and theoretically sound, also failed to produce commercially applicable results.

Schäffner and Helbig (Eng. Pat. March, 1878) worked out a process at Aussig in Saxon Switzerland, based upon the following operations:—

1. The decomposition of alkali waste by heating it with a solution of magnesium chloride

$$CaS+MgCl_2+2H_2O=CaCl_2+Mg(OH)_2+H_2S$$

The magnesium hydroxide thus produced was found to be held in suspension by the calcium chloride.

2. Magnesium chloride was reformed by acting upon the suspended magnesium hydroxide with carbon dioxide, and the calcium chloride converted into carbonate of lime available for industrial use

$$CaCl_2+Mg(OH)_2+CO_2=MgCl_2+CaCO_3+H_2O$$

It was subsequently found by Frederick Chance that in this reaction, the average loss of magnesium choride (calculated as magnesium) amounted to 1·05 parts per 100 parts of alkali waste operated upon.

3. The sulphuretted hydrogen gas liberated was treated for sulphur production with a view to effect the reaction

$$2H_2S+SO_2=2H_2O+3S$$

This had been previously attempted, but no satisfactory yield could be obtained owing to the formation of thionic acids (Debus, Chem. Soc. Trans. 53, 278).

This formation Schäffner and Helbig endeavoured to prevent by causing the gases to react in the presence of a definite quantity of calcium chloride or magnesium chloride. By their process the necessary sulphur dioxide was obtained by burning one-third of the H_2S into SO_2 and steam, and this mixture was passed, together with the remaining two-thirds of the H_2S, up a tower filled with blocks of wood over and down which a solution of calcium chloride was caused continuously to trickle. The latter on issuing from the tower contained the free sulphur in suspension and it was subsequently recovered.

This process, although a great improvement upon what had previously been achieved, did not entirely prevent the formation of thionic acids. Indeed, it was stated by Weldon that such formation amounted to nearly 10 p.c. of the total sulphur present, and that the maximum yield of free sulphur amounted to a very little over 80 p.c.

The process was taken in hand by A. M. Chance and his colleagues at their works at Oldbury and two years of experimental trials were devoted to it. As a result, it was proved that the production of sulphur, as such, by this process, did not constitute a commercial proposition owing to low yield, &c., but it was also proved that by burning all the sulphuretted hydrogen gas into sulphur dioxide it was possible to produce sulphuric acid at a price corresponding to 3*d*. per unit of sulphur per ton of Spanish pyrites, whereas the price had been previously maintained at 6*d*. per unit. The process was industrially worked for some little time, but had to be stopped when the Tharsis Company reduced their price of pyrites to 3*d*. per unit and made contracts with alkali makers at this price extending over a period of years.

Undaunted by this reverse, Chance continued his work, and with the able assistance of H. W. Crowther and others he succeeded, four years later, in 1887, in producing sulphur at a price which permitted of competition with Sicilian brimstone. There can be no doubt that the adoption of this process by the Leblanc alkali makers was very largely responsible for their being able to continue the Leblanc as opposed to the Solvay ammonia soda process, and thereby avoid the scrapping of plant involving huge loss of capital. The process has been worked continuously since its introduction and is still employed by the Leblanc alkali makers. It is difficult to obtain accurate data as to the quantity of sulphur which has been thus produced, but from trustworthy information it may be stated that the minimum output has been about 35,000 tons per annum, mainly manufactured in Great Britain, and that therefore since the installation of the process it has yielded a minimum production of about 840,000 tons of sulphur.

The process, known as the Chance-Claus process, is based upon the lines followed by Gossage, of decomposing the calcium sulphide of vat waste by means of the carbon dioxide obtained from lime kilns and of recovering the sulphur from the sulphuretted hydrogen gas thus generated. But one of the essential features of success was to obtain both the carbon dioxide and the sulphuretted hydrogen gas in a state of concentration.

It had previously been found impossible to obtain lime-kiln gases containing more than an average of 30 p.c. of carbon dioxide, the remaining 70 p.c. consisting essentially of nitrogen. The presence of this latter obviously caused the dilution of the sulphuretted hydrogen and to such an extent that the economic production of sulphur was impossible. It was further found that the amount of sulphuretted hydrogen varied from 1 p.c. of the total gases up to not exceeding 35 p.c.

Chance succeeded in obtaining a constant yield of sulphuretted hydrogen of very high strength (Eng. Pat. 8666, 1887). This was effected by employing a series of communicating vessels provided with inlet and outlet mains. The vessels contained the alkali waste mixed with water in the form of cream to which a given proportion of caustic lime was, if necessary, added. The lime kiln gases, on being passed into the first vessel of the series, give up the carbon dioxide to the free lime present, forming calcium carbonate, and the sulphuretted hydrogen together with the nitrogen is passed on into the next vessel of the series. The sulphuretted hydrogen is then absorbed, calcium hydrosulphide (CaH_2S_2) being formed. This process of absorption is continued throughout the series, and as finally worked out acts so efficiently that the gas issuing from the last vessel contains only traces of sulphuretted hydrogen and carbon dioxide, the former being recovered by passing through bog oxide or lime and the nitrogen allowed to escape into the air. The inlet and outlet mains are so devised that the respective vessels can be arranged in any order to constitute the series. In due course the carbon dioxide acts upon the calcium hydrosulphide formed as above described

$$CO_2+CaH_2S_2+H_2O=CaCO_3+2H_2S$$

The gas thus generated is mixed with sulphuretted hydrogen issuing from another vessel, and by suitable regulation of the vessels high strength of gas is obtained. The sulphuretted hydrogen is then conducted to a gas holder of about 30,000 cubic ft. capacity, escape of gas being prevented by the use of 'dead oil.' In practical working it has been found that the sulphuretted hydrogen thus conveyed to the gas holders contains about 2 p.c. of carbon dioxide. So long as there is no condensation of moisture on the plates of the gas holder, this amount of carbon dioxide will do no harm, but in presence of moisture the corrosion of the gas holder plates may become a serious matter. To ensure the absence of such moisture the gas holders should be placed a few hundred yards from the series of vessels, which are termed carbonators. The gas is conveyed to the holders through a 12-inch main and when leaving the carbonator it is distinctly warm; but by passing through say 300 yards of this main the gas is found to be cooled practically to atmospheric temperature before it enters the holder, and thus condensation in the holder itself is prevented. This precaution has been found to prolong the life of the holder very greatly and thereby to exercise a very important effect upon the economical working of the process.

The yield of sulphur obtained as sulphuretted hydrogen by this process may be taken as not less than 90 p.c. of the total sulphur contained in the vat waste.

Vat waste contains salts of soda, and when the decomposition as above described is completed these are found to be converted by the action of the carbon dioxide into sodium bicarbonate. This is ultimately recovered, because the mud which contains it is used for black ash making instead of chalk. In this way about 3 p.c. of soda calculated upon the alkali produced, which by the old method of working was lost, is recovered.

The concentrated sulphuretted hydrogen thus obtained is next treated with a view to the recovery of the contained sulphur by a process invented by C. F. Claus (Eng. Pats. 3608, 1882; 5070, 5958, 5959, 5960, 1883). This was originally devised for the recovery of sulphur from the sulphuretted hydrogen contained in coal gas, but it was recognised by Chance that it could be made applicable to the solution of one important part of the problem at which he was working. He therefore acquired the patent rights, and after four years' work at Oldbury, largely devoted to securing a continuous exact supply of the necessary quantity of air to decompose the sulphuretted hydrogen, success was achieved.

Anhydrous ferric oxide is used for the absorption of the sulphuretted hydrogen. This oxide is placed upon a bed within the kiln, which bed consists of broken fire brick or other suitable chemically inert material. It is maintained at a temperature which keeps the ferric oxide at a dull red heat. This temperature results from the heat of the reaction, but it may if necessary be supplemented. The sulphuretted hydrogen mixed with the necessary quantity of air to bring about the formation of sulphur and steam is passed through the anhydrous ferric oxide: the volatilised sulphur together with steam pass out of the kiln into chambers where the sulphur is deposited. It may be obtained either as fused or sublimed sulphur, dependent upon the temperature of the kiln and of the depositing chambers. The ferric oxide undergoes no change and may be continuously used. The sulphur obtained by this process is of a high degree of purity.

See Journal Society of Chemical Industry, 1881, vol. 1, p. 45; Journal Society of Arts, 1882, p. 724; Journal Society Chemical Industry, 1882, vol. 1, p. 264; Journal Society Chemical Industry, 1883, vol. 2, p. 10; Journal Society Chemical Industry, 1883, vol. 2, p. 202; Journal Society Chemical Industry, 1884, vol. 3, p. 392; Journal Society Chemical Industry, 1888, vol. 7, p. 162. See also SODIUM, p. 54 *et seq.*

Uses of sulphur. Notwithstanding that the use of sulphur has practically become negligible in connection with the preparation of black gunpowder, and also that as it has, except to a very limited extent, been replaced by pyrites in the manufacture of sulphuric acid—the two industries which at one time accounted for the major portion of the consumption—there has nevertheless been a great increase in the world's annual requirements.

This is largely accounted for by the enormous development in the manufacture of paper from wood, due principally to the work of Ekman, Kellner and Partington. It is estimated that upwards of 180,000 tons of sulphur are yearly used in this connection, and that about 280 pounds of sulphur are required for every ton of wood pulp produced. The sulphur is used for the manufacture of calcium bisulphite and magnesium, but more particularly the former. The bisulphite thus manufactured is added to the wood chips in a very dilute solution: indeed 5 p.c. of total SO_2 may be regarded as the maximum, and of this about 2 p.c. is purposely uncombined. It is essential that not more than traces of sulphuric acid be present, otherwise the pulp is injuriously affected. These two facts account for sulphur not having been replaced by pyrites in the manufacture of wood pulp bisulphites, because the dilute solution employed makes it practically necessary to manufacture the bisulphite where the wood pulp is made. The cost of transport per unit of sulphur available for conversion into sulphur dioxide is therefore a serious consideration. Moreover, it has not been found practicable to sufficiently limit the quantity of sulphuric acid present if the sulphurous acid is made from pyrites.

Sulphur is used to the extent of upwards of 100,000 tons per annum in Europe alone for preventing the growth upon the shoots and grapes of vines of the microscopic mould fungus *oidium*, which if allowed to develop causes the vine leaves to dry up: as a result, the grapes, when ripe, produce an unsound wine. The sulphur employed for this purpose is largely in the form of flowers of sulphur, although winnowed sulphur prepared as already described is also used.

The efficiency of sulphur as a preventive of the growth of *oidium* is considered to be largely dependent upon its physical condition. Thus, flowers of sulphur contain a certain proportion of amorphous sulphur which is much more easily oxidised than the crystals, even when in a very fine state of division. It is believed that by air exposure minute quantities of sulphurous acid and sulphuric acid are formed, which by their presence cause the destruction of the *oidium*. The question of the autoxidation of sulphur has been investigated by Windisch, August Harph (Zeitsch. anorg. Chem. 1904, 39, 387–388) and others, and from their work the conclusion as to the cause of destruction of the *oidium* would appear to be justified. In connection with the use of sulphur in viticulture, it should be pointed out that a very large quantity is used in addition to that mentioned above in the form of what is known as 'Bouillie Bordelaise,' which consists of a mixture of sulphur, copper sulphate, and various porous substances. This mixture is applied to the shoots and grapes of the vines.

Sulphur is also effectively used to prevent the growth of mould on hops. If the growth is not prevented the hops are practically useless. The mould in question is also an *oidium*, the species being similar to that found upon the vine. The fungus grows upon the upper and lower surfaces of the hop leaves, and if allowed to develop forms a white powdery spot on the 'burr' or buds of the hop cones. This stops the development of the cone into the hop, and hard, white knobs are formed which later on turn black. This black colour is due to mould, but when the hops get ripe a further variation in colour is apt to appear, known as 'red mould.' Flowers of sulphur are used as a preventive of hop mould. The total quantity used will vary from season to season, but on the average it is considerable.

Sulphur is also always burnt in the oast houses when the ripe hop-cones are being dried. For this purpose, 'rolled brimstone' is employed. The sulphur is burnt underneath the hops and fumes of sulphur dioxide are passed through the hops. The amount of sulphur thus employed averages about half a pound of sulphur per 10 bushels of green hops. The effect of the passing of sulphur dioxide through the hops is to bleach them, to improve their flavour, and to hasten the drying process (Amos, J. Inst. Brewing, 1910, 16, 142).

Sulphur is used upon a very considerable scale for the manufacture of bisulphite, mainly of calcium, employed as a preservative for fermented beverages, notably ale. It is also used for making sulphurous acid, which is employed to remove the smell of sulphuretted hydrogen which is liable to accumulate in wine barrels, and also to act as a disinfectant.

Sulphur is used in these cases because of its freedom from arsenic. The same remark applies to its application to the manufacture of sulphuric acid when the latter is required for the preparation of foodstuffs or pharmaceutical products. Sulphur is used in the treatment of cutaneous diseases, mostly in the form of ointments. It is also employed medicinally under the name of *milk of sulphur*, which is a precipitated amorphous powder prepared by precipitating the sulphur from a solution of calcium sulphide and thiosulphate by means of hydrochloric acid. Its medicinal properties are stated to be similar to those of sublimed sulphur only more active. Milk of sulphur should be completely soluble in carbon disulphide.

It has already been pointed out that one reason for employing sulphur instead of pyrites in the manufacture of bisulphite for wood pulp treatment is due to the great economy in transport per unit of available sulphur. The same argument holds good in connection with the manufacture of sulphuric acid employed in the making of high explosives for blasting purposes in South Africa, where sulphur is now used. A little more than 40 p.c. of sulphur is available for the production of sulphur dioxide calculated upon the weight of the pyrites, whereas 98 p.c. of available sulphur is derivable from brimstone.

Recent experiments indicate that flowers of sulphur will, in many cases, act as an efficient fertiliser. The addition of small quantities (0·023 grm. per kilo) to the soil was found to materially assist the growth of carrots, beans, celery, lettuce, sorrel, endive, potatos, onions, and spinach, the increase in the weight of the vegetables being, in some cases, as high as 40 p.c. and not lower than 10 p.c. It is suggested that the sulphur only acts indirectly by modifying the development of the soil bacteria. This view is based upon the fact that it was found useless when applied to sterilised soil. It is also asserted that sulphur exercises a favourable influence upon the development of chlorophyll, and plants grown upon a soil to which sulphur has been added are a much deeper green (E. Boullanger, Compt. rend. 1912, 154, 369–370, and A. Demolon, *ibid.* 1912, 154, 524–526).

The vulcanisation of rubber is effected by the addition under recognised conditions of sulphur to india rubber. Sulphur chloride, a solvent of sulphur, is used for vulcanising caoutchouc. The sulphur chloride of industry is a mixture of S_2Cl_2 and SCl_4.

Sulphur enters into the composition of certain cements. For this purpose, it is melted with iron filings and ammonium chloride; or, instead of melting the mixture, 100 parts of filings may be mixed with 5 to 15 parts of sulphur. To this mixture is added about 5 parts of ammonium chloride. The whole is then moistened with water and well mixed. Both mixtures yield cements useful for fixing glass to metal.

Sulphur is also used in the manufacture of carbon disulphide, artificially made sulphides, hyposulphites, in the bleaching of silk and wool by means of sulphur dioxide, in the manufacture of ultramarine, and of artificial vermilion, and in the making ot enamels.

Properties. Several allotropic varieties of sulphur are known, characterised by differences in crystalline form, specific gravity, behaviour towards solvents, &c. The two varieties known as α-sulphur and β-sulphur were first isolated by Mitscherlich (Pogg. Ann. 1825, 264).

α-Sulphur consists of rhombic octahedra which are obtained when sulphur is crystallised at normal temperatures or even at a temperature not exceeding 98°; also from solutions in carbon disulphide by evaporation in the cold. Fine crystals of this type are also obtained by oxidation in air of a solution of sulphuretted hydrogen in pyridine (Ahrens, Ber. 1890, 23, 2708). Natural sulphur as mined is always found in this crystalline form.

β-Sulphur belongs to the monoclinic system and is prismatic. It is formed when crystallisation is effected between 98° and 120°, this latter temperature being the fusion point of prismatic sulphur, as opposed to 114·5° for α-sulphur. β-Sulphur is also obtained from hot solutions of sulphur in alcohol, benzene and turpentine. Above 98° it is stable, but at normal temperatures it is slowly changed into the rhombic form. Heat is evolved as a result of the transformation, 2·27 cal. being liberated by the change of 32·07 grms. of the monoclinic into the rhombic form.

γ-Sulphur is obtained by slowly pouring molten sulphur into water. It is amorphous and to a certain extent elastic. It is insoluble in carbon disulphide, a property which, up to a varying proportion, is shared by flowers of sulphur. Indeed it has been suggested that the term flowers of sulphur should not be applied unless the sample, when newly made, contains not less than 33 p.c. of sulphur insoluble in carbon disulphide, and that if containing less than this it should be known as sublimed sulphur (A. Domergue, Ann. Chim. anal. 1904, 434).

When sulphur is melted at about 120°, it is very fluid, soft, and of a clear yellow colour, but if the temperature be raised to about 160° it becomes viscous and darker in colour: the maximum viscosity occurs at 180°. If the mass be cooled in water from this temperature, it is found that a portion is insoluble in carbon disulphide, but if the heating of the molten sulphur be continued and increased to near its boiling-point, the proportion insoluble in carbon disulphide greatly increases. At 250° sulphur is transformed into a blackish-red mass. At 444·5° (boiling-point) the sulphur has lost its viscosity and yields a reddish-brown vapour. Sulphur thus heated and subsequently cooled in water is known as *plastic sulphur*. If the insoluble sulphur thus obtained be kept for some time, it slowly reverts and is then soluble in carbon disulphide. Whilst at ordinary pressure molten sulphur yields prismatic crystals, under a pressure of 400 atmospheres it yields octahedral crystals (αS) without the necessity of superheating the molten sulphur (M. Lowry, Chemical World, September, 1912).

Amorphous sulphur is distinguished from γ-sulphur by being soluble in carbon disulphide. After several years keeping, it is found to change into α-sulphur. Milk of sulphur (*lac sulphuris*) or 'magister,' which is white, is another variety of amorphous sulphur. This, as stated already, is obtained by treating calcium pentasulphide (CaS_5) with dilute hydrochloric acid.

δ-Sulphur is obtained by passing sulphur dioxide into a saturated solution of sulphuretted hydrogen in glycerol (Sarazon, D. R. P. 216825), and is probably identical with the variety obtained by Debus (Chem. Soc. Trans. 1888, 53, 282) by passing sulphuretted hydrogen into an aqueous solution of sulphurous acid. This variety of sulphur is *colloidal*. According to Spring (Rec. trav. chim. 1906, 25, 253), it is a hydrate of sulphur S_8,H_2O. Colloidal sulphur can be obtained by a variety of methods (Engel, Compt. rend. 1891, 112, 866; Raffo, Zeits. Chem. Ind. Kolloide, 1908, 2, 358; Himmelbauer, *ibid*. 1909, 4, 307; Weimarn, J. Russ. Phys. Chem. Soc. 1910, 42, 481).

Nacreous sulphur (Gernez, Compt. rend. 1884, 98, 144, and M. Lowry, Chemical World, May, 1912) is also known as *mother-of-pearl sulphur*. It is produced by allowing a solution of sodium thiosulphate to diffuse into a solution of acid potassium sulphate. It may also be made by mixing and shaking hydrogen persulphide with ether, ethyl acetate or alcohol. Another method is by preparing a supersaturated solution of sulphur without residue when hot in benzene, toluene, carbon disulphide or alcohol. Place this in a tube and introduce the end of the tube only into a freezing mixture to which crystals of ammonium nitrate are added. Long nacreous flakes originate little by little at the cold point of the tube and gradually advance in the remainder of the liquid. The nacreous sulphur is formed in large colourless rhombic crystals.

Another variety of sulphur is prepared by submitting it to vaporisation in a transparent quartz vessel. By this means it is seen that, whereas the colour is at first deep reddish-yellow, this gradually disappears as the temperature is raised and the heating prolonged until it becomes practically colourless. It then acquires a pale blue colour, which remains until the vapour cools when the blue colour disappears. The same blue colour is observed when sulphur is volatilised in an atmosphere of carbon dioxide. Blue sulphur can also be prepared by heating it with soda. Black amorphous sulphur is thus obtained, and if this be thrown into fused borax or fused calcium chloride it acquires a very deep blue colour. It is also obtained by heating sodium thiocyanate (NaCNS) to 430° (N. A. Orloff, J. Russ. Phys. Chem. Soc. 1902. 34, 52; E. Paterno and A. Mazzucchelli, Atti. R. Acad. Lincei, 1907 [v.], 16, 1, 465).

An interesting variety of sulphur resembling india rubber, may be prepared by heating sulphur to above 400° and pouring it in a thin stream into liquid air. It is then obtained in the form of a thin thread of diameter 0·5 mm. to 1 mm. This thread, when first removed from the liquid air, is brittle and hard, but if it be exposed to heat it acquires great elasticity. A thread of 1 mm. diameter may be stretched to about six times its length and will then return to almost its original length. The sulphur, however, loses its elasticity about half an hour after it has been removed from the liquid air, and it becomes plastic although not permanently so. When elastic, the sulphur has a polished appearance and is quite transparent (P. P. Von Weimarn, J. Russ. Phys. Chem. Soc. 1910, 42, 474).

Molecular weight. This has been determined by measuring the molecular surface energy of sulphur dissolved, respectively, in carbon disulphide and in disulphur dichloride. In both solvents the molecular weight of sulphur corresponds with S_6 or S_8 molecules (Desiderius Pekar, Zeitsch. physikal. Chem. 1902, 39, 433). It has also been shown by Gerhard Preuner (*ibid*. 1903, 44, 733) that S_2 and S_4 molecules also exist. The curve representing the change of gas density at 448°, with change of pressure and also the calculation of the equilibrium constants of the experimental data, supply information as to the whole course of the dissociation which appears to justify this statement. The molecule, as determined by vapour density, is S_8 at low temperatures, but it commences to dissociate as the temperature is raised, and at 850° to 900° only S_2 molecules are left.

Specific gravity. Amorphous sulphur, 2·04; rhombic sulphur, 2·06; monoclinic sulphur, 1·96; molten sulphur, 1·801–1·815. At boiling-point (444·5°), 1·46–1·52.

Melting-point. Rhombic crystals, if pure and melted without being transformed, melt at 114·5°; prismatic crystals, if pure, melt at 120°. Plastic sulphur has no definite melting-point, increase of temperature merely diminishing viscosity and increasing the tendency for the sulphur to pass into the crystalline form (J. H. Kastle and W. P. Kelley, Amer. Chem. J. 1904, 32, 483).

Boiling-point. As determined on the constant air pressure thermometer, sulphur boils between 443·58° and 443·62° (N. Eumorfopoulos, Proc. Roy. Soc. 1908, A, 81, 339). According to Callendar and H. Moss (*ibid.* 1909, A. 83, 106) it boils at 444·5°.

Specific heat. Mean specific heat between 0° and 100° is 0·1712.

Ignition point. The ignition point, determined by means of a U tube through which air or oxygen is slowly drawn, is found to be 261° (255° uncorr.) in air at ordinary atmospheric pressure, and 257° to 264° (uncorr.) in oxygen (R. H. McCrae and A. Wilson, Chem. News, 1907, 96, 25).

The heat of combustion of sulphur burning to sulphur dioxide is 71,720 cal. for the monoclinic and 71,080 cal. for the rhombic variety (Thomsen, Thermochem. Unters. 2, 247).

Solubility. Sulphur is insoluble in water and only slightly soluble in alcohol, ether and ethereal oils. In carbon disulphide it is soluble to the extent of about 40 p.c. in the cold and about 182 parts are dissolved in 100 parts at 55°, which is the boiling-point of the saturated solution.

Sulphur dissolves freely in benzyl chloride. The solubility increases from 1 p.c. at 0° to 55·8 p.c. at 134°. It melts in benzyl chloride at 106·2° to 106·8°, and does not mix with the excess of solvent, but above 136° it mixes with benzyl chloride in all proportions (J. J. von Bojuski, J. Russ. Phys. Chem. Soc. 1905, 37, 92).

It is soluble in light petroleum; benzene and toluene dissolve about 26·4 parts at 100°. Tar oil dissolves about 50 p.c. at 100°. a-Sulphur is freely soluble in boiling acetic acid and also in boiling ethyl or methyl alcohol.

Combinations with oxygen, v. infra.

HYDRIDES OF SULPHUR.

Sulphuretted hydrogen H_2S. This gas must have been known from very early times. It is described by the writers of the sixteenth and seventeenth centuries under the general name of 'sulphurous vapours.' Geber prepared milk of sulphur, but no mention is made of a fœtid-smelling gas being given off in the process. Scheele was the first, in 1777, to examine the gas minutely, and its chemical composition was definitely established by Berthollet.

Occurrence.—Sulphuretted hydrogen occurs in the gases issuing from volcanos, sometimes to the extent of 25 p.c. of their volume. It also occurs in the natural gas of Point Abino, Canada. Decaying vegetable substances, particularly the leguminous plants, peas, beans, and lentils, when heaped together in a moist condition evolve this gas, and it is also produced during the decomposition of animal substances such as blood, hair, flesh, &c. It is present in the hepatic waters of Harrogate, Aix-la-Chapelle, and other places. Decomposing organic matter in contact with sulphates frequently generates this gas, and from this cause sulphides are occasionally found at the mouths of large rivers which bring down much organic matter. The smell of sewer gas is in part due to sulphuretted hydrogen, and this latter also occurs in coal-gas, from which it has to be removed by a special arrangement in gas manufacture.

Preparation.—(1) It is usually prepared by the action of dilute sulphuric acid on ferrous sulphide $FeS+H_2SO_4=FeSO_4+H_2S$. It should be collected over hot water, in which it is less soluble than in cold. The gas obtained by this method is never pure, as the sulphide used contains small particles of metallic iron, which give rise to hydrogen. The gas should be washed in water to free it from acid or salt which may pass over. Excess of sulphuric acid causes the precipitation of white, anhydrous ferric sulphate which coats the sulphide and stops the evolution of gas.

(2) A purer gas is obtained by heating antimony sulphide with hydrochloric acid of sp.gr. 1·1; $Sb_2S_3+6HCl=2SbCl_3+3H_2S$. If native antimony sulphide be used, it should be first treated with dilute hydrochloric acid to decompose any carbonates which may be present.

(3) The gas may be prepared on a large scale by heating a mixture of equal parts of sulphur and paraffin, vaseline, or many other organic bodies.

(4) By heating a damp mixture of sulphur and charcoal.

(5) Sulphuretted hydrogen is formed together with sulphur dioxide when steam is passed over boiling sulphur, or even when sulphur is boiled with water; $3S+2H_2O=2H_2S+SO_2$. The two gases thus obtained mutually decompose one another, so that only a portion of the sulphuretted hydrogen remains, and sulphur is deposited.

(6) By the decomposition of aluminium sulphide by water

$$Al_2S_3+6H_2O=Al(OH)_3+3H_2S.$$

(7) By passing dry hydrogen over certain heated sulphides, such as powdered antimony sulphide; $Sb_2S_3+3H_2=Sb_2+3H_2S$. The gas is also formed by passing a current of hydrogen through boiling sulphur; by burning a jet of hydrogen in sulphur vapour, and by burning sulphur in an atmosphere of hydrogen.

(8) Pure H_2S may be prepared by passing

the impure gas first through a drying apparatus and then through a series of vessels cooled by liquid air, in which it is solidified. When a sufficient amount has been collected, all residual gas is drawn out of the apparatus by means of a pump, and the condensed H_2S is then allowed to boil, the first 500 c.c. being rejected. The gas so obtained is completely absorbed by alkalis (Moissan, Compt. rend. 1903, 137, 363).

Properties.—Sulphuretted hydrogen is a colourless, inflammable gas, possessing a most disagreeable smell, resembling that of rotten eggs, which is due in part, when the gas has been prepared from ferrous sulphide, to volatile sulpho-carbon compounds derived from the iron. It has a sp.gr. of 1·1895 (Leduc), and 1 litre at 0° and 760 mm., weighs 1·5392 grms. It burns with a pale-blue flame, forming water and sulphur dioxide, and usually depositing more or less sulphur—

$$H_2S+3O=SO_2+H_2O$$
$$SO_2+2H_2S=2H_2O+3S.$$

A mixture of two volumes of sulphuretted hydrogen and three volumes of oxygen explodes violently when an electric spark is passed through it, complete combustion taking place.

The gas when inhaled acts as a powerful poison, producing asphyxia; even in small quantities it causes sickness and headache. According to Thénard, an atmosphere containing $\frac{1}{800}$ of its volume of this gas will kill a dog, and smaller animals die with even less than that amount. An atmosphere with $\frac{1}{250}$ part of H_2S is sufficient to kill a horse, while cold-blooded animals are not affected by this proportion of gas. The best antidote is the inhalation of very dilute chlorine obtained by moistening a towel with dilute acetic acid, and sprinkling bleaching powder upon it.

Sulphuretted hydrogen is soluble in water, one volume of this liquid dissolving about 4·4 volumes of the gas at 0°, and 3·2 volumes at 15°. The solubility at other temperatures is given by the expression

$$c=4{\cdot}4015-0{\cdot}089117t+0{\cdot}00061954t^2$$

(Henrich, Zeitsch. physikal. Chem. 9, 435).

Alcohol dissolves 17·89 times its volume of the gas at 0°. The aqueous solution of the gas reddens blue litmus, and possesses the peculiar smell and taste of the gas. The solution decomposes on standing, the hydrogen combining with the oxygen of the air to form water, while sulphur deposits, imparting a milky appearance to the liquid. A solution of the gas in glycerol keeps better, and is occasionally used as a reagent.

A hydrate of sulphuretted hydrogen, of the formula $H_2S,7H_2O$, has been described by Forcrand (Compt. rend. 1902, 134, 281), and a series of mixed hydrates of the type

$$M,2H_2S,23H_2O,$$

where M is a volatile organic halogen compound, have also been prepared.

Sulphuretted hydrogen is decomposed by almost all oxidising agents. The halogens unite with its hydrogen, liberating sulphur

$$H_2S+Cl_2=2HCl+S.$$

(The reaction with iodine only takes place in the presence of water.) Fuming nitric acid, dropped into a jar of the gas, decomposes it with explosive violence. Sulphuric acid is decomposed by H_2S forming S, SO_2, and polythionic acids, hence it cannot be used for drying the gas. On account of its ready oxidisability, sulphuretted hydrogen is occasionally employed in organic chemistry as a mild reducing agent. Sulphuretted hydrogen is easily decomposed by heat; according to Myers (Annalen, 159, 124) decomposition commences at a temperature of 400°. When a spiral of platinum is heated in the gas, sulphur is deposited and hydrogen liberated, which occupies the same volume as the original gas. The dissociation at various temperatures has been studied by Preuner (Zeitsch. anorg. Chem. 1907, 55, 279).

Sulphuretted hydrogen acts on most metals and many metallic oxides, forming sulphides; thus silver and mercury are immediately tarnished in contact with the gas. The sulphides are also formed when the gas is passed through solutions of many metallic salts as insoluble precipitates, several of which possess characteristic colours. Thus cadmium sulphide is yellow, antimony sulphide orange, and stannous sulphide chocolate-brown. Hence sulphuretted hydrogen is largely used in analytical operations, a current of the gas being passed through the solution under examination. Paper impregnated with a solution of a lead salt, *e.g.* the acetate, is used as a test for H_2S, such paper being blackened in contact with sulphuretted hydrogen. For the same reason, paintings containing white lead are darkened by exposure to the air of towns, while cards glazed with white lead, and engravings on paper whitened with that substance suffer similarly.

The sulphuretted hydrogen occurring in coal gas may be removed by passing the gas over hydrated ferric oxide

$$2Fe(OH)_3+3H_2S=2FeS+S+6H_2O.$$

Sulphuretted hydrogen may be liquefied by pressure; its critical temperature and pressure are 100° and 90 atmospheres respectively. At the ordinary temperature a pressure of 17 atmospheres condenses it to a colourless, mobile liquid, of sp.gr. 0·9. The liquid boils at −61°, and freezes to an ice-like solid at −82·9°. The density of the liquid at its b.p. is 0·964. Liquid H_2S can also be obtained by cooling the gas to about −70° with a mixture of solid carbon dioxide and ether, or by sealing up a quantity of hydrogen persulphide in one limb of a V-shaped glass tube. The persulphide slowly decomposes, and the pressure eventually becomes sufficient to liquefy the sulphuretted hydrogen produced. The chemical activity vanishes almost entirely when the gas is liquefied; metallic potassium and sodium are unchanged in contact with the liquid, and it is also without action on chromates and permanganates.

Small amounts of H_2S in mineral waters may be detected by adding to the water a few c.c. of hydrochloric acid, stirring in a little solid *p*-aminodimethylaniline, and then adding a drop of ferric chloride. If H_2S be present a blue colour (methylene blue) will develop. This reaction will detect 0·018 mgm. of H_2S in a litre of water.

Salts. A solution of sulphuretted hydrogen in water acts as a weak acid, whence the name sometimes given to it of 'hydrosulphuric acid.' It forms two series of salts, the sulphides R_2S and the hydrosulphides RHS. Of this latter class only the salts of the alkalis and alkaline earths are known; they are produced by the action of an excess of sulphuretted hydrogen on the oxides or hydroxides of these metals.

The normal sulphides can be obtained by the following methods—

(1) By the direct union of a metal, *e.g.* Fe with sulphur at a high temperature.

(2) By the action of sulphur on certain metallic oxides, SO_2 being evolved.

(3) By the reduction of sulphates with carbon.

(4) By the action of CS_2 on some metallic oxides, *e.g.* Cr_2O_3 at about 250°.

(5) By the action of sulphuretted hydrogen on a metallic oxide or salt.

Besides the normal sulphides, many polysulphides of the type R_2S_2, R_2S_3, R_2S_4, &c., exist. Those of the alkalis and alkaline earths can be prepared by boiling a solution of the normal sulphide with an excess of sulphur. All the sulphides except those of the alkalis and alkaline earths are insoluble in water; many are decomposed by dilute acids with evolution of sulphuretted hydrogen. Many sulphides, *e.g.* those of lead, copper, and zinc, occur native as minerals and constitute important ores.

Uses. Sulphuretted hydrogen is employed on the large scale to remove arsenic from sulphuric acid, for precipitating copper from solutions of the salts of that metal, and for precipitating gold and silver from waste material containing them. It is also largely employed in the laboratory in analytical operations.

HYDROGEN PERSULPHIDES.

Hydrogen persulphide was discovered by Scheele in 1777, and more completely investigated by Berthollet. It was first obtained by pouring a concentrated solution of potassium pentasulphide into dilute, ice-cold hydrochloric acid, when, on standing for some time, yellow drops of a transparent, oily liquid separated out. Berthollet believed it to be analogous in composition to the potassium sulphide used in its preparation, and assigned to it the formula H_2S_5. Thénard, however, who found it possessed many properties in common with hydrogen peroxide, gave it the formula H_2S_2, though his analyses always showed a larger proportion of sulphur than is demanded by this formula. Hofmann, who obtained it by decomposing with hydrochloric acid a crystalline compound formed by the action of ammonium persulphide on strychnine, believed it to possess the formula H_2S_3. It has been shown that the so-called 'hydrogen persulphide,' hitherto obtained is really a mixture of a di- and tri-sulphide (Schenck and Falcke, Ber. 1908, 41, 2600).

Preparation. A solution of sodium or calcium polysulphide is carefully poured into an equal volume of concentrated hydrochloric acid, kept well cooled by ice. A heavy, yellowish oil separates out, which is then submitted to distillation under reduced pressure. The di- and tri-sulphides are separated by fractional distillation. Care must be taken to remove all traces of alkali from the distillation apparatus by previously treating it with sulphuric acid, as the hydrogen persulphides are very readily decomposed by even traces of alkali.

Hydrogen disulphide H_2S_2. The disulphide thus obtained is an oil, boiling at 74°–75° (2 mm.) of sp.gr. 1·376. It is more volatile than the trisulphide, and not so readily attacked by alkalis.

Hydrogen trisulphide H_2S_3. Hydrogen trisulphide forms a colourless, strongly refracting liquid of sp.gr. 1·496 at 15°. It boils at 43°–50° (4½ mm.), and solidifies at about −53°. It has an odour resembling that of camphor, and decomposes slowly in the dark, more rapidly on exposure to light, evolving H_2S and depositing sulphur. It dissolves in many organic solvents without decomposition, and its solutions in ether, benzene, and carbon disulphide are relatively stable (Schenck and Falcke, *l.c.*). It forms a well-crystallised compound with benzaldehyde of the composition

$$(C_6H_5{\cdot}CHO)_2,H_2S_3$$

(Brunner and Vuilleumier, Chem. Zentr. 1908, ii. 588).

HALOGEN COMPOUNDS OF SULPHUR.

The affinity of sulphur for the halogens decreases rapidly from fluorine to iodine. The hexafluoride is a very stable compound, while the only well-defined chloride is S_2Cl_2, the tetrachloride being easily decomposed. The only known compound of sulphur and bromine has the formula S_2Br_2, whilst no iodide is known, all the compounds previously classed as such (with the possible exception of S_3I_2) being merely mixtures of sulphur and iodine.

Sulphur hexafluoride SF_6. This body was discovered in 1900 by Moissan and Lebeau, who obtained it by the direct union of sulphur and fluorine (Compt. rend. 1900, 130, 865). It possesses a theoretical interest as being the first hexahalogen derivative of sulphur to be prepared. It is a colourless, inodorous, incombustible gas, condensible to a liquid at a low temperature (b.p. about −57°). It is slightly soluble in water, rather more so in alcohol. Chemically, it is a very inert body, but it is slowly decomposed when mixed with hydrogen and submitted to a powerful spark discharge, producing HF, H_2S and S, and it is also attacked by sodium or calcium vapour at a red heat.

Sulphur chlorides. Only two chlorides of sulphur are definitely known, *i.e.* S_2Cl_2 and SCl_4. An intermediate chloride SCl_2 was formerly thought to exist, but later work points to its being merely a solution of chlorine in S_2Cl_2 (Ruff and Fischer, Ber. 1903, 36, 418; *see*, however, Beckmann, Zeitsch. physikal. Chem. 1909, 65, 289).

Sulphur monochloride S_2Cl_2. This chloride was first obtained by Hagemann in 1781, but its composition was not fully established until the year 1810, when it was studied by Davy and Bucholz.

Preparation. Sulphur monochloride may be obtained by passing dry chlorine gas over melted sulphur, and distilling the chloride from the excess of sulphur. The chlorine is generated in the ordinary way, and passed through a wash bottle containing water, then through calcium chloride, and thence over melted sulphur contained in a retort. The chloride of sulphur is condensed in a receiver cooled by a stream of cold water. On the large scale, sulphur monochloride is obtained as a by-product in the preparation of carbon tetrachloride from carbon disulphide and chlorine: $CS_2+3Cl_2=CCl_4+S_2Cl_2$.

Properties. Sulphur monochloride is an amber-coloured liquid which fumes strongly in moist air, and possesses a peculiarly penetrating smell, its vapours attacking the mucous membrane. Its sp.gr. is 1·70941 at 0°/4° (Thorpe), m.p. −75° to −76° (Beckmann), and b.p. 138·1°. Water slowly decomposes it, forming at first sulphur, hydrochloric acid, and thiosulphuric acid, this latter then further splitting up into sulphur and sulphurous acid

$$2S_2Cl_2+3H_2O=4HCl+S_2+H_2S_2O_3, \text{ and}$$
$$H_2S_2O_3=S+H_2SO_3.$$

Sulphur monochloride is easily soluble in benzene and carbon disulphide. It readily dissolves sulphur, and the saturated solution contains at ordinary temperatures 66·7 p.c. of sulphur. It acts on many metals, *e.g.* iron, tin, aluminium, and mercury, producing chlorides (Nicolardot, Compt. rend. 1908, 147, 1304), and most metallic oxides yield chlorides when heated in its vapour. This latter reaction affords a means of preparing certain chlorides free from oxychlorides (Bourion, *ibid.* 1909, 148, 170). Sulphur monochloride acts on many organic compounds to form sulpho derivatives; for example, with benzene it yields (in the presence of aluminium chloride) phenyl sulphide $(C_6H_5)_2S$. This reaction affords support to the formula $S{=}SCl_2$ for the chloride (Böeseken, Chem. Soc. Abstr. 1905, i. 583). Hicks (J. Amer. Chem. Soc. 1911, 38, 1492) has utilised sulphur monochloride for the decomposition of minerals containing rare earths, by heating them in a current of the vapour.

Uses. Sulphur monochloride is used in defecating cane-juice and refining sugar, in the so-called Eastes' process. Its principal application is, however, for vulcanising india-rubber.

The articles to be vulcanised are first coated with india-rubber in the usual way, and are then placed in a closed chamber in which sulphur chloride is vapourised, by which means the vulcanisation of the india-rubber is effected (Abbot, Eng. Pat. 1878, 166).

Parkes' process, which has been in use since 1846, consists in immersing the india-rubber goods in a solution of sulphur chloride (saturated with sulphur) in carbon disulphide or benzene for a short time. It is used extensively in preparing the surface of tobacco pouches, tubing, rings, &c.

Sulphur tetrachloride SCl_4. Sulphur tetrachloride is formed by saturating the monochloride with chlorine at a temperature of −20°. It forms a brown-red liquid, which on being strongly cooled freezes to a yellowish-white solid, of m.p. −31°. On removal from the freezing mixture the tetrachloride at once commences to decompose, evolving chlorine. Water decomposes it violently, forming sulphurous and hydrochloric acids $SCl_4+2H_2O=SO_2+4HCl$.

Sulphur tetrachloride forms well-defined crystalline double chlorides with many metallic chlorides, such as $SbCl_5,SCl_4$, $FeCl_3,SCl_4$, &c. (Ruff, Ber. 1904, 37, 4513).

Sulphur bromide. Sulphur monobromide S_2Br_2 is formed by direct union of its elements when sulphur is dissolved in a slight excess of bromine, and the excess of the latter then removed by a current of dry CO_2. It is a ruby-red liquid, which boils at about 210°, and can be completely separated into its constituents by repeated distillation. Water decomposes it in a similar manner to S_2Cl_2. Caustic potash acts on it, giving a mixture of potassium bromide and sulphite with liberation of sulphur.

Determinations of the melting-points and vapour densities of mixtures of S_2Br_2 and bromine have failed to show the formation of any other compounds of bromine and sulphur (Ruff and Winterfeld, Ber. 1903, 36, 2437).

Sulphur iodide. A compound of the composition S_2I_2 has been described as obtained by the action of sulphuretted hydrogen on a solution of iodine chloride, the current of gas being stopped before the whole of the chloride was decomposed (MacIvor, Chem. News, 1902, 86, 5).

Other observers have, however, made detailed studies of the system sulphur-iodine, and rendered it probable that the above body is really only a mixture of sulphur and iodine, as no evidence of the formation of any compounds of the two elements could be obtained; *see* Boulouch, Compt. rend. 1903, 136, 1577; Smith and Carson, Zeitsch. physikal. Chem. 1907, 61, 200; Ephraim, Zeitsch. anorg. Chem. 1908, 58, 338; Olivari, Chem. Soc. Abstr. 1909, ii. 37.

OXYHALOGEN COMPOUNDS OF SULPHUR.

Two series of compounds of this class are known, corresponding to the two oxides of sulphur SO_2 and SO_3. The former class are termed thionyl, and the latter sulphuryl compounds.

Thionyl fluoride SOF_2, prepared by heating arsenic fluoride with thionyl chloride in a sealed tube at 100°, is a colourless gas with an odour like carbonyl chloride, liquefying at −32°. Water decomposes it into hydrofluoric and sulphurous acids.

Thionyl chloride $SOCl_2$ was first obtained in an impure state by Persoz and Block, and more fully investigated by Carius. It may be prepared by the action of dry sulphur dioxide on phosphorus pentachloride

$$SO_2+PCl_5=SOCl_2+POCl_3.$$

Other methods of preparation consist in the action of PCl_5 on thiosulphates, sulphites, and dithionates, and the direct union of chlorine monoxide with sulphur dissolved in carbon disulphide.

Thionyl chloride is a colourless, strongly-fuming, pungent-smelling liquid, of sp.gr. 1·675 at 0°. It boils at 78°, and on heating to 440°, splits up into sulphur monochloride, sulphur dioxide, and chlorine. Water decomposes it, giving sulphurous and hydrochloric acids. It acts on oxygen acids as a chlorinating agent; thus with sulphuric acid it yields chlorsulphonic acid. On account of the ease with which it parts with its chlorine it is employed in organic chemistry in preparing chloro-derivatives from certain hydroxy acids. It also acts on many organic aldehydes, *e.g.* piperonal, forming dichlorides, but the method is not of general application (Hoering and Baum, Ber. 1908, 41, 1914). Thionyl chloride may be made technically by adding SO_3 to S_2Cl_2 at a temperature of 75°–80°

$$SO_3+S_2Cl_2=SOCl_2+SO_2+S.$$

Chlorine is passed continuously into the product to reconvert the sulphur into chloride, and a nearly theoretical yield of thionyl chloride can thus be obtained (Chem. Fab. Griesheim Elektron Chem. Soc. Abstr. 1903, ii. 420).

Thionyl bromide $SOBr_2$ has been prepared from thionyl chloride and sodium bromide by Hartog and Sims (Chem. News, 1893, 67, 82). It is an orange-yellow liquid, boiling at 68°, and of sp.gr. 2·61 at 0°.

Thionyl chlorobromide $SOBrCl$, prepared from thionyl chloride and hydrobromic acid, is a clear yellow liquid of sp.gr. 2·31 at 0°, boiling at 115° with slight decomposition (Besson, Compt. rend. 1896, 122. 320).

Sulphuryl fluoride SO_2F_2 is obtained by the direct union of sulphur dioxide and fluorine. It is a gas, colourless and odourless, which liquefies at −52°, and solidifies at −120°. It dissolves in water without undergoing decomposition, and attacks glass. Alkalis decompose it, forming sulphurous and hydrofluoric acids (Moissan and Lebeau, Compt. rend. 1901, 132, 374).

Sulphuryl chloride SO_2Cl_2. This body was discovered by Regnault in 1838, who obtained it by acting with chlorine on a mixture of ethylene and sulphur dioxide. It is best prepared by passing well-dried chlorine and sulphur dioxide simultaneously into a large glass flask containing some camphor which has previously been saturated with sulphur dioxide. Care must be taken that the chlorine is never in excess. The two gases combine to form sulphuryl chloride, the camphor remaining unaltered. The product is rectified, and the portion boiling at 70°–72° collected separately. Formic acid can be used in place of the camphor. Sulphuryl chloride is a colourless liquid, b.p. 69·2°, sp.gr. 1·7045 at 0°. A small quantity of water converts it into chlorsulphonic acid, but a larger quantity decomposes it entirely, into sulphuric and hydrochloric acids

$$SO_2Cl_2+2H_2O=H_2SO_4+2HCl.$$

Added in small portions to ice-cold water, sulphuryl chloride forms a crystalline hydrate, stable at 0° (Baeyer and Villiger, Ber. 1901, 736).

On heating it splits up into SO_2 and Cl_2, the dissociation being complete at about 450°. On account of the ease with which it dissociates it acts as a powerful chlorinating agent, and has been patented for this purpose (for preparing the chlorides and anhydrides of organic acids)

$$2RCOONa+SO_2Cl_2=Na_2SO_4+2ROCl, \text{ and}$$

$$4RCOONa+SO_2Cl_2 =Na_2SO_4+2NaCl+2\genfrac{}{}{0pt}{}{R{\cdot}CO}{R{\cdot}CO}{>}O.$$

Pyrosulphuryl chloride $S_2O_5Cl_2$ is produced by the action of sulphur trioxide on sulphur monochloride, phosphorus pentachloride, and other chlorine compounds. It is best prepared by acting on fuming sulphuric acid with carbon tetrachloride, a method first introduced by Schützenberger; $2SO_3+CCl_4=COCl_2+S_2O_5Cl_2$. The carbon tetrachloride is placed in a flask fitted with a reflux condenser, and the oleum slowly added through a tap funnel. The flask is heated for some time after the evolution of phosgene has ceased, and the contents are then fractionated. The crude pyrosulphuryl chloride, thus obtained, is purified by the addition of fused sodium chloride and redistillation under reduced pressure, the sodium chloride combining with the chlorsulphonic acid present to form a salt, which remains behind in the distilling flask.

Pyrosulphuryl chloride is a colourless, fuming liquid, of sp.gr. 1·872 at 0°. It boils at about 153° at the ordinary pressure with slight decomposition, but may be distilled unchanged under 19 mm. pressure. It is slowly decomposed by water with formation of chlorosulphonic acid, which in turn yields hydrogen chloride and sulphuric acid as final products.

Fluorsulphonic acid $SO_2{<}\genfrac{}{}{0pt}{}{F}{OH}$ is formed by the direct union of sulphur trioxide with hydrogen fluoride at a low temperature. It is a colourless, mobile liquid, boiling at 162·6°, with slight decomposition (Thorpe and Kirman, Chem. Soc. Trans. 1892, 61, 921).

Chlorsulphonic acid $SO_2{<}\genfrac{}{}{0pt}{}{Cl}{OH}$. This compound was first obtained by Williamson by the direct union of sulphur trioxide and hydrogen chloride, and by distilling a mixture of sulphuric acid and phosphorus oxychloride

$$2SO_2{<}\genfrac{}{}{0pt}{}{OH}{OH}+POCl_3=2SO_2{<}\genfrac{}{}{0pt}{}{Cl}{OH}+HPO_3+HCl$$

It is best prepared by the first-named reaction, by passing well-dried hydrogen chloride into fuming sulphuric acid until no further absorption takes place. The contents of the flask are then distilled in a current of dry hydrogen chloride, and the portion boiling at 145°–160° collected separately. The product thus obtained may be further purified by redistillation, but if required perfectly pure must be crystallised several times at a low temperature. The melting-point of the pure acid is −80°.

It had a special importance at the time of its discovery, as it was the first example of a substance to be referred to mixed types.

$$\begin{matrix}\text{Mixed water}\\ \text{type}\end{matrix}\quad \begin{matrix}\left.\begin{matrix}H\\H\end{matrix}\right\}O\\ HCl\end{matrix}\qquad\qquad \begin{matrix}\text{Chlorsulphonic}\\ \text{acid}\end{matrix}\quad \begin{matrix}H\\ SO_2{<}\end{matrix}\!\!\begin{matrix}\}O.\\ Cl\end{matrix}$$

It is a colourless, fuming liquid of sp.gr. 1·784 at 0°, and boils with slight decomposition at 151°–152°. Its vapour dissociates on heating, the decomposition being complete at 200°. $2SO_2{<}\genfrac{}{}{0pt}{}{Cl}{OH}=SO_2+Cl_2+H_2O+SO_3$. At a red heat the products are sulphur dioxide, steam, and chlorine (Ruff, Ber. 1901, 34, 3509).

Chlorsulphonic acid is decomposed by water with explosive violence, forming hydrochloric and sulphuric acids, and when added to strong sulphuric acid, disulphuric acid and hydrochloric acids are formed

$$SO_2{<}\genfrac{}{}{0pt}{}{OH}{Cl}+SO_2{<}\genfrac{}{}{0pt}{}{OH}{OH}=\begin{matrix}SO_2{<}OH\\ \quad{>}O\\ SO_2{<}OH\end{matrix}+HCl$$

With finely divided tellurium and selenium chlorsulphonic acid gives a cherry-red and a moss-green colour respectively. On standing for a considerable time the liquid becomes colourless.

Chlorsulphonic acid acts on many organic bodies with formation of sulpho derivatives, and hence is often employed in the preparation of these compounds.

For an account of the literature on chlorsulphonic acid and pyrosulphuryl chloride, *v.* Sanger and Riegel, Proc. Amer. Acad. of Arts and Sciences, 1912, 47, 18.

Oxides and Oxyacids of Sulphur.

Sulphur dioxide SO_2. The ancients knew that when sulphur was burnt it evolved pungent fumes, and these fumes have long been used for fumigating purposes and for purifying cloth. It was formerly supposed that sulphuric acid was produced by burning sulphur in the air, but Stahl proved the fallacy of this idea; the gas was then known as phlogisticated vitriolic acid, in accordance with the views of that time. Priestley in 1775 first prepared the pure gas.

Occurrence. Sulphur dioxide occurs among the gases issuing from volcanos, and in a state of solution in the waters of certain volcanic springs. It also occurs to a small extent in the air of towns, being mainly derived from the pyrites contained in coal.

Preparation. (1) By burning sulphur in air or oxygen. The sulphur ignites at a temperature of about 250°–260°, and sulphur dioxide is obtained equal in volume to that of the oxygen consumed: $S+O_2=SO_2$.

(2) By roasting pyrites. This method is mainly employed in the manufacture of sulphuric acid on the large scale.

(3) By heating a mixture of manganese dioxide and sulphur: $MnO_2+S_2=MnS+SO_2$.

(4) By the action of warm, dilute sulphuric acid on sulphites, as sodium sulphite

$$Na_2SO_3+H_2SO_4=Na_2SO_4+H_2O+SO_2.$$

(5) By heating sulphuric acid with certain deoxidising substances, such as sulphur and charcoal

$$S+2H_2SO_4=2H_2O+3SO_2$$
$$C+2H_2SO_4=2H_2O+CO_2+2SO_2.$$

This latter reaction has been employed on the large scale in the manufacture of alkaline sulphites; the carbon dioxide simultaneously evolved is not detrimental, as it is almost insoluble in water containing sulphurous acid.

Properties. Sulphur dioxide at ordinary temperatures is a colourless, irrespirable, incombustible gas, of sp.gr. 2·2639 (air 1). 1 litre of the gas at 0° and 760 mm. weighs 2·9266 grms. It may be collected by downward displacement like carbon dioxide, but if required quite free from air should be collected over mercury. It possesses the well-known smell of burning sulphur. Sulphur dioxide is very soluble in water, the solution being accompanied by a slight rise in temperature. At 0° water dissolves 79·79 times its volume of the gas, at 20° 39·37 volumes, and at 40° 18·77 volumes, prolonged ebullition being required to expel the last traces of the gas from the solution (Bunsen and Schoenfeld, Annalen, 95, 2). The solution of the gas has a strongly acid reaction, reddens blue litmus, and afterwards bleaches it, but the perfectly dry gas has not these properties. The gas is also soluble in alcohol, and in strong sulphuric acid, this last liquid taking up at ordinary temperatures 58 times its own volume of SO_2. By cooling a saturated solution of the gas in water, a number of hydrates containing 5, 8, 10, and 14 molecules of water have been obtained. They are colourless, crystalline bodies which melt at about 4°, and evolve SO_2 slowly on exposure to air. Sulphur dioxide is poisonous; $\frac{1}{2500}$ part in air causes dyspnœa, and affects the eyes. It is absorbed by the blood, and transformed in the system into sulphuric acid. Sulphur dioxide, both as a gas and in solution, is a powerful bleaching agent, and is used in bleaching those materials which would be injured by chlorine; this property was known to Paracelsus. The bleaching action of sulphur dioxide is a reducing one, whilst that of chlorine is an oxidising one; thus sulphur dioxide in the presence of moisture is oxidised to sulphuric acid, the liberated hydrogen reducing the colouring matter to a colourless compound. The colouring matters are probably in many cases not destroyed by the acid, but reduced to colourless leuco compounds, for in time the original colour often reappears, as in the case of bleached straw and flannel, which become yellow with age. Sulphur dioxide and sulphuretted hydrogen mutually decompose one another in the presence of moisture, with decomposition of sulphur and formation of water and polythionic acids (Wackenroder's solution). When sulphur dioxide and oxygen or air are passed over heated spongy platinum, the two gases combine to form sulphur trioxide. The platinum can be replaced by other substances, and the sulphur trioxide so produced is now used commercially in the manufacture of sulphuric acid (*see* under Sulphuric acid). With ammonia gas sulphur dioxide forms various compounds, according as the one or other gas is in excess. With an excess of SO_2, aminosulphinic acid $NH_2{\cdot}SO_2H$ is always formed, but with excess of ammonia either white $NH_2{\cdot}SO_2NH_4$ or red $NH_4N(SO_2NH_4)_2$ are obtained (*see* Divers and Ogawa, Chem. Soc. Trans. 1901, 79, 1102; Ephraim and Pistrowski, Ber. 1911, 44, 379). Many metals are attacked when heated in the gas; potassium burns with formation of potassium thiosulphate and sulphite, and tin and finely divided iron are changed partly into sulphides and partly into oxides. When the gas is passed over metallic peroxides, *e.g.* lead peroxide, sulphates are formed, often with considerable evolution of heat. Sulphur dioxide is a strong reducing agent, being readily converted into sulphuric acid by addition of oxygen; the halogens are converted by it into the halogen acids, and solutions of the noble metals are reduced with precipitation of the metal. At a temperature of about 1200° sulphur dioxide is decomposed into sulphur and oxygen, part of the latter combining with a portion of the undecomposed sulphur dioxide to form the trioxide. The same decomposition takes place when electric sparks are passed through the gas, but the decomposition is only complete when the sulphur trioxide is removed as soon as formed by absorption with sulphuric acid. Tyndall has shown that the gas is also decomposed by passing a beam of sunlight through a long tube filled with the gas, when a white cloud is formed, consisting of sulphur trioxide.

The composition of sulphur dioxide is ascertained by burning sulphur in a flask of oxygen inverted over mercury. The sulphur is placed in a cup inside the flask, and is so arranged that the sparks from an induction coil, on passing between wire terminals come in contact with, and ignite the sulphur. The volumes of oxygen before the combustion and of sulphur dioxide after combustion, are found to be the same.

Liquid sulphur dioxide. Sulphur dioxide is condensible to a liquid at the temperature obtainable by a mixture of ice and salt, or by a pressure of about 2½ atmospheres at ordinary temperatures. Its critical temperature is 156°, and critical pressure 78·9 atmospheres. The liquid acid is a colourless, mobile fluid, of sp.gr. 1·4338. It boils at −10°, and on being cooled solidifies to a white mass melting at −72·7°. The liquid oxide dissolves many salts and organic bodies and acts as a dissociating medium when used as a solvent in cryoscopic molecular weight determinations. It is miscible with many organic liquids, such as carbon disulphide and chloroform. With potassium iodide at temperatures below 0°, it forms a compound $KI(SO_2)_4$, and the formation of similar compounds has also been observed in the case of other salts. If free from water it has no action on iron, hence the liquid oxide can be transported in wrought iron cylinders. Owing to the rapid increase in the pressure of the SO_2 with rise of temperature, these must only be seven-eighths filled. The pressure in atmospheres of SO_2 at various temperatures is given below—

Pressure	Temperature	Pressure	Temperature
0	−10°	3·51	30°
0·53	0°	5·15	40°
1·26	+10°	7·18	50°
2·24	20°		

The liquid oxide is now sold in glass syphons, fitted with a screw valve, so arranged that either the liquid oxide or the gas may be obtained as desired, the current of gas being capable of adjustment to any desired speed by regulating the screw. A single syphon will evolve 500 litres of gas. Sulphur dioxide can be employed in the artificial production of low temperatures; a mixture of 3 p.c. CO_2 and 97 p.c. SO_2 was employed by Pictet for this purpose. This mixture boils at −19°. The low temperature of −140° is obtained by the evaporation of a solution of solid carbon dioxide in liquid sulphur dioxide, and has been utilised in the liquefaction of oxygen and nitrogen.

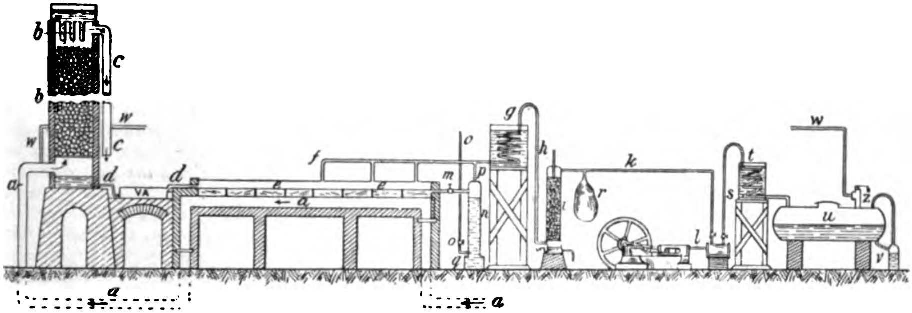

FIG. 1.

Detection of sulphur dioxide. For this purpose paper steeped in a solution of potassium iodate and starch is brought into the gas under examination, when a blue colour is at once produced if only traces of sulphur dioxide are present, iodide of starch being formed

$$2KIO_3+5SO_2+4H_2O=2I+2KHSO_4+3H_2SO_4$$

When the sulphur dioxide is in excess the blue paper is again bleached, hydriodic acid being formed

$$2I+SO_2+2H_2O=2HI+H_2SO_4.$$

This latter reaction is utilised in determining the amount of sulphur dioxide present in a solution. The solution under examination is placed in a burette and run into standard iodine solution containing a little starch paste, until the blue colour of the liquid disappears. The reverse process—running the iodine into the SO_2 solution—is not applicable, as in this case the action proceeds partly according to the following equation

$$SO_2+4HI=4I+2H_2O+S$$

the hydriodic acid formed reducing a part of the sulphurous acid to free sulphur.

Commercial manufacture of sulphur dioxide. The action of sulphuric acid on sulphur and charcoal is used only in the production of an aqueous solution of the gas. Liquid sulphur dioxide was first produced on a large scale by Pictet, who prepared the gas from sulphur and sulphuric acid in an iron retort lined with firebricks, cooled it to −10°, when all the moisture separated out in the form of hydrates, and compressed the residual dry gas with a pump. This process, however, is now superseded by that of Hanisch and Schröder. By means of this process, liquid SO_2 can be manufactured in a pure condition directly from the gases obtained by roasting zinc blende; these gases contain about 6–7 p.c. of SO_2. The method adopted is as follows, Fig. 1 being a sketch of the apparatus employed.

The gases from the roasting furnaces pass through the channel *a* under the leaden pans *e, e*, and in so doing part with their heat to these. They then enter the tower *b*, packed with coke or firebrick, down which a stream of cold water trickles. Practically complete absorption of the sulphur dioxide takes place, the residual air escaping through the pipe *c*. The aqueous solution of sulphur dioxide which collects at the bottom of the tower runs through the preliminary heater VA, composed of thin plates of lead around which hot waste liquors from a subsequent stage of the process circulate. The temperature of the issuing liquid is thus raised to about 85°. The liquid next runs over the lead pans *e, e*, and its temperature is raised to boiling by the heat of the flue gases passing underneath. The expelled sulphur dioxide passes through the pipe *f* to the worm *g*, where it is cooled and most of the accompanying moisture deposited. The last traces of moisture are removed by passage through the tower *i*, packed with coke, down which concentrated sulphuric acid trickles. The perfectly dry gas passes on through *k* (*r* is a taffeta bag to regulate the pressure), into the pump *l*, which is made of bronze. The gas is forced through *s* into *t*, where it is liquefied (for which a pressure of 2–3½ atmospheres is necessary, according to the season of the year). The liquefied gas then passes into the wrought-iron vessel *u*, whence it is drawn off as required, into small iron cylinders *v*. In order to recover the sulphur dioxide which remains in the liquid running away from the pans *e*, *e*, it is run into the small tower *n*, packed with lead wire. Steam is blown in through the pipe *o*, the remaining sulphur dioxide is completely expelled, and passes along with some steam into *g*, and the boiling water which collects at the bottom of *n* is used to circulate round the plates of the heating apparatus VA.

The pans *e*, *e*, are frequently omitted in practice, and the preliminary heater VA connected direct with the tower *n*. Instead of a simple worm, a tower (*see* Fig. 2) may be used for depriving the sulphur dioxide of the greater part of its moisture. The upper part of this tower is packed with coke, the lower half filled with perforated stoneware plates; the moist gas enters at the bottom, whilst a stream of water is run in at the top. By carefully adjusting the proportions of water and gas, boiling water collects at the bottom of the tower, whilst a steady stream of practically dry sulphur dioxide escapes through the tube *d*.

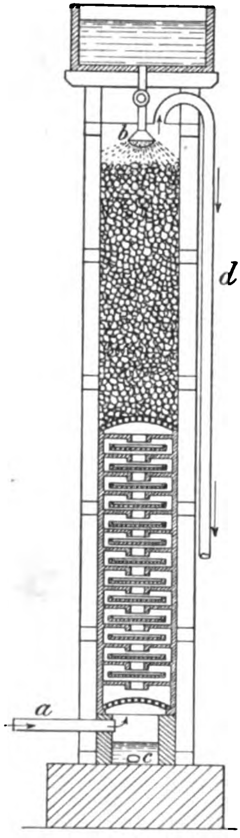

Fig. 2.

For this process to be successfully worked a minimum percentage of 4 p.c. sulphur dioxide must be present in the entering gas, otherwise too much water is required for the complete condensation of the sulphur dioxide.

The liquid sulphur dioxide sold commercially has frequently a purity of 99·8 p.c.

Uses. Sulphur dioxide is largely employed in the arts and manufactures. Its principal use is in the manufacture of sulphuric acid, enormous quantities of the gas being produced for this purpose, principally from pyrites. The liquid acid was formerly largely used in the paper industry in the manufacture of wood pulp, but has now been superseded to a great extent by sulphur dioxide prepared by roasting pyrites. In this process the fir or pinewood is deprived of the bark, cut up into small pieces, and boiled in large lead-lined boilers with a solution of calcium sulphite in excess of sulphurous acid until all incrusting matter is dissolved, and the cellulose can easily be separated from the residue by washing and beating. Sulphur dioxide is also employed to remove the last traces of chlorine after bleaching the pulp: $SO_2+Cl_2+2H_2O=H_2SO_4+2HCl$. It is also used in the refining of sugar, to decolorise the crude sugar juice; it does not invert the sugar, unless exposed to the air for a long time, and has a slight preservative action. It has been employed in tanning to soften dry hides and skins in the bath or 'soak,' which consists of a solution of sulphur dioxide, and in the 'puring' operation for the purpose of curtailing or dispensing with the use of animal excrement. Sulphur dioxide is a powerful antiseptic and has been successfully employed in preserving meat and stopping fermentation, fumigating clothes, and disinfecting the air of rooms. Instead of burning sulphur for disinfecting purposes, the sulphur dioxide can conveniently be obtained from the liquid oxide.

Sulphur dioxide is used in the extraction of alum from shale in a process worked at Ampsin near Lüttich; in the Hargreaves process for the manufacture of salt cake; as a fire extinguisher; and in the bleaching of wool, silk, feathers, sponges, starch, and many other substances.

The materials to be bleached may be treated either with the gas or the solution, the latter being less effective. The goods, after washing and wringing, are brought, while still damp, into a closed chamber, and covered with a thick cloth. They are then exposed to the action of sulphur dioxide for 12–24 hours according to the whiteness required. They are then washed in lukewarm, dilute hydrochloric acid to remove particles of adhering sulphur deposited on them. For bleaching loose wool a solution of sodium bisulphite is preferably used, the substance being afterwards passed through lukewarm, dilute hydrochloric acid, whereby sulphur dioxide is evolved in the nascent condition and bleaches the wool (Dingl. poly. J. 245, 183).

Sulphurous acid has been used to a considerable extent for the purpose of giving to old barley the fine yellow colour of the new grain. Such treatment is injurious to the germinating power, and may be detected by steeping the barley in hot water for a quarter of an hour, then adding zinc and hydrochloric acid to the aqueous extract, the presence of sulphur being indicated by the evolution of hydrogen sulphide (Eckenroth).

Sulphur dioxide has been employed in the treatment of cutaneous diseases, the patient sitting in a box provided with an aperture at the top, through which his head passes, while a wet cloth around his neck prevents the escape of gas from within. The box is over a small fireplace in which sulphur is burned, so that the patient sits in an atmosphere of sulphur dioxide.

The liquid oxide is employed principally as a source of the gas, but is also used directly to some extent in the manufacture of artificial ice, and the extraction of certain fats and oils.

Sulphurous acid. This acid is known only in solution, which is prepared by saturating water with sulphur dioxide. The resulting liquid smells and tastes of the gas, and has a strongly acid reaction. On preservation for some time in contact with air the smell disappears, oxygen being absorbed, and sulphuric acid formed. The acid is dibasic, and forms two series of salts known as sulphites, the two types $R'HSO_3$ and R''_2SO_3 being termed acid and normal sulphites respectively. The normal sulphites of the alkalis are easily soluble in water, while those of the other metals are almost, or quite, insoluble. These latter dissolve, however, in aqueous sulphurous acid with formation of the acid sulphites, but the solution thus obtained is again decomposed on evaporation with evolution of SO_2, and formation of the normal salt. In addition to the two series of sulphites mentioned above, a third series is known, termed metabisulphites, of the formula $R''_2S_2O_5$. Only the alkali salts of this last class have been prepared.

The normal sulphites have no odour, and those which dissolve in water possess a sharp taste. They are easily detected by the addition of sulphuric acid when they evolve the pungent-smelling SO_2. Their neutral solutions give a white precipitate with barium chloride, which is easily soluble in dilute hydrochloric acid; on adding nitric acid to this solution and warming, a precipitate of barium sulphate is obtained.

The existence of isomeric double sulphites, which are theoretically possible owing to the unsymmetrical formula of sulphurous acid $H{\cdot}SO_2{\cdot}OH$, has been announced by Schwicker (Ber. 22, 1728), who describes two different salts to which he assigns the formulæ $Na{\cdot}SO_2{\cdot}OK$ and $K{\cdot}SO_2{\cdot}ONa$. Subsequent observers have, however, failed to obtain these compounds, and their existence is not satisfactorily established, *see* Godby, Chem. Soc. Proc. 1907, 241; Arbusoff, Chem. Soc. Abstr. 1909, ii. 573.

Sulphur sesquioxide. Buchholz was the first to observe the formation of a blue solution when flowers of sulphur were dissolved in Nordhausen sulphuric acid. Vogel found that the same colour was produced with S and SO_3, but Weber was the first to show that it was due to the formation of a new oxide of sulphur (Pogg. Ann. 1875, 156, 531).

Sulphur sesquioxide is obtained by dissolving flowers of sulphur in an excess of sulphur trioxide cooled to 15°, when it forms bluish-green crusts resembling malachite. It may be isolated by pouring off as much as possible of the excess of SO_3, and distilling off the rest at a temperature of about 38°, the sesquioxide remaining behind. It forms a crystalline, blue-green mass, which easily decomposes, especially on heating, into sulphur and sulphur dioxide. In moist air it absorbs water, giving a brown liquid, which soon decomposes with precipitation of sulphur. It is soluble in fuming sulphuric acid, producing a blue solution, which is comparatively stable, and may be kept for a considerable time in a sealed tube, but eventually decomposes, giving a brown solution with evolution of sulphur dioxide and precipitation of sulphur. This solution is used in the manufacture of certain colours (sulphur colours), such as thiopyronine.

Sulphur trioxide SO_3. Sulphur trioxide was known to the alchemists under the name of 'philosophical salt,' and a method for its preparation by the distillation of ferric sulphate is mentioned by Lemery in 1675. Its relations to oil of vitriol were first recognised by Scheele and Guyton de Morveau in 1786.

Preparation. Sulphur trioxide may be prepared by carefully heating fuming sulphuric acid in a retort, and collecting the distillate in a well-cooled receiver. It is also formed when concentrated sulphuric acid is distilled with an excess of phosphorus pentoxide, and by the dry distillation of many metallic sulphates, especially ferric sulphate. Sulphur dioxide unites directly with oxygen to form sulphur trioxide in the presence of certain substances such as platinised asbestos and ferric oxide, which act as catalysts, and this reaction is now employed on the large scale in the contact process for manufacturing sulphuric acid (*q.v.*). Sulphur trioxide is also produced to some extent when sulphur dioxide is decomposed by heat or by passing electric sparks through it, as well as during the combustion of sulphur and the roasting of metallic sulphides. If pure sulphur trioxide be required, the product obtained by any of the above processes must first be redistilled several times, and finally purified by repeatedly heating it until it has almost entirely melted and then pouring off the liquid from the portions still remaining solid. The sulphur trioxide may be regarded as pure when the whole mass melts easily and completely on gentle warming.

Properties. Sulphur trioxide exists in two modifications termed α and β respectively. The two substances have different physical properties but resemble one another in their chemical behaviour.

α-Sulphur trioxide forms long colourless needles of sp.gr. 1·944 at 11° (Schenck, Annalen, 1901, 316, 1), which melt at 14·8° (Rebs), 16·79° (Lichty), and at temperatures below 25° gradually pass over into the β modification. The liquid boils at 44·88° (Lichty, Amer. Chem. J. 1912, 34, 1440), and its molecular weight corresponds with the formula SO_3 (Oddy, Gazz. chim. ital. 1901, 31, (2), 158).

β-Sulphur trioxide crystallises in colourless needles of sp.gr. 1·97 at 20°, which resemble asbestos in appearance. On heating, it volatilises at about 50° without previous fusion, and is converted into the α modification by distillation. According to Oddy, the molecular weight of the β compound corresponds with the formula S_2O_6 (see, however, Lichty, *l.c.*). The β modification is chemically rather less active than the α modification.

Perfectly dry sulphur trioxide shows no acid reaction and is not corrosive. On heating, it is decomposed into sulphur dioxide and oxygen, but a temperature of 1300° is required for the reaction to be complete. On exposure to air it absorbs moisture rapidly, emitting dense white fumes, whilst it combines with water with explosive violence, producing sulphuric acid. Owing to this avidity for water, sulphur trioxide chars many organic substances.

Sulphur trioxide forms stable compounds with many substances, such as iodine, with which it gives the compounds $I_2(SO_3)_6$ and $I_2(SO_3)_2$. With tellurium it forms $TeSO_3$, a solid possessing a characteristic red colour. Compounds of sulphur trioxide with the oxides of arsenic and nitrogen are also known.

Uses. Sulphur trioxide is manufactured on the large scale for use in the preparation of artificial dyestuffs, in which it is employed as a sulphonating and oxidising agent. It is formed as an intermediate body in the contact process for manufacturing sulphuric acid (*q.v.*).

Hyposulphurous acid (*Hydrosulphurous acid*). Berthollet, in 1789, found that iron dissolved in an aqueous solution of sulphur dioxide without evolution of hydrogen, and Fourcroy and Vauquelin discovered in 1798 that tin and zinc behave similarly. Schönbein studied the reaction between zinc and sulphurous acid, and showed that the solution thus obtained possessed strong reducing properties, and that it contained the salt of a sulphur acid containing less oxygen than sulphurous acid, but the true nature of the reaction was first traced by Schützenberger, to whom the credit of the discovery of hyposulphurous acid is due (Compt. rend. 1869, 69, 196).

Preparation. The zinc salt of the acid is produced when zinc is dissolved in a strong solution of sulphurous acid, and the solution so obtained was mistaken by Schützenberger for the free acid: $Zn+2SO_2=ZnS_2O_4$.

A better method for preparing hyposulphites is that of Bernsthen and Balzen (Ber. 1900, 33, 126). A concentrated solution of sodium bisulphite is shaken with zinc dust, and sulphur dioxide is passed into the liquid

$$2NaHSO_3+SO_2+Zn=Na_2S_2O_4+ZnSO_3+H_2O$$

Milk of lime is then added until the zinc is precipitated, the solution filtered, and the filtrate saturated with sodium chloride. On cooling the liquid, crystals of $Na_2S_2O_4,2H_2O$ separate out.

Sodium hyposulphite is formed in the electrolytic reduction of sodium bisulphite, but it is difficult to prevent the reduction from proceeding further, with the consequent formation of thiosulphate: $Na_2S_2O_4+H_2=Na_2S_2O_3+H_2O$.

By using suitable precautions, solutions containing 30–40 grms. of hyposulphite per litre can be obtained (Frank, Zeitsch. Elektrochem. 1904, 10, 460). If the bisulphite be electrolysed in the presence of indigo, indigo-white is produced, the hyposulphite first formed acting on the indigo, and this process is now employed commercially.

The hyposulphites can also be prepared in a pure condition by means of a reaction discovered by Moissan (Compt. rend. 1902, 135, 647) which consists in passing a current of sulphur dioxide over metallic hydrides

$$K_2H_2+2SO_2=K_2S_2O_4+H_2.$$

The hyposulphites of potassium, sodium, rubidium, caesium, lithium, calcium, and strontium have been obtained in this way.

The free acid is known only in solution; it can be prepared by decomposing a solution of the sodium salt with oxalic acid. A yellow liquid is thus obtained, which soon decomposes, absorbing oxygen from the air with formation of thiosulphuric acid, which itself rapidly splits up into sulphur and sulphur dioxide.

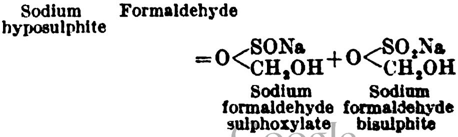
Constitution and properties of hyposulphites. Schützenberger in 1869 obtained a crystalline salt to which he assigned the formula $NaHSO_2$. Bernsthen, from his own work, regarded the sodium salt as $Na_2S_2O_4$, but as neither chemist had succeeded in preparing the salt in a pure condition, and the percentage composition corresponding to the two formulæ is almost the same, the true formula of the hyposulphites remained uncertain until Nabl succeeded in obtaining a pure zinc salt by passing SO_2 into absolute alcohol in presence of zinc turnings, and established the formula $H_2S_2O_4$ for the acid. This was confirmed by Bernsthen and Balzen (Ber. 1900, 33, 126).

The hyposulphites are to be regarded as derived from a mixed anhydride of sulphurous acid and the hypothetical sulphoxylic acid H·SO·OH, the sodium salt being represented by the formula $O{<}\begin{smallmatrix}SO_2Na\\SONa\end{smallmatrix}$. This view of its constitution is borne out by its behaviour towards organic reagents (*see*, however, Bucherer and Schwalbe, Ber. 1906, 39, 2814).

The hyposulphites are strong reducing agents, and on this property their commercial importance depends; both in the solid state when moist, and in aqueous solution, they absorb oxygen rapidly, forming metabisulphites. When added to dilute acid solutions of copper, silver, gold, &c., they precipitate the metal in a colloidal condition; a strong solution of copper sulphate gives a mixture of copper and copper hydride. This latter reaction distinguishes hyposulphurous acid from the other sulphur acids. For the analysis of solutions containing hyposulphites, *see* Orloff, Chem. Soc. Abstr. 1905, ii. 200; Seyewetz and Block, Bull. Soc. chim. 1906, 35, 293.

For the method of preparing pure sodium hyposulphite from the commercial salt, *see* Jellinek, Zeitsch. anorg. Chem. 1911, 71, 96.

Sodium hyposulphite. Sodium hyposulphite is now prepared on the large scale for use as a reducing agent in the dyeing and calico-printing industries. It is usually made by the action of zinc on a solution of sodium bisulphite, and subsequent removal of the zinc by milk of lime, the sodium hyposulphite being precipitated from the filtered solution by the addition of salt, when the compound $Na_2S_2O_4,2H_2O$ is obtained. This salt is unstable, but on treating it with boiling alcohol the water of crystallisation can be removed, and the resulting anhydrous salt is comparatively stable. This latter compound is sold under the name of 'Hydrosulphite BASF,' and contains about 90 p.c. of pure hyposulphite. It is fairly stable in a dry state, but cannot be used in calico-printing as a discharge, as it is oxidised on steaming. This objection was overcome by the discovery of the formaldehyde compounds of sodium hyposulphite, first used at the print-works of Zündel in Moscow. These compounds are obtained by adding a solution of formaldehyde to a solution of sodium hyposulphite. The resulting substance is a mixture in equimolecular proportions of sodium formaldehyde bisulphite and sodium formaldehyde sulphoxylate



$$\underset{\text{Sodium hyposulphite}}{O{<}\begin{smallmatrix}SO_2Na\\SONa\end{smallmatrix}}+\underset{\text{Formaldehyde}}{2CH_2O}+H_2O$$

$$=\underset{\substack{\text{Sodium formaldehyde}\\\text{sulphoxylate}}}{O{<}\begin{smallmatrix}SONa\\CH_2OH\end{smallmatrix}}+\underset{\substack{\text{Sodium formaldehyde}\\\text{bisulphite}}}{O{<}\begin{smallmatrix}SO_2Na\\CH_2OH\end{smallmatrix}}$$

These salts, the mixture of which is sold under the names of Hydrosulphite NF, Rongalite C, &c., are perfectly stable at ordinary temperatures, and are not in themselves reducing agents. On steaming, or boiling with water, they are decomposed into their constituents, and the hyposulphite set free acts as a reducing agent in the usual way. They are employed as discharges for cotton. It was found that by the action of zinc on sodium formaldehyde bisulphite the whole of this could be converted into the sulphoxylate compound which is now manufactured in the above manner, the resulting sodium formaldehyde sulphoxylate being sold as Hydrosulphite NF conc., Hyraldite C extra, &c. It has the formula $NaHSO_2,CH_2O,2H_2O$.

The various commercial brands of hydrosulphite are used as discharges in calico-printing, as stripping agents, and in the dyeing of certain vat colours, such as indigo. Mixtures of the sodium formaldehyde sulphoxylate with small amounts of certain anthraquinone derivatives (which act as catalytic agents), are used for discharging some insoluble azo colours developed on the fibre, *e.g.* α-naphthylamine claret, which resist the action of hydrosulphite alone. Mixtures of the above-named compound with the zinc compounds of some quaternary ammonium bases, such as the zinc compound of dimethylphenylbenzylammonium chloride are used in discharging indigo and other vat dyestuffs, the 'leucotrope' as it is termed, combining with the reduced dyestuff, and preventing its re-oxidation.

Sodium hyposulphite is also employed as a decolouriser for sugar juice, and as an absorbent for oxygen to replace pyrogallol in gas analysis.

Thiosulphuric acid $H_2S_2O_3$. This acid was first prepared in the form of its sodium salt by Chaussier in 1799, who obtained it whilst trying to make sodium carbonate by fusing sodium sulphate with carbon. The acid received at first the name of hyposulphurous acid, the present name, thiosulphuric acid, being proposed by Wagner. The free acid is known only in solution, and even this is very unstable and rapidly decomposes with evolution of sulphur dioxide and precipitation of sulphur. Small quantities of the acid are formed by the action of a solution of sulphurous acid on flowers of sulphur at ordinary temperatures, more rapidly at 80°.

Preparation of thiosulphates. Thiosulphates may be obtained by boiling solutions of the sulphites with flowers of sulphur

$$K_2SO_3+S=K_2S_2O_3.$$

They are also produced, together with polysulphides, by fusing the alkaline carbonates with sulphur, or by boiling the caustic alkalis with water and sulphur

$$6KOH+12S=2K_2S_5+K_2S_2O_3+3H_2O.$$

Alkaline and alkaline earth sulphides, particularly the polysulphides, furnish thiosulphates on oxidation either by the oxygen of the air or by suitable oxidising agents.

When iodine acts on a mixture of equimolecular proportions of sodium sulphide and sulphite, a quantitative yield of thiosulphate is obtained (Spring, Ber. 1874, 7, 1157).

Thiosulphates may also be prepared by the electrolysis of ammoniacal sulphite solutions (Halphen, J. Pharm. Chim. 1894, 29, 371).

Properties. The thiosulphates are mostly soluble in water, and frequently crystallise well. The most important one is the sodium salt commonly known as sodium hyposulphite (*see* under SODIUM).

All the soluble thiosulphates contain water of crystallisation, which cannot usually be completely expelled without the salt undergoing decomposition. On strongly heating they all decompose, leaving a mixture of sulphate and sulphide. The same decomposition takes place when their aqueous solutions are boiled for a considerable time, hydrogen sulphide being evolved, and a sulphate remaining in solution. Their solutions are oxidised by mild oxidising agents, such as iodine, and ferric chloride, to tetrathionates (*q.v.*), and the electrolytic oxidation of neutral or acid thiosulphate solutions yields the same compounds. Powerful oxidising agents, on the other hand, convert the thiosulphates into sulphates, in some cases with intermediate formation of tetrathionates (Longi, Gazz. chim. ital. 1896, 26, 119). Reducing agents convert them into a mixture of sulphite and sulphide. The constitutional formula of thiosulphuric acid being $SO_2<\substack{OH\\SH}$, it might be expected that isomeric thiosulphates, such as $SO_2<\substack{OK\\SNa}$ and $SO_2<\substack{ONa\\SK}$ might exist. According to Schwicker (Ber. 22, 1733), such isomerides have been prepared, but later workers have failed to obtain them, and their existence must at present be regarded as doubtful (*see* Rohrig, J. pr. Chem. [ii.] 37, 250; Barth, Zeitsch. physikal. Chem. 9, 176; Meyer and Eggeling, Ber. 1907, 1351; Gutmann, *ibid.* 1908, 307).

A very large number of double thiosulphates have been prepared and examined, for details as to which the original papers should be consulted (*see* C. and J. Bhaduri, Zeitsch. anorg. Chem. 1898, 17, 1; Rosenheim and Steinhauser, *ibid.* 1900, 25, 72; Meyer and Eggeling, *l.c.*).

Dithionic acid $H_2S_2O_6$. This acid was discovered by Welter and Gay-Lussac in 1819. It may be prepared by passing a current of sulphur dioxide through ferric hydroxide suspended in water at a temperature of 0°. At first a reddish-brown solution of ferric sulphite is obtained, which rapidly changes to pale green, the solution then containing ferrous sulphite and dithionate. Baryta water is then added, and the liquid filtered. The calculated quantity of sulphuric acid necessary to precipitate the barium in solution is added to the filtrate, and the resulting solution evaporated *in vacuô* until it attains a sp.gr. of 1·347. On attempting to concentrate it further, it is resolved into sulphur dioxide and sulphuric acid, and its aqueous solution on exposure to air also oxidises with formation of the latter body.

Instead of ferric hydroxide, manganese dioxide can be employed in the above method of preparing dithionic acid, but the yield is then not so satisfactory. The action of sulphur dioxide on various metallic oxides with production of dithionates has been studied by Carpenter (Chem. Soc. Trans. 1902, 1). Dithionates are also obtained by the addition of hydrogen peroxide to a 33 p.c. solution of sodium thiosulphate, the solution being kept neutral during the addition of the peroxide by the simultaneous addition of an acid, the reaction being represented by the following equation

$$2Na_2S_2O_3+H_2O_2=Na_2S_2O_6+2NaOH.$$

The dithionates are most easily obtained from the barium salt, by double decomposition with the sulphate of the corresponding base. Only the neutral salts are known. They are all soluble in water, and usually crystallise well, all except the potassium salt containing water of crystallisation. Their solutions are not oxidised by atmospheric oxygen in the cold, but on heating a sulphate is produced; nascent hydrogen reduces dithionates to sulphites. On heating the dry salts they decompose, partially at 100°, completely at a higher temperature, evolving sulphur dioxide and leaving a residue of sulphate.

The formation of dithionate by heating silver sulphite or silver-sodium sulphite shows that dithionic acid is composed of two sulphoxyl radicles $(SO_3H)_2$, and has not the formula SO_2,OH assigned to it by Kolbe (Baubigny, Compt. rend. 1910, 150, 973).

Dithionic acid may be separated from the other thionic acids by treatment of the mixture with alkaline permanganate, or sodium hypobromite. A solution of barium acetate is then added, and the barium sulphate filtered off. The filtrate contains the dithionate.

Trans. 1902, 1; Friessner, Zeitsch. Elektrochem. 10, 265.

Trithionic acid $H_2S_3O_6$. This compound was discovered by Langlois in 1842, who obtained the potassium salt by gently heating a solution of potassium bisulphite with sulphur

$$6KHSO_3+S_2=2K_2S_3O_6+K_2S_2O_3+3H_2O.$$

The reaction probably takes place in two stages, in the first of which the thiosulphate is formed, and this is then converted into trithionate by the action of sulphur dioxide. This view is supported by the fact that potassium trithionate can be obtained by acting on the thiosulphate with sulphur dioxide:

$$2K_2S_2O_3+3SO_2=2K_2S_3O_6+S.$$

The sulphur then acts further on the trithionate to form tetra- and pentathionate (Plessy). The free acid may be prepared by adding hydrofluosilicic acid to a solution of the potassium salt, when insoluble potassium silicofluoride is precipitated, and trithionic acid set free. The dilute solution of the acid thus obtained is stable, but on attempting to concentrate it, even *in vacuó*, it decomposes into sulphur, sulphur dioxide, and sulphuric acid

$$H_2S_3O_6=S+SO_2+H_2SO_4.$$

It has no smell, but possesses a strongly bitter taste.

Preparation of trithionates. A convenient way of preparing trithionates consists in acting on a thiosulphate with a persulphate, the former salt being kept in excess, when a good yield of trithionate is obtained (Marshall, J. Soc. Chem. Ind. 1897, 16, 396).

Certain double thiosulphates undergo decomposition when boiled with water, producing trithionates. Colefax has shown (Chem. Soc. Trans. 1892, 181, 1083; 1908, 811) that iodine does not oxidise a mixture of sodium sulphite and thiosulphate directly to trithionate, as was formerly thought to be the case, but that when the iodine is present in insufficient quantity to convert all the sulphite into sulphate, the residual sulphite abstracts sulphur from the tetrathionate (formed by oxidation of the thiosulphate) to produce a trithionate. According to Willstätter (Ber. 1903, 36, 1831) the oxidation of sodium thiosulphate by hydrogen peroxide gives rise to trithionate and sulphate.

Properties. The trithionates are all soluble in water, with the exception of the silver and mercury salts, and frequently crystallise well. Their solutions oxidise on exposure to air, forming sulphates and liberating sulphur and sulphur dioxide, and the same decomposition ensues on heating the solid salts. Sodium amalgam converts the salts into a mixture of sulphite and thiosulphate, whilst sodium arsenite or stannite reduces them completely to sulphites (Gutmann, Ber. 1905, 38, 1728, 3277).

The trithionates of potassium, rubidium, and cæsium have been prepared and crystallographically examined by Mackenzie and Marshall (Chem. Soc. Trans. 1908, 1726). *See* also Plessy, J. pr. Chem. 1844, [i.] 33, 348; Chancel and Diacon, Compt. rend. 1863, 56, 710; Fordos and Gélis, *ibid.* 1843, 16, 1070; Rathke, J. pr. Chem. 1865, [i.] 95, 1; Hertlein, Zeitsch. physikal. Chem. 1896, 19, 287.

Tetrathionic acid $H_2S_4O_6$. This acid was discovered in 1843 by Fordos and Gélis, who also prepared certain of its salts. They obtained it from its barium salt, which is formed when iodine acts on barium thiosulphate suspended in water $2BaS_2O_3+I_2=BaS_4O_6+BaI_2$. The thiosulphate of lead is, however, preferable to that of barium in preparing the acid, since the latter salt gives rise to the simultaneous formation of a little trithionate as well. The lead thiosulphate is suspended in water and iodine carefully added, when soluble lead tetrathionate and insoluble lead iodide are produced. The liquid is filtered, the lead in the filtrate precipitated by the addition of a slight excess of sulphuric acid, and the excess of the latter removed by the cautious addition of baryta water. The solution of the free acid thus obtained may be concentrated by evaporation *in vacuó*. Tetrathionic acid is only known in the form of its aqueous solution; this is colourless, odourless, and strongly acid. On concentration beyond a certain point it decomposes in a similar manner to trithionic acid. Sulphuric acid and hydrochloric acid have no action on it in the cold; on heating, this latter acid disengages sulphuretted hydrogen. Oxidising agents, such as nitric acid, convert tetrathionic acid into sulphuric acid, while reducing agents (sodium amalgam) form thiosulphate.

Preparation. The tetrathionates are formed by the partial oxidation of thiosulphates, a convenient oxidising agent being potassium persulphate (Marshall, J. Soc. Chem. Ind. 1897, 16, 396)

$$K_2S_2O_8+2BaS_2O_3=2BaSO_4+K_2S_4O_6.$$

If an excess of thiosulphate be employed a trithionate is produced (v. *supra*).

The electrolytic oxidation of thiosulphates in neutral or acid solution also gives rise to tetrathionates, the oxidation under these conditions not proceeding further (Thatcher, Zeitsch. physikal. Chem. 1904, 47, 641).

Properties. The tetrathionates are all soluble in water; their solutions oxidise on exposure to air, forming sulphate, pentathionate, and other products. On boiling the solution, the products are sulphur dioxide, sulphur, and a sulphate (Gutmann, Ber. 1908, 41, 300).

The dry salts decompose on heating into mixtures of dithionates and trithionates, or, in the case of the tetrathionates of the heavy metals, into sulphide and sulphate.

Pentathionic acid $H_2S_5O_6$. This acid was discovered by Wackenroder in 1846. It is obtained by passing a slow current of sulphuretted hydrogen into water which has been previously almost saturated with sulphur dioxide, allowing the liquid to stand for some time, then again passing in sulphur dioxide, and repeating this cycle of operations several times. The liquid so obtained contains in addition to pentathionic acid, free sulphur, both in solution and in suspension, sulphuric acid, thiosulphuric acid, and small amounts of tri- and tetrathionic acids, possibly also hexathionic acid. The liquid is filtered as far as possible from the sulphur, and a little freshly-precipitated barium carbonate added, which precipitates the sulphuric acid formed, together with the remainder of the sulphur, which is removed along with the barium sulphate by filtration. The clear filtrate is concentrated on a water-bath until it attains a sp.gr. of 1·32, and the concentration is then continued *in vacuô* at the ordinary temperature to a sp.gr. of 1·46, when the residual liquid consists mainly of pentathionic acid (Wackenroder, Ann. Chim. Phys. 1846, 60, 189; Kessler, Pogg. Ann. 74, 249; Takatmatsu and Smith, Chem. News, 1880, 41, 290; Lewes, Chem. Soc. Trans. 39, 68; 41, 300). On attempting to concentrate it further, or on heating its solution, the acid decomposes into sulphuric acid, sulphur dioxide, sulphuretted hydrogen, and sulphur. On adding, with constant stirring, to the concentrated solution of the acid about half the quantity of caustic potash required for complete neutralisation, and filtering from any precipitated sulphur, the clear liquid gives on spontaneous evaporation well-defined crystals of potassium pentathionate $K_2S_5O_6,H_2O$ (Lewes). This salt can be recrystallised from solutions at 50° containing a little free sulphuric acid, but it is at once decomposed in the presence of alkalis. A better method of obtaining the salt consists in adding potassium acetate instead of caustic potash to the concentrated solution of the acid. The potassium salt dissolves in about twice its weight of water to form a clear neutral solution, which decomposes on standing, more quickly on heating, forming a tetrathionate and free sulphur. The dry salt, if freed from water by washing with alcohol, is much more stable, and can be kept unaltered for a long time. On heating the salt it evolves sulphur dioxide and sulphur, and leaves a sulphate:

$$2K_2S_5O_6=2K_2SO_4+2SO_2+3S_2.$$

Oxidising agents convert pentathionates into sulphates. Caustic soda decomposes pentathionates, the action varying with the conditions. With dilute alkali a tetrathionate and sulphur are produced in the cold; sulphur and a trithionate on heating. With an excess of alkali a thiosulphate and sulphite are formed, or on heating to boiling, thiosulphate alone

1. $2K_2S_5O_6+6KOH=2K_2SO_3+3K_2S_2O_3+S_2+3H_2O$
2. $2K_2S_5O_6+6KOH=5K_2S_2O_3+3H_2O.$

Sodium amalgam converts pentathionates into thiosulphates; or on continued action, into sulphides.

Pentathionic acid is also produced by the action of hydriodic acid and iodine, or sulphuretted hydrogen, on lead thiosulphate (Persoz; Takatmatsu and Smith).

The pentathionates have been little examined; the copper salt $CuS_5O_6,4H_2O$ forms small blue crystals, easily soluble in water (Debus).

Hexathionic acid $H_2S_6O_6$. The possible existence of the potassium salt of this acid in the mother liquor of Wackenroder's solution has been indicated by Debus (Chem. Soc. Trans. 1888, 53, 278), but neither the acid nor any of its salts have been prepared in a pure condition. The potassium salt is said to form a warty, non-crystalline mass, which readily decomposes in solution, even in the presence of dilute sulphuric acid.

Takamatsu and Smith (*ibid.* 37, 608) give a table (p. 310) of reactions to distinguish tetra- and pentathionic acids from each other, and from the other thionic acids.

Sulphur heptoxide S_2O_7. This oxide of sulphur was discovered by Berthelot, who obtained it by submitting a mixture of equal volumes of SO_2 and O to the silent electric discharge. It forms a viscid liquid, which becomes solid at 0°, forming white, crystalline needles. It is very volatile, and decomposes slowly at the ordinary temperature, rapidly on heating, into sulphur trioxide and oxygen, but may be kept unchanged for some time at a low temperature. Water decomposes it with formation of sulphuric acid and oxygen.

Persulphuric acid. A solution of this acid is obtained by the electrolysis of dilute sulphuric acid, and its formation was observed by Berthelot, although he did not isolate it. It is best prepared by the electrolysis of an acid of sp.gr. 1·35–1·50, the current density being 500 ampères per square decimetre (Elbs and Schönherr, Zeitsch. Elektrotech. and Elektrochem. 1895, 245, 468). It slowly undergoes decomposition in solution into sulphuric acid and Caro's acid,

Reagents	Dithionic acid $H_2S_2O_6$	Trithionic acid $H_2S_3O_6$	Tetrathionic acid $H_2S_4O_6$	Pentathionic acid $H_2S_5O_6$

which itself slowly breaks up into hydrogen peroxide and sulphuric acid

1. $H_2S_2O_8+H_2O=H_2SO_5+H_2SO_4$
2. $H_2SO_5+H_2O=H_2SO_4+H_2O_2$

A solution of the acid can also be obtained by decomposing barium persulphate with the theoretical quantity of dilute sulphuric acid.

Persulphuric acid is obtained in an almost pure condition by the action of 100 p.c. hydrogen peroxide on well-cooled chlorsulphonic acid (*see* under *Caro's acid*). It forms a white, crystalline mass, melting with decomposition at a little above 60°. At the ordinary temperature it is stable and can be kept for months.

Persulphuric acid is formed during the working of accumulators (Robertson, Proc. Roy. Soc. 1892, 105).

Persulphates. The persulphates were first prepared in 1898 by Hugh Marshall, who discovered that crystals of the potassium salt were formed at the anode during the electrolysis of a solution of the sulphates of potassium and cobalt in a 'divided cell'; and also by the electrolysis of a saturated solution of potassium bisulphate in the same apparatus. The ammonium salt was prepared by replacing the $KHSO_4$ by ammonium sulphate and dilute sulphuric acid. By treating a saturated solution of the ammonium salt with barium hydroxide Marshall obtained the barium salt, the excess of baryta being removed by a current of carbon dioxide. The lead salt was obtained by decomposing a solution of the barium salt with sulphuric acid and neutralising the liquid with lead carbonate. By acting on the barium salt with zin sulphate a solution of the zinc salt was obtained

The persulphates are now manufactured o the large scale for use as oxidising agents. Th potassium salt is prepared, as stated above, b electrolysing a solution of potassium bisulphat in a divided cell. If the anode potential be raise by the addition of hydrofluoric acid to the liqui the yield of persulphate is greatly increase and the diaphragm can be dispensed with. current density of 5 ampères per square c gives a good yield of persulphate. Ammoniu persulphate is prepared in a similar manner b electrolysing a solution of ammonium sulphat in dilute sulphuric acid (1 : 7) in a divided ce the inner compartment containing the anod and the ammonium salt, the outer cell th kathode, and dilute acid alone. In the prepar tion of persulphates by electrolysis, the yiel gradually falls off, owing to the formation Caro's acid; the essential conditions for obtain ing a satisfactory yield are, that the curren density at the anode should be high, the anod itself small, and that the solution should be ke cool (*see* Elbs and Schonherr, *l.c.*).

Lithium persulphate cannot be obtained i this manner, since although the salt is formed i cannot be isolated from the solution (Otin Zeitsch. Elektrochem. 1911, 919).

The persulphates are all soluble in water, th least soluble being the potassium salt, whic requires about 56 parts of water at 0° for solu tion. Their solutions slowly decompose o standing with evolution of oxygen and formatio of a sulphate and free sulphuric acid, and th same change takes place rapidly on boiling the liquid. The dry salts decompose on heating according to the following equation

$$2K_2S_2O_8=2K_2SO_4+2SO_3+O_2.$$

The molecular formula of the persulphates has been found from electrical conductivity measurements to be $R_2S_2O_8$ and not RSO_4 (Löwenherz, Chem. Zeit. 16, 838).

Solutions of the persulphates give no precipitate with barium chloride; on warming, however, barium sulphate slowly separates out, and oxygen is evolved. An alkaline lead solution gives a precipitate of the peroxide on boiling. Fehling's solution gives a red precipitate of cuprous oxide. Ferrous sulphate is rapidly oxidised to ferric sulphate, with rise of temperature. Solutions of manganous, nickel and cobalt salts all yield precipitates of the higher oxides when mixed with a persulphate and warmed, and chromium compounds are oxidised to chromates. Persulphuric acid oxidises many organic bodies, converting alcohol into aldehyde, and aniline into a brown colouring matter, and bleaching indigo, litmus, and turmeric solutions. Paper and cloth become quite rotten after being dipped in a solution of a persulphate. Silver nitrate gives, with potassium persulphate, a black precipitate of silver peroxide

$$2AgNO_3+K_2S_2O_8+2H_2O \\ =2KHSO_4+2HNO_3+Ag_2O_2.$$

If, however, a strong solution of ammonium persulphate is treated with ammonia and a small amount of silver nitrate, a vigorous evolution of nitrogen takes place, and the liquid becomes heated to boiling. Silver peroxide is first formed, and this oxidises the ammonia to water, setting free nitrogen. .

By warming a persulphate with concentrated sulphuric acid the oxygen is liberated largely in the form of ozone. With hydrochloric acid chlorine is evolved.

Persulphuric acid may be distinguished from hydrogen peroxide on the one hand, and Caro's acid on the other, by its neither giving a reddish-brown coloration with a solution of a titanium salt, nor reducing a dilute solution of potassium permanganate, whilst it does not immediately liberate iodine from an acidified solution of potassium iodide.

Commercial ammonium persulphate may be purified by making a saturated solution of the salt at 90°, adding ammonia to neutralise the free acid present (due to the partial decomposition of the persulphate), filtering, allowing to cool to 30°, and then adding twice the bulk of alcohol and cooling with ice applied externally. The crystals which separate out are well drained and washed with alcohol and ether, and allowed to dry in the air.

The potassium salt has been employed in photography to remove the last traces of the sodium thiosulphate from negatives after fixing.

Monopersulphuric acid or **Caro's acid** H_2SO_5. This acid was discovered by Caro in 1898, whilst studying the action of sulphuric acid on persulphates, and was more fully investigated by Baeyer and Villiger (Ber. 1901, 34, 853).

A solution of the acid can be obtained by triturating 10 grms. of potassium persulphate with 20 grms. of concentrated sulphuric acid, allowing the mixture to stand for an hour, pouring it on to ice, and removing the sulphuric acid from the resulting solution by the addition of barium phosphate. The solution thus prepared, containing free phosphoric acid, is tolerably stable, and only very slowly undergoes hydrolysis into hydrogen peroxide and sulphuric acid.

Monopersulphuric acid is also formed during the electrolysis of moderately concentrated sulphuric acid; if an acid of sp.gr. 1·4 be electrolysed, persulphuric acid is first produced, and this is then decomposed by the water present

$$H_2S_2O_8+H_2O=H_2SO_5+H_2SO_4.$$

The acid has been prepared in a nearly pure state by D'Ans and Friedrich (Ber. 1910, 43, 1880) by the subjoined method. The calculated amount of 100 p.c. hydrogen peroxide is added to well-cooled chlorsulphonic acid, when an evolution of hydrochloric acid gas takes place. The mixture is allowed to become warm, and the dissolved hydrochloric acid sucked off at the pump. The residue then solidifies to a colourless, crystalline mass, melting at about 45° with slight decomposition. The acid thus prepared has a purity of about 98 p.c. The following equation represents the reaction taking place—

$$SO_2{<}\begin{matrix}OH\\Cl\end{matrix}+H_2O_2=SO_2{<}\begin{matrix}OH\\O{\cdot}OH\end{matrix}+HCl$$

By using twice the quantity of chlorsulphonic acid persulphuric acid is produced (*v. supra*)—

$$2SO_2{<}\begin{matrix}OH\\Cl\end{matrix}+H_2O_2=H_2S_2O_8+2HCl$$

Properties. Monopersulphuric acid is slowly decomposed in aqueous solution with production of hydrogen peroxide and sulphuric acid

$$H_2SO_5+H_2O=H_2SO_4+H_2O_2.$$

This reaction is, however, a balanced one, as a mixture of hydrogen peroxide and concentrated sulphuric acid forms some Caro's acid. It may be distinguished from hydrogen peroxide by its not giving the reddish-brown coloration with titanium salts, and from persulphuric acid by its causing an *immediate* liberation of iodine from an acidified solution of potassium iodide; further, monopersulphuric acid converts aniline into nitrosobenzene, whereas persulphuric acid under similar conditions only produces a brown colouring matter. This reaction takes place more easily with *p*- substituted anilines, such as *p*-bromaniline, than with aniline itself (Morgan).

A mixture of monopersulphuric acid and potassium permanganate forms one of the most powerful oxidising solutions known.

No salts corresponding to this acid have as yet been obtained.

The formula assigned to Caro's acid by Baeyer and Villiger was H_2SO_5. Other chemists (Armstrong and Lowry, Chem. News, 1902, 85, 193; Lowry and West, Chem. Soc. Trans. 1900, 950) regarded it as $H_2S_2O_9$ or $H_2S_4O_{14}$ ($H_2O_2,4SO_3$). The formula H_2SO_5 has been established by Slater Price (Ber. 1902, 291) and D'Ans and Friedrich (*ibid.* 1910, 880).

According to Armstrong and Robertson (Proc. Roy. Soc. 1892, 50, 105) a series of persulphuric acids exist. The acid $H_2O_2,4SO_3$ is supposed to be formed in the presence of strong sulphuric acid and by dilution, acids of the type $H_2O_2,3SO_3$, $H_2O_2,2SO_3$, &c., are successively obtained.

If a persulphate in the state of powder be treated with 100 p.c. sulphuric acid in the cold, a mass possessing a strong odour, recalling that of chloride of lime, is produced. This substance has quite different properties from Caro's acid; thus it reduces potassium permanganate and gives a reddish-brown coloration with titanium salts. The composition of this body has not been definitely established, but according to Baeyer and Villiger its behaviour is possibly due to the presence of a higher oxide of sulphur of the formula S_2O_8.

A method to determine hydrogen peroxide, persulphuric acid, and monopersulphuric acid, when all three are present in solution, has been devised by Baeyer and Villiger (*l.c.*). The amount of monopersulphuric acid present is first determined by adding an acidified solution of potassium iodide, and immediately titrating the liberated iodine with sodium thiosulphate and starch paste. The solution thus decolorised slowly turns blue again on standing, and after 12–24 hours it is again titrated, the iodine now representing the amount of persulphuric acid present. In another portion the hydrogen peroxide is estimated by titration with potassium permanganate. Though not strictly accurate, the method yields satisfactory results.

SULPHURIC ACID. Sulphur trioxide, or sulphuric anhydride, the substance indicated by the formula SO_3, and consisting of 40 parts of sulphur and 60 parts oxygen, combines with water energetically to form a series of products capable of representation by the formula mSO_3nH_2O. Some of these hydrates in which m and n have certain simple integral values are usually recognised as distinct compounds, either on account of certain well-marked physical properties or because of the existence of definite metallic salts derived from them by replacement of the hydrogen by metals, whilst others are considered to be mixtures of these hydrates, or solutions of one or other of them in excess of water.

Starting from **sulphur trioxide** SO_3, which is a crystalline solid, melting at 14·8°, when quite pure and free from water, the more generally accepted compounds are—

Pyrosulphuric acid $2SO_3,H_2O$. A crystalline solid melting at 35°, the melting-point being lowered on the addition of SO_3 or H_2O. Pyrosulphuric acid forms definite crystalline salts, known as the pyrosulphates.

Sulphuric acid SO_3,H_2O. A liquid at the ordinary temperature, but solidifying at about 10·5°, and also forming a large number of well-defined salts, the neutral and acid sulphates.

Dihydrated sulphuric acid $SO_3,2H_2O$. A liquid forming crystals at low temperatures which melt at 8°. Basic lead sulphate Pb_2SO_5 is a salt corresponding to this acid.

Trihydrated sulphuric acid $SO_3,3H_2O$, the hydrate in the formation of which the maximum amount of contraction takes place, and which is represented by the salt, mercury orthosulphate (Turpeth mineral) Hg_3SO_6.

The existence of numerous hydrates in addition to those above-mentioned has been inferred by Pickering (Chem. Soc. Trans. 1890, 648, 331) from the study of various physical phenomena connected with acids of different strengths. One of these $SO_3,5H_2O$ has been isolated in hard, well-defined crystals melting at −25°, whereas mixtures containing either more or less water (within certain limits) melt at lower temperatures.

PHYSICAL PROPERTIES OF SULPHURIC ACIDS.

Commercially, sulphuric acids may be divided into two classes, viz. 'fuming acids' or substances indicated by the formula $m\cdot SO_3\cdot nH_2O$ where $m>n$; and 'non-fuming acids' where $m<n$ varying from O.V. (oil of vitriol), where m very nearly equals n, down to 'chamber acids' of sp.gr. 1·5 and less. The weaker acids on heating lose water, becoming more and more concentrated until finally a product is obtained boiling and distilling at above 300°, and containing between 98 and 99 p.c. H_2SO_4, the remainder being water. Monohydrated acid 100 p.c. H_2SO_4 cannot be obtained in this way, but is readily formed by the addition of the appropriate amount of sulphur trioxide; the monohydrated acid cannot be distilled unchanged, as, on heating, the boiling-point rises from 290° to 338°, a mixture of H_2SO_4,SO_3 and water passing over. It may also be obtained from 98 p.c. acid by cooling it to below 0°, and separating the crystals which form about that temperature, melting them and recrystallising. At ordinary temperatures it is a colourless oily liquid. Its sp.gr. is 1·8385 at 15° (Lunge and Naef), and the addition of a little SO_3 or water raises the sp.gr. It fumes slightly in air, even at ordinary temperatures giving off SO_3, and it is completely dissociated into SO_3 and H_2O at about 440° (Deville and Troost).

NON-FUMING OR ORDINARY SULPHURIC ACIDS.

The following table of the freezing- and melting- and boiling-points is compiled from the results obtained by Lunge (Ber. 1878, 370; and 1881, 2649; Technical Chemists' Handbook, 132).

Per cent. H_2SO_4	Sp.gr.	Boiling-point	Freezing-point	Melting-point

The specific gravity of dilute sulphuric acid of various degrees of concentration and at various temperatures has been examined by a number of chemists and physicists with results not always exhibiting as close concordance as might be desired; the earlier tables given by Vauquelin, d'Arcet, Ure, Parkes, &c., have long been regarded as superseded by the more exact ones of Bineau and Kolb; and these have been further corrected as a result of the investigations of Lunge, Isler, and Naef. Ure's table, although incorrect, is still largely used as a standard for commercial purposes. For acids approaching the concentration of O.V. the sp.gr. is a fallacious test of strength, because acid of strength 98 p.c. H_2SO_4 has a maximum density as compared with either stronger or weaker acid.

Knietsch's Table.

P.c. SO_3	Melting-point	P.c. SO_3	Melting-point
1	−0·6°C.	65	−4·2°C.
3	−1·7	66	+1·2
5	−2·7	67	+8·0
7	−4·4	68	+8·0
9	−6·0	69	+7·0
11	−7·2	70	+4·0
13	−8·2	71	−1·0
15	−9·3	72	−7·2
17	−11·4	73	−16·2
19	−15·2	74	−25
21	−22·5	75	−34
23	−40·1	76	−32
—	below −40	77	−28·2
61	−40	78	−16·5
62	−20	79	−5·2
63	−11·5	80	+3
64	−4·8	80·63	+10

Apart from this, the effect of temperature variation in altering the sp.gr. is greater, whilst the effect of a given increment in strength is less, the stronger the acid. The table on p. 314 is taken from Lunge's Technical Chemist's Handbook,[1] and is based on the latest results of the above-mentioned investigators with some corrections introduced by the Imperial German Standards Commission.

S. U. Pickering has published (Chem. Soc. Trans. 1890, 64) a number of observations on the sp.gr. of sulphuric acid of strengths between 0·997007 and 99·85700 p.c. of H_2SO_4, in which it is claimed that the limit of error does not, as a rule, exceed 0·000008 (eight parts in one million), notwithstanding that the eight determinations of the strength of the strong sulphuric acid used to prepare other strengths by dilution varied between 99·704 and 99·962 p.c., showing a range of 0·258, or about 1 part in 400. Founded on these results, H. D. Richmond has calculated a table (J. Soc. Chem. Ind. 1890, 479) of specific gravities of sulphuric acid between the limits 1·8248 and 1·8384 referred to water at 15° (90·86–100 p.c.).

Another table, 'the result of a careful selection of figures from standard authorities,' has been calculated by A. H. Elliott (The Chemical Trade Journal, March 24, 1888, 182). W. C. Ferguson (J. Soc. Chem. Ind. 1905, 781) gave the table adopted by the Manufacturing Chemists Association of the United States.

The specific gravity of commercial sulphuric acid, as compared with its strength, usually differs slightly from that found in the case of chemically pure acid, owing to the presence of lead sulphate and other impurities.

---

Specific heat of dilute sulphuric acid. F. Bode gives the foregoing table indicating the relationship between the sp.gr. at 15°, and the specific heat of sulphuric acid (Zeitsch. angew. Chem. 1889, 244; also J. Soc. Chem. Ind. 1889, 543).

A number of determinations of the heat capacity of sulphuric acid solutions of different strengths have also been recorded by S. U. Pickering (Chem. Soc. Trans. 1890, 64).

Tension of aqueous vapour emitted by dilute sulphuric acid. E. Sorel has made a number of experiments, leading to the following results, abridged from much fuller tables (Bull. Soc. Ind. Mulhouse, 1890, 240; also J. Soc. Chem. Ind. 1890, 175). The figures represent tensions in millimetres of mercury; obviously they are much below the tensions of aqueous vapour in contact with water.

Percentage of H_2SO_4 in acid	Temperature

Tension of nitrous anhydride dissolved in sulphuric acid at different temperatures. E. Sorel (*l.c. supra*) has made a number of determinations of the amounts of nitrous anhydride given off when sulphuric acid of different strengths, and containing different proportions of dissolved nitrous gases, was made to flow through a spiral tube 5 metres long placed in a water-bath at constant temperature, whilst a current of pure nitrogen gas passed through the spiral in the opposite direction; the results obtained varied from 0·009 milligram of N_2O_3 per litre of nitrogen at 0°, and 760 mm., when acid of sp.gr. 1·774, containing 28·4 grms. N_2O_3 per litre, was passed through at 40·1°, up to 109·15 milligrams, when acid of sp.gr. 1·597, containing 12·5 grms. N_2O_3 per litre, was passed through at 89·9°; in general, the weaker the acid and the higher the temperature the more N_2O_3 was evolved.

G. Lunge (Zeitsch. angew. Chem. 1891, 37; also J. Soc. Chem. Ind. 1891, 364) has carried out a large number of further observations on this point, employing substantially the same method, with the difference that carbon dioxide was used instead of nitrogen, and a 10-bulbed tube instead of a spiral. Pure nitrosulphonic acid dissolved in pure sulphuric acid was used; no nitric acid was found in the solution. The following tables, representing grms. per litre throughout, are abridged from those given for nitrous vitriol of gravity respectively 1·720, 1·686, 1·633, and 1·60, and for temperatures of 50°–90°. When plotted as curves, the figures show that in presence of strong acid, and at low temperatures, nitrosulphonic acid exists as a compound in the fluid; but, on diluting the liquid and raising the temperature, the compound is dissociated, and the nitrous acid formed removed by the gases into which it diffuses.

LOSS OF N_2O_3 AFTER 1 HOUR, DURING WHICH TIME 5 LITRES OF CO_2 WERE PASSED.

Fuming Sulphuric Acids.

Fuming acid is generally valued in proportion to the amount of trioxide present, the balance being H_2SO_4. The sp.gr. is sometimes employed as a test of strength, but is fallacious, since the density of acid containing about 60 p.c. of SO_3 is a maximum, both stronger and weaker acids exhibiting lower densities. The following table is given by R. Messel (J. Soc. Chem. Ind. 1885, 573), all the specimens being liquid at 26·6°.

Physical character at 60°F.	Percentage of SO_3	Specific gravity	
		At 80°F. =26·6°C.	Calculated to 60°F. =15·5°C.
—	8·3	1·842	1·852
Liquid . .	30·0	1·930	1·940
Crystalline mass resembling nitre	40·0	1·956	1·970
	44·5	1·961	1·975
	46·2	1·963	1·977
—	59·4	1·980	1·994
Liquid . .	60·8	1·992	2·006
	65·0	1·992	2·006
	69·4	2·002	2·016
Crystalline .	72·8	1·984	1·998
	80·0	1·959	1·973
	82·0	1·953	1·967

C. Winkler has obtained values slightly differing from Messel's, the acid used being 'commercial,' and therefore possibly not quite pure.

Specific gravity at 20°C.	Percentage of SO_3	Specific gravity at 20°C.	Percentage of SO_3
1·860	1·54	1·920	15·95
1·870	4·28	1·930	21·34
1·880	6·42	1·940	28·03
1·890	8·16	1·950	31·46
1·900	10·07	1·960	35·87
1·910	11·43	1·970	44·64

Knietsch (Ber. 1901, 4101) gives a more complete table of sp.grs. at 35°, also for commercial fuming acid, and in addition a series of observations at 15° and 45°. He finds that acid containing 60 p.c. free SO_3 has the maximum density at 15°, 56 p.c. free SO_3 at 35°, and 50 p.c. free SO_3 at 45°.

A more accurate method consists in weighing out a portion of the acid to be examined in a sealed bulb, which is then broken under water by shaking up in a bottle; sulphurous acid, generally present, is first determined by titration with iodine solution, and then the SO_3 by precipitation as barium sulphate or volumetrically (Messel, *l.c.* p. 521). Lunge and Rey (Zeitsch. angew. Chem. 1891, 163) recommend a special form of bulb-tap pipette instead of a sealed bulb for this purpose. The table on p. 317 is abridged from a longer one given by Lunge and Hurter (Technical Chemists' Handbook, p. 134), for the reduction of percentages of total SO_3 thus found to percentages of SO_3, the balance being H_2SO_4.

Setlik finds (Chem. Zeit. 13, 1670; Chem. Soc. Abstr. 1890, 414; J. Soc. Chem. Ind. 1890, 417) that a simple method of valuation, with sufficient accuracy for most purposes, is to titrate 100 grms. in a flask with water until the acid ceases to give off fumes, the flask being kept cool. At first a thick cloud is formed on the addition of each drop, but latterly the fumes become less apparent. The flask must then be shaken after each addition of water until the fumes are

absorbed before adding the next portion: 1 c.c. of water represents 4·444 grms. SO_3. Acids containing more than 35 p.c. of SO_3 should be diluted down to about that strength by addition of pure H_2SO_4. Lunge regards this method as insufficiently accurate for use between buyer and seller, although otherwise convenient.

It may, however, be rendered quite reliable for practical purposes by using sulphuric acid of known strength instead of water.

Melting- and boiling-points of fuming acids. The following tables are given by Knietsch (Ber. 1901, 4100 and 4101).

The numbers in the brackets denote the fusing-points of fresh not yet polymerised acids.

Sulphur trioxide, or sulphuric anhydride, when quite pure and free from traces of water is a crystalline solid melting at 14·8° to a colourless liquid which boils at 46·2° (Weber, Ber. 19, 3187). The crystals are long transparent prisms similar to those of potassium nitrate. The presence of a trace of water renders this form unstable, and on standing for some time it changes to an asbestos like solid which begins to melt at about 50°, gradually passing back to the original form. Oddo (Chem. Zentr. 1901, 969) showed that the second modification was a polymer of the first, and should be represented by the formula S_2O_6. Schenck (Annalen, 316, 1) regards the more liquid modification as a solution of the asbestos like polymer in real SO_3 in a state of unstable equilibrium. Knietsch (Ber. 1901, 4100) gives the melting-point of pure SO_3 as 17·7°. On adding small quantities of water the melting-point is raised until at 85 p.c. free SO_3 it is 27° (maximum). On standing this polymerises; it no longer melts on heating, but

sublimes and passes back again to the original modification.

Knietsch also gives tables of electric resistance, vapour tensions, viscosities, capillarity, and action on iron, and he has plotted them out graphically in a series of curves representing the properties of sulphuric acid both fuming and ordinary (Fig. 1) (J. Soc. Chem. Ind. 1902, 343).

These curves show that the acid containing 98·3 p.c. H_2SO_4, which is the maximum strength obtainable on concentrating weaker acids by heat, and which distils unchanged, has certain well-defined properties. It has the maximum boiling-point and minimum vapour tension. It has the highest specific gravity of any hydrated acid. Electrical resistance begins suddenly to rise at this point to a maximum at 100 p.c. H_2SO_4, and the action of the acid on iron decreases at the same time to a minimum.

Other features of these curves to be noted are—

I. Melting-point. Shows sharply defined maxima and minima at points representing definite molecular proportions of H_2SO_4 to H_2O or to SO_3.

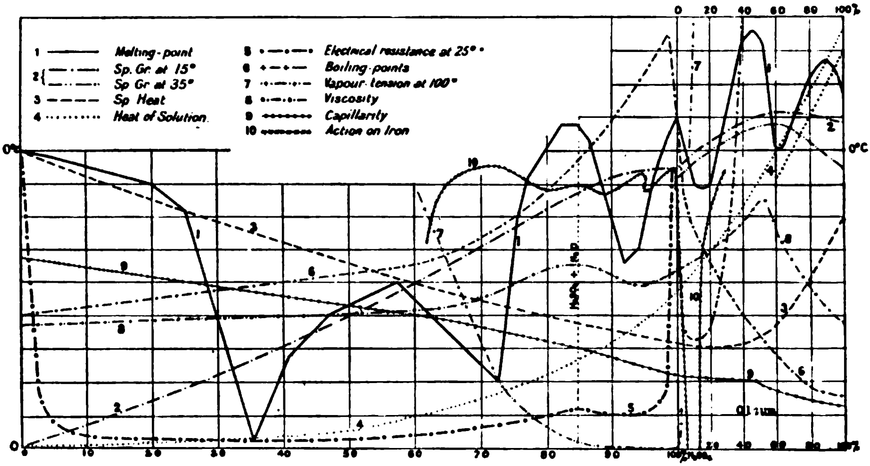

FIG. 1.

II. Density. Maxima at 98·3 p.c. H_2SO_4 and at 62 p.c. free SO_3.

III. Specific heat. Minimum at 20 p.c. free SO_3.

IV. Heat of solution. Rises steadily at increasing rate.

V. Electrical resistance. Great increase in conductivity caused by addition of a small quantity of acid to water. Indication of hydrate H_2SO_4,H_2O by small maximum there. Enormously rapid increase of resistance as H_2SO_4 approached (maximum resistance), and correspondingly rapid decrease on addition of SO_3 to H_2SO_4 until 10 p.c. free SO_3 reached, from which point there is again a rapid increase.

VI. Boiling-point. Maximum 98·3 p.c. H_2SO_4.

VII. Action on iron. Read from top of diagram. Maximum action at 10 p.c. free SO_3.

The action of sulphuric acids, both fuming and ordinary, on iron and lead is a matter of considerable importance, as these metals are used to a large extent in the processes of manufacture of these acids.

Cast iron. Acids of all strengths from chamber acid of 100°Tw. to 100 p.c. H_2SO_4 have very little action at ordinary temperatures, but if boiled in cast-iron vessels considerable action takes place with the weaker strengths, but it decreases as the acid becomes more concentrated, until at 98 p.c. H_2SO_4 the iron is scarcely attacked at all. Fuming acids below 20 p.c. free SO_3 have a somewhat greater action than 98–100 p.c. H_2SO_4, but above that strength the action practically ceases; but cast-iron vessels are not suitable for the manufacture of fuming acids, owing to the fact that the SO_3 penetrates into the pores of the metal causing strains (probably due to the formation of gases in the pores by action on the carbon) which cause them to suddenly crack without any warning.

On the other hand, wrought iron is unattacked by fuming acids above 27 p.c. free SO_3, but below that strength some action takes place, it being greatest about 10 p.c. free SO_3.

Wrought iron is acted on more rapidly than cast iron by acids below 100 p.c. H_2SO_4, especially at high temperatures, but in the cold the action is very slight with acids above 120°Tw., and wrought-iron or steel vessels are very largely used for conveying and storing acids of all strengths above 70 p.c. H_2SO_4.

Alloys of iron and silicon are much less attacked by boiling acids than iron itself, and vessels made of certain of these alloys (metillure and tantiron) may be used for concentrating even very weak acids up to 98 p.c. H_2SO_4. Fuming acids, however, energetically attack these alloys.

Lead. The action of acids up to 140°–150°Tw. is very slight even when heated to near the boiling-point of the acid, but if the latter is actually boiled the lead is strongly attacked. Above 150°Tw. up to 96 p.c. H_2SO_4 the action is still inconsiderable in the cold, but increases as the temperature rises, the lead being rapidly dissolved by ordinary concentrated sulphuric acid at about 250°–260°C. Monohydrate acts still more strongly, and fuming acids even at ordinary temperatures energetically attack this metal.

The impurities in ordinary lead have a considerable influence on its resistance to the action of sulphuric acid under different conditions. At ordinary temperatures, and even up to 100°C., the purest lead is least attacked by sulphuric acids concentrated or dilute. Impurities such as bismuth, antimony, zinc, or copper all have a harmful effect, but for very high temperatures approaching 200° as in the hottest concentrating pans the addition of a little copper (0·1–0·2 p.c.) appears to be of advantage (Lunge, Sulphuric Acid, vol. i. 209). The influence of physical condition and chemical composition on commercial lead for pan concentration of sulphuric acid has also been investigated by Hart (J. Soc. Chem. Ind. 1907, 504).

THE MANUFACTURE OF SULPHURIC ACID.

Two methods have been employed for the manufacture of sulphuric acid: (1) By decomposing natural or artificially prepared sulphates by heat, and (2) by burning sulphur or ores containing sulphur to sulphur dioxide, and further oxidising the latter to sulphur trioxide or sulphuric acid. Since about 1900 the first method has fallen into disuse, but before that time it had been employed for a great many years for making fuming acid, and it has been known for centuries, and was the original method by which sulphuric acid was first obtained.

During the last century, however, by far the larger quantity of acid has been obtained by the second method. If sulphur or materials containing sulphur are burnt in excess of air sulphur dioxide is produced, together with a little sulphur trioxide, and the oxidation of the sulphur dioxide is completed in one of two ways. 1. By the action of oxides or acids of nitrogen in the presence of steam or water; these oxides or acids act as carriers of oxygen from the excess of air present to the sulphur dioxide producing sulphuric acid more or less diluted with water. This is the basis of what is known as the chamber process, as it is carried out in large leaden chambers. 2. By the catalytic or surface action of certain substances, such as platinum, oxide of iron, &c., which under certain conditions have the power of causing the rapid combination of sulphur dioxide and oxygen to form sulphur trioxide. This is the basis of the contact process, and all fuming acid is now made by this method, and also a considerable amount of highly concentrated non-fuming or ordinary sulphuric acid.

THE LEAD CHAMBER PROCESS.

Early history. It has long been known that when brimstone and a small quantity of saltpetre are burnt together in moist air or in vessels containing water to absorb the fumes produced, an acid liquid results, which can be concentrated by evaporation. About 1740, Ward started a small factory at Richmond, Surrey, for the preparation of sulphuric acid by such a process. 8 parts of sulphur and 1 part of saltpetre were burnt together in a glass vessel shaped like a bell containing a little water at the bottom and kept warm on a sand-bath. As soon as the fumes from one charge were condensed, a second was introduced and fired, and this was continued until the acid was strong enough for use either at once or after concentration in glass retorts. The first improvement was the substitution by Roebuck in 1746 of lead vessels or chambers for glass bells; and 50 or 60 years later the use of steam from a separate boiler and of a continuous current of air with a sulphur burner separate from the leaden chamber were introduced. About 1818 a Mr. Hill of Deptford was the first to substitute pyrites for brimstone; in 1827 the Gay-Lussac tower for the recovery of the nitrous fumes carried away in the spent gas was invented, and in 1859 Glover built his first tower for denitrating the nitrous vitriol obtained from the Gay-Lussac tower, and for economising fuel by utilising the heat evolved in the combustion of the pyrites for concentrating the dilute chamber acid and supplying the chamber with a portion of the steam required for the process.

The essential characteristic of the chamber process is the action of the oxides of nitrogen in the presence of water in conveying oxygen to the sulphur dioxide, being reformed each time so that they react over and over again with successive quantities of sulphur dioxide, until the oxidation is practically complete; then the greater part of them may be recovered by absorption from the exit gas and introduced into the process again.

RAW MATERIALS FOR SULPHURIC ACID MANUFACTURE.

Brimstone. Commercial brimstone as used in the manufacture of sulphuric acid contains generally 95–98 p.c. sulphur, 2–5 p.c. ash, which is chiefly sand and calcium sulphate, and also a little bituminous matter. For European consumption the great bulk of it comes from Sicily.

A certain amount of sulphur recovered from alkali waste by the Chance-Claus process, and also from spent oxide of gas works, is used for acid making. The latter is usually dark-coloured owing to the presence of tarry matters. In the United States all the sulphur required for home consumption is obtained from Louisiana by the Frasch method of extraction (*v.* SULPHUR).

Technical analysis. Determination of moisture. 100 grms. are roughly crushed and dried at 212° in the steam oven until the weight is constant.

Determination of ash. 10 grms. are burnt in a tared porcelain dish and the residue weighed.

Direct estimation of sulphur (Macagno, Chem. News, 43, 192). 50 grms. of finely-ground brimstone are dissolved in 200 c.c. carbon disulphide in a well-stoppered bottle, and the specific gravity of the solution is determined at a given temperature *t*°. This is reduced to the sp.gr. at 15° by means of the formula

$$S = s \times 0{\cdot}00014\ (t-15)$$

(valid up to 25°), and the percentage of sulphur determined from the following table.

S	Percentage of sulphur	S	Percentage of sulphur
1·271	4×0	1·321	4×12·1
1·274	4×0·6	1·324	4×12·8
1·276	4×1·2	1·327	4×13·5

1·312	4×9·9	1·363	4×22·7
1·315	4×10·6	1·366	4×23·6
1·318	4×11·3	1·369	4×24·8

F. B. Carpenter (J. Soc. Chem. Ind. 1902, 832) states that if much gypsum is present, it interferes with the carbon disulphide treatment, and must previously be removed by boiling with hydrochloric acid.

Pyrites. Pure iron pyrites has the composition FeS_2, but commercial pyrites mostly contains more or less copper pyrites $Cu_2S{\cdot}Fe_2S_3$, together with varying amount of silicious gangue and small quantities or traces of arsenic, zinc, lead, antimony, selenium, mercury, thallium, &c. Its value is dependent quite as much on the quantity of copper present as on the amount of sulphur. The analyses given on p. 321 show the composition of the various kinds of pyrites that are, or have been, somewhat extensively used for the manufacture of sulphuric acid. It will be seen from the table that the sulphur may vary from 30 to about 50 p.c. The poorer ores, such as Wicklow containing only from 30 to 35 p.c. sulphur, are seldom used now, manufacturers preferring the richer Spanish and Norwegian ores, owing to the fact that the cost of handling and working pyrites is much the same, no matter what the percentage of sulphur may be, and at the same time the proportion of unburnt sulphur left in the 'cinders' will be the greater the lower the percentage in the ore before burning.

A certain quantity of pyrites is obtained in coal mining, and is picked from the coal (coal brasses). It always contains some adhering carbonaceous matter, which causes trouble in the chambers when it is burnt for sulphuric acid making.

Along the coast of the isle of Sheppey in Kent a considerable amount of pyrites has from time to time been collected on the beaches (having been washed out of the clay) and burnt for the production of sulphuric acid.

Analysis of pyrites. Determination of sulphur (Lunge's Technical Chemists' Handbook, 110). 0·5 grm. pyrites is heated with about 10 c.c. of a mixture of 3 volumes nitric acid (sp.gr. 1·4), and 1 of strong hydrochloric acid, solution being accelerated by heating now and then, and the whole is evaporated to dryness, heated with 5 c.c. more hydrochloric acid and evaporated again. The residue is moistened with 1 c.c. hydrochloric acid, and taken up with 100 c.c. hot water filtered and washed. The insoluble residue consisting of silica and silicates and perhaps some sulphates of lead or barium is usually ignited and weighed. The filtrate is heated with ammonia in slight excess, and after keeping hot, but not boiling, for 10–15 mins., the precipitated ferric hydroxide is filtered off and washed. If the filtrate and washings exceed 200 c.c. they are concentrated, slightly acidified with hydrochloric acid, heated to boiling, and 20 c.c. of a 10 p.c. solution of barium chloride (also hot) added. The precipitate is allowed to stand half an hour, the clear portion run off through a filter, and the residue heated with 100 c.c. of boiling water and allowed to settle 2 or 3 mins. This is again poured through the filter, and the washing by decantation repeated three or four times. The precipitate is finally transferred to the filter, washed, dried, and ignited, and the sulphur calculated from the weight of barium sulphate obtained. If the iron is not first removed a deficiency of 1–2 p.c. is apt to be occasioned owing to the solubility of barium sulphate in solutions of iron salts; whilst, on the other hand, a small quantity of ferric oxide is present in the ignited precipitate due to the precipitation of a double sulphate of iron and barium (Jannasch and Richards, J. pr. Chem. [ii.] 39, 321; J. Soc. Chem. Ind. 1889, 819). Lunge (Zeitsch. angew. Chem. 1889, 473; J. Soc. Chem. Ind. 1889, 966) finds that the precipitated ferric hydroxide may carry down some basic iron sulphate if the liquid is boiled until the smell of ammonia is all but gone, but not if the method is carried out as above described. A large number of other methods may be employed for the estimation of sulphur in pyrites, among which may be mentioned that of Fresenius (Zeitsch. anal. Chem. 1877, 335), in which the pyrites is fused with a mixture of sodium carbonate and potassium nitrate. That of List (Zeitsch. angew. Chem. 1903, 414), in which sodium peroxide is used, and Zulkowskys' method in which the pyrites is burnt in a stream of oxygen and the vapours are absorbed by potassium hypobromite solution.

To determine the sulphur left in the burnt ore, the material is dissolved in *aqua regia* and evaporated, the residue taken up with hydrochloric acid and water and precipitated as above by barium chloride whilst boiling, the removal of iron by ammonia being omitted.

J. Watson (J. Soc. Chem. Ind. 1888, 305) heats 3·2 grms. of the burnt ore with 2 grms. of sodium bicarbonate in a nickel crucible over

* Calcium carbonate.

low Bunsen flame for 5 or 10 mins.; the mass is then cautiously stirred with a wire stirrer, and the heat increased for 10–15 mins. more when the oxidation of the sulphur is complete. Finally, the mass is treated with water, and the excess of alkali titrated with standard acid, using methyl orange as indicator.

Lunge has investigated this method (Zeitsch. angew. Chem. 1889, 239; J. Soc. Chem. Ind. 1889, 572–1890, 1014), and finds that it is not only the simplest and cheapest, but also the quickest and most accurate test for the purpose.

Determination of arsenic. The method recommended in Lunge's Technical Chemists' Handbook is that of Reich, as modified by McCay. 0·5 grm. is decomposed by concentrated nitric acid, the solution evaporated nearly to dryness, and fused with 4 grms. Na_2CO_3 and 4 grms. KNO_3 for 10 mins. The mass is extracted with hot water, filtered, the filtrate acidified with nitric acid, and the arsenate precipitated with silver nitrate solution, the excess of acid being carefully neutralised with ammonia. The silver arsenate is dissolved in nitric acid, and the silver estimated by titration with ammonium thiocyanate, or the solution may be evaporated to dryness and the silver arsenate weighed.

Other metallic sulphides have recently come into considerable use for the manufacture of sulphuric acid, chiefly owing to legislation which has forced zinc and copper smelters to take measures to deal with the sulphurous gases liberated from their furnaces.

Zinc blende, which is the principal zinc ore, contains between 20 and 30 p.c. of sulphur, and the sulphur dioxide formed during the preliminary roasting process is very largely utilised for the production of sulphuric acid.

The following analyses of Rhenish blende are given by Minor (Chem. Zeit. 1889, 1602)—

Sulphur	30·24 p.c.	27·94 p.c.	22·11 p.c.	21·05 p.c.
Zinc .	27·76	31·92	40·29	37·81
Iron .	15·98	13·12	2·06	2·33
Gangue	21·02	27·02	35·54	38·84

The products from the roasting of copper ores and copper matte are now also largely used for vitriol manufacture.

The use of the **spent oxide** of gas-works for vitriol making has increased considerably during the last few years owing to its increased production. The sulphuretted hydrogen in coal gas is removed from it by means of a mixture of hydrated ferric oxide and sawdust, which can be made to take up so much sulphur by alternately exposing it to coal gas and air, that a product is obtained containing as much as 60 p.c. of sulphur available for conversion into sulphuric acid.

Davis (Chem. News, 29, 30; 36, 189) gives a number of other analyses.

Sulphuretted hydrogen, recovered from alkali waste, and from ammonia liquor during the manufacture of sulphate of ammonia is sometimes used for the manufacture of sulphuric acid. It is burnt either by itself or in conjunction with spent oxide.

The available sulphur in spent oxide is usually estimated by extracting the free sulphur in a Sohxlet extraction apparatus by means of carbon disulphide and weighing it; but this method is not altogether satisfactory as the tarry matters are dissolved out also by the disulphide, whilst any sulphur existing in the insoluble form is not estimated. A more satisfactory method is to burn the spent oxide in a current of oxygen, and to absorb the evolved sulphur dioxide in bromine water, estimating the sulphuric acid formed by precipitation with barium chloride. Davis and Foucar (J. Soc. Chem. Ind. 1912, 100) convert the sulphur into sodium thiocyanate by digestion with alcoholic sodium cyanide solution, the thiocyanate being then titrated with N/20 silver nitrate solution in the usual way.

Nitrate of soda. In the early days of vitriol-making, *saltpetre*—*i.e.* potassium nitrate—was the only salt practically available; but this has so long been superseded by the cheaper 'Chile saltpetre' or 'soda nitre' (approximately pure sodium nitrate[1]) that the term *nitre* in the vitriol trade is always understood as referring to the latter.

PLANT USED FOR THE MANUFACTURE OF SULPHURIC ACID BY THE CHAMBER PROCESS.

In a modern sulphuric acid plant for the manufacture of chamber acid there are required: (1) A burner for the production of the mixture of sulphur dioxide, oxygen, and nitrogen; (2) an arrangement for introducing nitrogen oxides or nitric acid into the burner gas; (3) a steam generator; (4) one or more large leaden chambers in which the oxidation can take place; (5) a Gay-Lussac tower for recovering the bulk of the nitrogen oxides from the exit gases; and (6) a Glover tower for introducing these oxides again and concentrating the chamber acid.

The production of sulphur dioxide. Brimstone burners. The simplest form consists of a brick chamber covered by an arch, the bottom being formed by an iron plate. There is a door in front, through which the brimstone is charged from time to time, and at the back a pipe for taking away the gas. The burner is started by heating the iron plate by lighting a small fire on it, and when hot enough to ignite the sulphur, the latter is charged at regular intervals through the door, which slides in a frame and is adjusted by a chain and balance weight, the admission of the necessary amount of air being regulated by it. There is an air channel beneath the iron plate to prevent it from becoming too hot, and so

---

[1] The average composition of sodium nitrate as used for vitriol making may be taken to be:

Sodium chloride . . .	0·5	
Sodium sulphate . . .	0·75	
Moisture	2·75	
Total 'refraction' (impurities) . . .		4·00
Sodium nitrate (by difference) . . .		96·00
		100·00

When the chloride present exceeds 1 p.c., the substance is apt to cause a considerable amount of loss of nitrogen oxides in the chambers.

causing the sulphur to sublime. The nitre pots containing the nitre and sulphuric acid may be placed in the midst of the burning sulphur, or better in a brick extension at the back of the burner. Several furnaces of this kind are usually combined together and charged at different times in order to obtain a gas of as uniform composition as possible. Each of them with plates 8 ft. by 4 ft. can burn 5 cwts. of brimstone in 24 hours. In some cases the gas passes from the burner into an upper chamber divided into two compartments, so that it has to pass from back to front and then back again before passing to a common flue; some additional air is admitted into this upper chamber in order to burn any sulphur which sublimes.

Harrison Blair's continuous burner consists of three parts. In front is a brick chamber into which the brimstone is charged either continuously by means of a hopper or at regular intervals. Here just sufficient air is admitted to keep up the heat of the furnace. The sulphur partly sublimes into a second compartment at the back, where sufficient air is admitted to complete the combustion, and the gas then passes to a chamber above in which the nitre pots are placed.

Fig. 2 represents Glover's brimstone burner. **A** is the burner plate fed by the hopper **B**; **C** is a chamber the upper part of which is filled with a network of firebricks, **D**, into which air is admitted by the pipes **F** to complete the combustion of the sulphur; **E** is a platinum dish, and **J**, **G** leaden pans for concentrating the acid; **K** flue to the Glover tower.

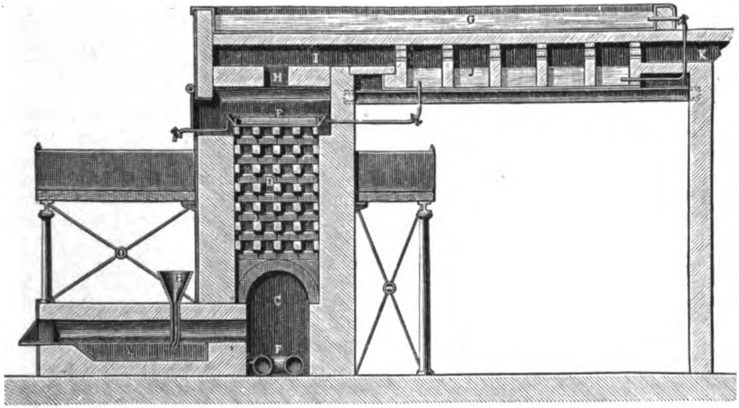

FIG. 2.

Pyrites burners. The bulk of the pyrites used for sulphuric acid manufacture arrives in large fragments which have to be broken either by hand or by crushing machines to a size suitable for burning. The broken ore is divided into 'smalls' and 'lumps' by screening through a ¼-in. or ½-in. sieve. The lumps should all pass through a screen with about 3-in. holes. Crushing machines produce more smalls than breaking by hand.

Burners for lump ore. These are generally known as kilns and they are constructed in such a way that the heat of combustion of the ore is utilised for maintaining the process without any extraneous fuel.

They are built in two rows back to back to avoid loss of heat (Fig. 3). The walls are of firebrick, the fronts being encased by cast-iron plates provided with various doors necessary for working. They are rectangular in section, and the ore in each kiln rests on a grate consisting of movable bars of 2-in. square section which can be rotated by a key which will fit on to the ends projecting through the front plate. By this means the space between the bars may be varied, being 2 ins. when their sides are vertical, and only 1¼ ins. when they are on edge. By rotating these bars the burnt ore is worked down into the ash pit below. The front of each kiln is also provided with a charging door about 2 ft. above the grate, and an ashpit door below the bars for removing the burnt ore. There is usually another opening between the charging door and the bars, which is only used occasionally when the ore forms slags or clinkers, which have to be raised and removed through the charging doors. The projecting ends of the bars are also boxed in and doors provided. The air admitted to each kiln is regulated by openings in the ash-pit doors. Fig. 3 shows a sectional elevation of two kilns built back to back. **A** is the charging door, **B** the small occasional working door, **C** the opening for turning the grate bars, and **D** the ash-pit door. The top of each burner is formed by a firebrick arch with an opening through which the gases pass to a common flue. These openings may be provided with dampers

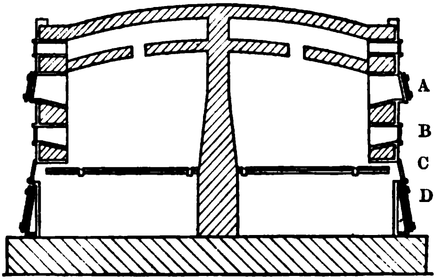

FIG. 3.

worked from the front. In some cases, usually in Continental works, the side walls do not completely separate the kilns, and the gases mix in the space above the burning ore, so that a common flue on the top of each row is not required. The ore may also be charged through the top by means of a hopper closed by a cone which can be lowered by a lever worked from the front of the kiln, and if the latter is well raised above the ground level the bottom of the ash pit may also be in the form of a hopper closed by a sliding door, so that the burnt ore can be dropped into a receptacle below the burner; or the ash pit may be made deep enough to allow the introduction of an iron bogie into which the burnt ore drops, and it can be thus expeditiously removed. The walls generally have a slight slope inwards below the charging door, so that the area at the grate bar level is a little smaller than that at the charging door. English burners are usually 4–5 ft. wide, and 4½–6 ft. from back to front at the grates. The depth of ore, which is determined by the height of the working door above the bars, may vary from 14 ins. to 2 ft. 6 ins., and depends usually on the percentage of sulphur in the pyrites, poor ores requiring a much greater depth than rich ores. In England for rich ores a depth of at least 2 ft. is employed, but on the Continent 16–18 ins. is more common.

In order to start a burner it is filled up with burnt ore up to about 3 ins. below the working door, and the top layer is brought to a dull-red heat by lighting a coke fire on the top. After about 24 hours the ore is hot enough, when the partially burnt coke is removed as far as possible, and the charge of pyrites is thrown in by the kiln-man and spread evenly over the surface. The amount charged will depend on the area of the kiln, the richness of the ore and the length of time between two successive charges. Usually with large kilns of 25–30 square ft. area the charge is put on every 24 hours, and with rich Spanish ore containing 48 p.c. sulphur, 6–9 cwt. is the weight charged, or from 30–40 lbs. per sq. ft. area. With poorer ores, such as Westphalian, containing 40–42 p.c. sulphur, 50–60 lbs. may be burnt per 24 hours per sq. ft. area (Hasenclever). Davis (Chem. Engineering, ii. 88) states that with Aguas Tenidas ore containing 50 p.c. sulphur he has burnt 55 lbs. per sq. ft. per 24 hours down to 1 p.c. sulphur, but the area employed only amounted to 14 sq. ft. With kilns of small area it is more usual to charge every 12 hours.

When the charge appears to be burnt off and shows no more sulphur flames (18–20 hours after charging for 24-hour charges) the surface is broken up by poking and raking, a certain amount of burnt ore being at the same time allowed to drop into the ash pit by turning the grate bars, and the burner gradually cools and is ready to charge again at the end of the 24 hours. The amount of air necessary is regulated by opening or closing the slides or holes in the ash-pit door as required. Usually 20–24 kilns are charged in rotation during the 24 hours, in order that the composition of the burner gas may be as uniform as possible. By the time the ore reaches the bars (5 or 6 days after it is charged) it should be nearly cold, and should not contain more than 3 p.c. sulphur, in the case of rich cupreous ores such as Rio Tinto or Tharsis pyrites. With non-cupreous pyrites the sulphur may be burnt as low as 1 p.c. The regulation of the draught requires considerable care. If too little is employed the ore will form slags or clinkers owing to the formation of fusible iron monosulphide FeS, and at the same time sulphur will sublime. These slags must not be allowed to get down on the bars, where they would stop the draught, but must be lifted by means of heavy pokers and broken up and pulled out of the working door. If the draught is too great the burners get cold and will not light readily when charged, and the burner gas will get too weak owing to the excess of air employed.

The air supply for a set of kilns is controlled behind the burners by means of a damper which may be placed either before or behind the chambers, and before each burner by holes in the ash-pit door. If the Glover tower and chambers are well raised above the kilns, or mechanical draught is employed, these means of control may be so regulated that no escape of gas takes place when the working doors are open for charging or poking, but at the same time a good deal of air enters and disturbs the uniform working of the chamber process; and this also happens when the ash-pit door is open during the removal of the burnt ore. Charging by means of a hopper in the top of the kiln, and discharging the burnt ore in a similar way below the ash pit, reduces this disturbance to a minimum. In many cases every time a working door is opened a good deal of gas escapes into the atmosphere; attempts have been made to prevent this by closing all the air slides in the ash-pit doors whenever a kiln is being charged (Norrington, Eng. Pat. 4131, 1878); or by connecting the ash pit when a door is open by means of a special flue with a chimney, the draught from which is so regulated that no burner gas is drawn down into it, but it is sufficient to prevent any blow out at the door during charging. The admission of air may also be checked from time to time by analyses made of the percentage of sulphur dioxide in the burner gas and of oxygen in the gases escaping from the chambers, the latter figure giving the average amount of surplus air admitted during the whole process of charging, burning, poking, &c.

Burners for smalls. At one time the use of smalls burners was mainly confined to the working up of the dust of the pyrites produced in transport or during breaking; if this does not amount to more than 7½ p.c. of the ore it may be burnt with the lumps if it be carefully distributed along the sides and back, and in the front corners of the kilns, leaving the central part free; or it may be made into balls or cakes after grinding up with water and drying on the top of the kilns; incipient oxidation takes place, and the mass binds together sufficiently hard to burn with the lumps. Formerly balls were made by the addition of clay and drying, but this method is no longer used, as the clay interfered with the burning and with the subsequent extraction of copper. During recent years large quantities of smalls have been received direct from the mines, being produced during the mining operations or from ore from which the copper has been extracted by weathering and washing out with water. Special smalls burners are necessary for burning these. In the earliest type, of which Spence's is an example, the ore was heated in a closed muffle or roaster by the flame from a coal fire, but this has long been superseded by arrangements requiring no extraneous heat. Sometimes the smalls are burnt on fire-clay shelves arranged above the burning pyrites in ordinary lump ore kilns, but this method has not proved satisfactory, much surplus air entering the burner during charging and removing the dust. Hasenclever and Helbig employed a series of alternate sloping shelves, one above the other in a square tower up which ordinary kiln gases passed, but this type of burner has become obsolete. In the Maletra furnace the heat of combustion of the smalls alone is sufficient to desulphurise the ore, and this type of burner has been worked successfully for many years both on the Continent and in England. As originally constructed, the burners are arranged back to back, there are six shelves to each, and each shelf is provided with a working door in front. In Schaeffner's modification (Fig. 4) the burners are arranged in a single row, there are seven shelves, the doors being alternately arranged four in front and three at the back. The chief drawbacks to this type of furnace are the considerable amount of labour required in working, and the excessive introduction of 'false' air during the frequent opening of the doors for the purpose of moving the ore from shelf to shelf. The cost of repairs for the furnaces is also considerable.

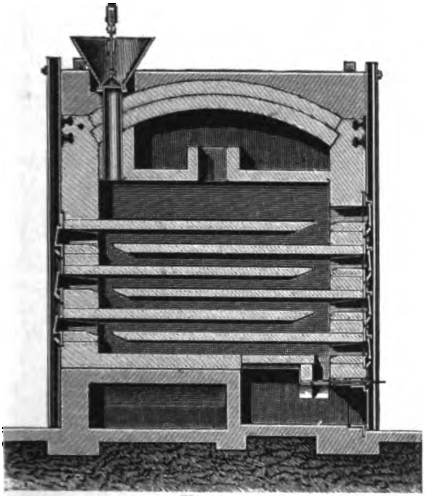

FIG. 4.

W. Crowder (J. Soc. Chem. Ind. 1891, 295) gives the following figures as the average of a number of daily tests of the sulphur contained in the partly-burnt ore on each of the seven beds of a Schaeffner kiln, charged with pyrites containing 50 p.c. sulphur every 8 hours, so that it took 56 hours for the ore to pass through the kiln from shelf to shelf.

Mechanical smalls burners. The MacDougall furnace, patented in 1868, was the first burner of this type to be employed for burning smalls. It consists of a cast-iron cylinder, 6 ft. diameter by 12 ft. high, made in seven sections, bolted together, and is divided into seven chambers by fire-brick arches. Through the centre a vertical cast-iron shaft passes to which are attached a number of rakes, the teeth of which are so arranged that as the shaft revolves they move the ore alternately from centre to periphery and from periphery to centre on successive beds. The ore is continuously charged on to the top of the furnace by an elevator, and after travelling to the outer edge it drops into a receptacle from which it is continuously pushed into the top closed chamber by a ram, the rate of movement of which regulates the feed, and after passing from shelf to shelf is finally discharged at the bottom completely burnt. The air is continuously supplied by means of an air pump into the lowest chamber, and travels up the furnace in the opposite direction to the ore, the burner gas leaving the top section by a pipe leading to the chambers. The enormous amount of dust carried forward was the chief drawback to the MacDougall furnace when first introduced, and also the great wear and tear of the shaft and rakes due to excessive heat. The first-mentioned drawback was due to the small diameter of the burner, and the method of introduction of the air. The wear and tear was considerably reduced by making the shafts and rakes hollow and cooling them by air, and the dust carried away was somewhat reduced by substituting ordinary induced draught for the air pump, and providing dust chambers with perforated baffle plates for the interception of the dust (MacDougall, Eng. Pat. 3985, 1883). The MacDougall furnace has been further improved by Frasch, who employs water as the cooling medium for the shaft and rakes. Another modification is the Herreshoff burner (Fig. 5), in which the shaft is air-cooled. It is described by Gilchrist (J. Soc. Chem. Ind. 1899, 460). It consists of an upright steel shell lined with firebrick about 10 ft. high and 10 ft. diameter; the arms or rakes are inserted into sockets in the shaft and can be detached and replaced in a few minutes. There are five shelves with two rakes to each shelf. The ore is fed automatically from a hopper on to the top shelf by means of a plunger moving backwards and forwards, so much dropping at each revolution of the shaft. These furnaces will burn up to 3 tons of rich Spanish pyrites per 24 hours, between 2 and 3 p.c. of sulphur being left in the 'cinders,' and will furnish a richer gas than hand-worked furnaces. The hot air leaving the hollow shaft may be utilised for drying the ore by a suitable arrangement. The power required is about ⅔ h.p. per furnace.

Spence's mechanical furnace, patented in 1878, has met with some success in America (Lunge). It is a shelf burner of the Maletra type, provided with mechanical stirrers which travel to and fro from the front to the back of each shelf.

In the Kaufmann furnace, which is of the Herreshoff type, there are only three shelves, and the teeth on the rakes are so constructed that the ore is moved forward a certain distance, and then back a shorter distance during each revolution (Truchot, Proc. Seventh Int. Congr.

App. Chem. 1909; J. Soc. Chem. Ind. 1911, 280). The O'Brien furnace (U.S. Pat. 775147, 1904) is also a modification of the same type. The Wedge furnace represents the latest development of the mechanical burner. It can be constructed to burn 20 tons of pyrites per 24 hours, and is six or seven times as large as the ordinary Herreshoff burner. The shaft consists of a hollow steel cylinder, 4 ft. diameter, and its main feature is that it permits of repairs being made without interruption of its working (Hasenclever, J. Soc. Chem. Ind. 1911, 1291).

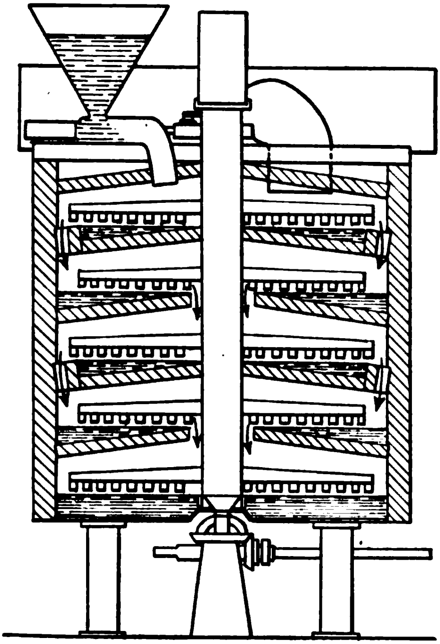

Fig. 5.

The new Herreshoff furnace (U.S. Pat. 976175, 1910) is also constructed to burn up to 20 tons pyrites per 24 hours. Both shaft and arms, which are hollow and of cast-iron, are cooled by forcing air through them by means of a fan. Part of the hot air so obtained is utilised for the combustion of the ore by introducing it into the lower beds, considerably increasing thereby the capacity of the furnace.

The chief advantage of the mechanical burner over hand-worked kilns is the saving of labour, but a good deal of this is counterbalanced by the cost of repairs. Lüty states (Zeitsch. angew. Chem. 1905, 1253) that hand-worked burners are cheaper than mechanical burners if the cost of labour is below 4*s*. per man per shift. An additional advantage is the regular composition of the burner gas obtained, owing to the fact that it is seldom necessary to open the doors of the furnaces.

Wherever smalls burners are employed it is necessary to provide a dust chamber to arrest the bulk of the dust carried forward from the furnaces. This chamber usually consists of a large expansion of the flue with or without baffle walls arranged in various ways, the main objects being to retard the speed of the gaseous current and to offer large surfaces on which the dust can deposit. At the same time the gas must not be too much cooled, nor must the baffle walls interfere seriously with the draught. If the surfaces are arranged in the direction of the current itself they do not seriously affect the draught, and yet collect a large amount of dust. With mechanical burners the amount of dust carried forward is very considerable, and it may contain as much as 10 p.c. unburnt sulphur. O'Brien's dust-catcher, described by Falding (Min. Ind. ix. 623) consists of a hopper-shaped iron shell 8 ft. wide at the top and 12 ft. high, lined with firebrick. The gas enters tangentially at the top and leaves by a central vertical pipe. The separation of the dust is due to centrifugal action, and it drops to the bottom and is discharged. 75 p.c. of the dust from five Herreshoff furnaces is retained by it. Benker and Hartmann (Fr. Pats. 372644, 1906; 387456, 1908) filter the gases and free them from dust by passing them horizontally through vertical filters composed of pieces of firebrick or burnt ore, the filtering material being continuously removed from the bottom and returned to the top after separating the dust.

Guttmann (J. Soc. Chem. Ind. 1903, 1331) states that good results have been obtained from tangential dust chambers on the principle of Meyer's acid chambers.

The Howard dust-chamber (U.S. Pat. 896111, 1910) consists of a brick chamber containing a large number of horizontal steel plates 2½ inches apart, between which the gases pass from one side to the other and deposit the dust on the large surface so obtained.

Furnaces for zinc blende. For this purpose, muffle furnaces were first employed, identical in principle with Spence's furnace for pyrites smalls, but not more than 60 p.c. of the sulphur could be utilised for sulphuric acid production from these, and they have been superseded by various forms of shelf-burner, which combine the heat produced by the burning of the ore with heat applied externally, but in such a manner that the fire gases are kept entirely separate from the roasting gases. Eichorn and Liebig (D. R. P. 21032) were the inventors of this type of furnace, by which the whole of the sulphur could be utilised for vitriol manufacture, and it has been modified and improved by Hasenclever in the Rhenania furnace, which consists of three superposed muffles, around which the fire gases circulate, and the ore is moved from one muffle to the next below, as in the Maletra furnace (Lunge, Sulphuric Acid, vol. i. 361; and Hasenclever, Chem. Ind. 1899, 25).

Of mechanical furnaces for roasting blende, Matthiessen and Hegeler's furnace has been worked successfully for a number of years in America at La Salle. It is a combination of Eichorn and Liebig's burner, with a stirring arrangement similar to Spence's. Hasenclever states that mechanical blende burners have not made much progress in Germany owing to the fact that the ores used contain lead and sinter when roasted, sticking to the moving parts and causing frequent stoppages (J. Soc. Chem. Ind. 1911, 1291).

Furnaces for galena. The gases from the roasting of galena or lead sulphide by the Huntington-Heberlein process are now used for sulphuric acid manufacture in several places in Germany; the working of these converters is intermittent, and a fairly continuous gas current can only be obtained by working a large number of converters charged at regular intervals. The Dwight-Lloyd furnace works continuously and can be made to deliver a regular gas current of 4–6 p.c. SO_2 by separating continuously the rich from the poorer gases and about 90 p.c. of the sulphur can be utilised for sulphuric acid manufacture (Hasenclever, *l.c.*).

Spent oxide of the gas works is usually burnt in a special kind of shelf burner (Hill's burner) of the Maletra type. MacDougall's furnace with four chambers only has also been used for a number of years for burning this material, and latterly a modification of the Herreshoff burner with three shelves has been introduced very successfully for this purpose.

The Harris mechanical furnace (Eng. Pats. 23331, 1910, and 25142, 1911) for roasting spent oxide (it is also used for pyrites) has special dust-trapped openings for discharging the oxide from bed to bed; it is said to require no dust-chamber (Chem. Trade J. Jan. 25th, 1913, p. 99).

Burners for sulphuretted hydrogen. Sulphuretted hydrogen, as obtained from ammonium sulphate works, may vary greatly in composition, and always contains a large amount of carbon dioxide; it is frequently burnt in conjunction with spent oxide in ordinary oxide burners or even in pyrites burners. As obtained from alkali waste in the Chance process, its composition is much more uniform, and it may be burnt by itself in a brick chamber provided with baffling walls which help to keep up the heat of the burner and also to mix the gases thoroughly and so ensure perfect combustion.

The burner gas. The quantity of air necessary for the complete combustion of sulphur in the different materials used for vitriol manufacture will vary considerably with the nature of those materials. Thus for free sulphur, pyrites, zinc blende, and sulphuretted hydrogen, the following equations represent the chief reactions taking place—

$$S+O_2=SO_2$$
$$4FeS_2+11O_2=8SO_2+2Fe_2O_3$$
$$2ZnS+3O_2=2SO_2+2ZnO$$
$$2H_2S+3O_2=2SO_2+2H_2O$$

which indicate that for a given weight of sulphur converted into sulphur dioxide the quantities of oxygen or air requisite will be in the proportion of 8, 11, 12, and 12 respectively. In addition to this, oxygen is required to convert the sulphur dioxide to sulphur trioxide, and a further excess is necessary to ensure the satisfactory working of the process. In the case of brimstone it is usual to employ such a surplus of air as will, after all the sulphur dioxide is oxidised and condensed, leave 5 p.c. oxygen in the exit gas, which corresponds to the following composition of the burner gas—

$$\begin{aligned} SO_2 &= 11{\cdot}23 \\ N &= 79{\cdot}00 \\ O &= 9{\cdot}77 \\ \hline & \quad 100{\cdot}00 \end{aligned}$$

For spent oxide no definite figures can be given, owing to the varying quantity of organic matter present.

For pyrites opinions differ as to the excess of oxygen required; Lunge considers 6·4 p.c. in the exit gas as about the proper amount, and the same for blende. Taking this figure the theoretical composition of the burner gases would be—

From pyrites	From zinc blende
$SO_2 = 8{\cdot}59$	$SO_2 = 8{\cdot}12$
$N = 81{\cdot}54$	$N = 82{\cdot}19$
$O = 9{\cdot}87$	$O = 9{\cdot}69$
100·00	100·00

(Lunge, Sulphuric Acid, vol. i. 398).

In addition to sulphur dioxide a certain amount of sulphur trioxide is always formed when these substances are burnt. In laboratory experiments with brimstone, Lunge found that 2·48–2·8 p.c. of the sulphur is obtained as sulphur trioxide, and 5·05 p.c. in the case of pyrites. In the latter case, the increased proportion is doubtless due to the catalytic action of the oxide of iron present, for if the gases be passed over a layer of hot ferric oxide, the percentage of sulphur trioxide may be largely increased. The author has found about 6 p.c. of the sulphur present as sulphur trioxide in the gases, both from lump burners and from smalls burnt in Herreshoff furnaces. From each lump ore burner the percentage may vary from 2 p.c., when the charge is freely burning and the sulphur dioxide is at its maximum, to 20 p.c. when the sulphur dioxide is a minimum and the charge is almost completely burnt. Lunge states that in blende roasting gases he has found as much as 25 p.c. of the sulphur present as sulphur trioxide. The presence of this sulphur trioxide affects the above-mentioned figures for the theoretical burner gas by reducing the percentages of sulphur dioxide and oxygen, and a further alteration is caused by the fact that the burnt ore contains some sulphates of iron and copper, which will also reduce the oxygen content slightly and increase the nitrogen, and also a little ferrous sulphide, the presence of which will have the reverse effect.

In practice brimstone burner gases generally contain from 10–11 p.c. sulphur dioxide, and the gases from rich pyrites 7–8 p.c. sulphur dioxide.

Analysis of the burner gas. Generally the process is controlled by determining the sulphur dioxide in the burner gas, and the oxygen in the exit gas. For the sulphur dioxide Reich's method is usually employed: a tube is inserted in the burner flue and the gas is aspirated slowly through a solution containing 10 c.c. N/10 iodine solution in 50 c.c. water, together with a little starch and sodium bicarbonate until the blue colour of the iodide of starch is discharged; the volume of water run out from the aspirating bottle+11 c.c. for the sulphur dioxide absorbed gives the volume of burner gas used from which the p.c. of sulphur dioxide may be calculated or taken from the following table (Lunge's Technical Chemists' Handbook, 117).

Volume of gas aspirated	P.c. SO_2 by volume	Volume of gas aspirated	P.c. SO_2 by volume
82	12	128	8
86	11·5	138	7·5
90	11	148	7
95	10·5	160	6·5
100	10	175	6
106	9·5	192	5·5
113	9	212	5
120	8·5		

Raschig (Zeitsch. angew. Chem. 1909, 1182) states that the addition of sodium acetate prevents nitrous acid from interfering with the iodine test for SO_2.

For the determination of oxygen the gas is first treated with caustic soda or potash to absorb any acid vapours or carbon dioxide present, and then the oxygen may be absorbed by phosphorus, alkaline solution of pyrogallol or ammoniacal cuprous chloride in an Orsat or similar apparatus. Alkaline pyrogallol absorbs oxygen very rapidly, only a few minutes being required for each test, but the solution does not keep well. With phosphorus about half an hour is required, and the temperature must be kept above 16°. Below that temperature the absorption is very slow. The phosphorus is employed in the form of thin sticks or beads, and is always kept under water except during its exposure to the gas which is being tested.

If the total acidity of the gas is to be determined a standard solution of caustic soda is employed with phenolphthalein as indicator. This will give the SO_2+SO_3 (Lunge, J. Soc. Chem. Ind. 1890, 1014). If the ore contain much organic matter, as when coal brasses or spent oxide are burnt, the carbon dioxide present will render this method inaccurate.

Comparison of brimstone and pyrites for sulphuric acid making. The advantages of using brimstone are—

1. Only about ⅔ of the chamber space is required as when pyrites is burnt owing to the burner gas being so much richer in SO_2; this means less cost of plant.

2. The burners give less trouble in working and require less labour.

3. The acid obtained is much purer than pyrites acid, being free from arsenic and iron.

But these advantages are mostly more than counterbalanced by the fact that in most countries pyrites-sulphur only costs about half the price of brimstone, and that for some of the largest applications of sulphuric acid (*e.g.* the manufacture by the Leblanc process of saltcake or crude sodium sulphate for glass-making and alkali-making, the preparation of superphosphate, ammonium sulphate, and artificial manures generally) the impurities in pyrites acid are of little or no importance.

For manufacturing articles of food, for storage batteries and certain other purposes, these impurities are harmful, and there is still a certain amount of brimstone acid made in this country for these purposes, but it is gradually being displaced by purified pyrites acid from which the arsenic has been eliminated by precipitation as sulphide and filtration, and by acid made by the contact process in which the burner gases have to be purified to such an extent that an acid is obtained quite equal to brimstone acid in purity. Acid made from spent oxide of gas works, being practically free from arsenic, is also used in many cases in place of brimstone acid.

In America (where the disproportion between the price of brimstone and pyrites suitable for vitriol-making is, in many localities, not so great as elsewhere) the manufacture of brimstone acid is still carried out to a considerable extent, but even there during the last few years the use of pyrites and other sulphur ores has enormously increased.

Apparatus for introducing nitrogen oxides. There are two chief ways in which the nitrogen oxides are introduced into the burner gas. In the first, nitric acid is evolved from a mixture of sodium nitrate and sulphuric acid introduced at intervals into an iron pot placed in the hot burner gas flue; whilst in the second, nitric acid is introduced in the liquid form either in the Glover tower along with the nitrous vitriol or into the first chamber.

Opinions differ as to the relative advantages of the two methods, the potting system being mostly in favour in Great Britain, whilst Continental manufacturers more often employ the liquid acid method. The points in favour of the latter are the following: A more uniform introduction of the nitric acid vapours is possible than in the potting system, the admission of 'false' air, which takes place when the pots are charged or discharged, is avoided, and if at any time an extra supply of nitrogen oxides is temporarily required it can be instantly procured by increasing the rate of flow of the nitric acid. On the other hand, the use of liquid acid involves extra cost in distilling the acid, and more outlay for labour, carboys, and appliances for introducing it into the process, and when introduced into the chamber it may cause corrosion of the lead if not completely vaporised before reaching the bottom; this danger, however, is completely avoided by introducing it into the Glover tower.

The nitre pot system as first applied to brimstone burners was carried into effect by placing the cast-iron pots containing the mixture of nitre and sulphuric acid on the floor of the burner. As, however, they frequently frothed over and damaged the burner, they are now always placed in an extension of the latter where they are heated by the hot burner gases.

With pyrites burners the pots are usually placed in a separate nitre oven, practically an enlargement of the flue just beyond the last kiln with a door in front for introducing them and withdrawing them by means of a stout fork. The bottom is protected by a cast-iron tray to catch boilings-over, and the pots are charged at regular intervals in order to keep as equable a supply of nitrous vapours as possible. Every time the oven door is opened much air gets into the flues, and much gas escapes, and to avoid this the following arrangement is now frequently employed. There are usually two pots, each large enough to hold ½ cwt. of nitre; they are fixed in the flue, and each is provided with a tubular spout at one end, which is plugged up when in use, and projects outwards from the oven. From 7 to 14 lbs. of nitre are charged into the pots alternately at regular intervals through a small hopper in the top of the oven, and a slow stream of sulphuric acid is run on to it by means of an S-shaped tube from a small tank provided with a stop-cock to regulate the rate of flow, so that a steady stream of nitric acid is liberated during each interval of charging; when about 56 lbs. of nitre have been worked off, the outlet plug is removed, and the fused nitre cake (acid sodium sulphate often designated Sally Nixon, *i.e.* sal enixon) is allowed to run out into a cast-iron saucer where it solidifies.

When the liquid acid method is employed, if there is no Glover tower the acid is introduced into the first chamber (usually a small preliminary one), being made to run intermittently or regularly over some distributing arrangement, exposing a large surface; such as a tall pyramid of glass or stoneware dishes or cylinders of such dimensions that the whole of the acid is volatilised before it reaches the lowest dish, which, however, should be provided with an overflow pipe to take away any acid which escapes vaporisation out of the chamber in order to prevent serious corrosion of the lead.

The acid may be introduced at a uniform rate by means of a Mariotte's bottle in which a constant pressure of liquid is maintained by only allowing the air to enter by a tube reaching down to within a short distance of the outlet.

Another method is to spray the acid into the chamber by a steam jet analogous to the arrangement used by Sprengel for spraying water. The best and simplest method is, however, to feed the acid in along with the nitrous vitriol and chamber acid at the top of the Glover tower; for although at one time it was thought that this mode of supply was likely to cause loss of nitre, experience has shown that there is no increase in the consumption when this method was substituted for the cascade system (Lunge).

Where the sulphuric acid is intended for the manufacture of saltcake or superphosphate the nitric acid is sometimes introduced as a solution of nitre in water or dilute sulphuric acid, either by spraying into the chambers or running through the Glover tower. In the chamber there is the danger that it may reach the bottom acid undecomposed and cause corrosion, whilst stoppage from crystallisation of solid sodium sulphate is apt to occur when it is used in the Glover tower.

Occasionally the chambers are fed with nitrous gases obtained as by-products. Lunge states that at the Uetikon works near Zurich nearly all the nitre required for the chambers is obtained in the manufacture of ferric sulphate (iron mordant) by treating ferrous sulphate with nitric acid.

The lead chambers. These are usually placed at a considerable height above the ground, and are supported on brick or stone walls or piers, or on pillars of wood, or cast-iron columns. The space below can be used for storage purposes, or even for the pyrites kilns if high enough. On these piers or walls are placed stout wooden beams which carry the transverse joists which support the chamber bottom. These joists project several feet beyond the chamber frame in order to allow for passages between and around the chambers, and they are covered with a smooth wooden floor. In some cases the beams are arranged from pier to pier across the width of the chamber and the joists then run in a longitudinal direction. Upon this floor the chamber frame is erected. The sides consist of two stout horizontal rectangles of wood, the sole-tree or sill, and the crown-tree or capping, connected by uprights or standards, which are mortised into them, and further tied by cross rails or stays. The crown-tree carries the transverse joists to which the roof of the chamber is attached. American pitch pine is usually employed for this framework, and is the best timber for the purpose, and wherever acids are concerned.

The chamber itself is usually constructed of sheet lead of such a thickness as to weigh 6 lbs. per square foot, occasionally 7 lbs., especially for the first chamber of the series, which being the hottest is the most readily attacked. In America 5 lb., or even 4 lb. lead is sometimes employed. The sides and roof are attached to the wooden framework by means of lead straps which are nailed to the uprights or cross rails and to the roof joists, the nails having lead-coated heads to enable them better to resist corrosion. These straps are burnt to the sheet lead by the flame of a blowpipe burning hydrogen in compressed air, or coal gas may be used with compressed oxygen from a steel cylinder. Usually the sheets themselves are similarly fused together, but sometimes unfused rabbet joints are employed, made by folding the edges over and then beating down flat. The roof and sides are burnt together at the crown-tree, and sometimes the bottom is also fused to the sides so that the whole chamber forms one gigantic water- and gas-tight leaden box; but more frequently the sides are suspended like a curtain in a large flat dish made by turning up the edges of the bottom 12 or 15 ins. or even to a greater height up to 2 ft. 6 ins. if much acid storage room is required, and the construction will allow it. This dish or saucer is always kept luted with acid when the chamber is at work, and the upstand is protected all round by a 1-in. board to resist the outward pressure of the acid.

In Great Britain the chambers are seldom roofed in, the tops sloping slightly from one side to the other to allow the rain water to run off into a gutter, but the sides are usually protected from the wind by light wooden or corrugated iron walls. On the Continent, however, where the variations in temperature from summer to winter are greater, they are usually completely enclosed in buildings. Wherever possible the lead should be kept clear of the wooden framework of the chamber in order to allow efficient air cooling, the lead being more rapidly attacked where it is in contact with the wooden uprights, joists, &c. At some places the chamber frame is made of angle iron. In the Moritz system of construction (Fr. Pat. 395694, 1908; Chem. Trade J. 1911, 493) a strongly built skeleton of iron encloses the chambers, which are suspended from overhead beams by tie rods attached to the walls by lead strips; the top of each chamber is arched to prevent the accumulation of dust and to avoid dead corners, and the floor rests on perforated sheet iron supported by brick columns; the upturned edge is also iron plate bent under the floor. The advantage claimed for this system is the uniform cooling which takes place, and which prevents local corrosion such as ensues where a wooden frame is in contact with the lead.

Chambers are usually of rectangular shape, 100–130 ft. long, 20–30 ft. wide, and 16–25 ft. high. They have been constructed up to 300 ft. in length, where there is only one large chamber employed. Since the introduction of water spraying instead of steam the tendency has been to increase the height to 25–33 ft., and at the same time to make them narrower, not more than 20 ft. wide. At the Rhenania Chemical Works the top corners are cut off to suit the shape of the roof and avoid dead corners (Lunge). The annular chambers of

Delplace (Eng. Pat. 5058, 1890) have been tried in several places, but do not seem to offer any advantages over those of the ordinary rectangular shape. Meyer's tangential chambers of circular or polygonal section (Eng. Pat. 18378, 1888) have been erected at a number of works on the Continent; the gas enters tangentially on the upper part of the sides, and the outlet pipes are in the centre of the bottom (Chem. Zeit. 1899, 296; Zeitsch. angew. Chem. 1899, 656; 1900, 739; 1901, 1245).

In England all the chambers are generally of equal size, three or four forming a set and taking the gas from one set of kilns; or five or six chambers may be combined and take the gases from two sets of burners, the fifth and sixth being common to the two sets; but in France one large chamber is frequently employed with small ones before and behind it. Hasenclever (Chem. Ind. 1899, 26), at the Rhenania Works, combines two large chambers with two small back ones, whilst other manufacturers prefer three chambers in series decreasing in size from the first to the last.

The capacity of each chamber varies between 25,000 and 70,000 cb. ft., but occasionally they may be constructed as low as 10,000 cb. ft., or as high as 140,000 cb. ft. The total capacity of a set is seldom more than 200,000 cb. ft., but Hasenclever mentions the existence of sets of 420,000 cb. ft. capacity. The average capacity will probably be between 100,000 and 150,000 cb. ft. Meyer's tangential chambers are usually about 33 ft. in diameter and 26 ft. high, and are combined in sets of three (66,250 cb. ft. total capacity). Falding (Eng. and Mining J. 1909, 441; U.S. Pat. 932771, 1909) recommends the use of one large chamber of such a height that its vertical axis is in the proportion of 3 to 2 over any horizontal axis. Small chambers require more lead and occupy more space than large ones of equal capacity, and it is taken as a practical rule that for every cubic foot of chamber space there should be about 0·2 sq. ft. of total surface (top, bottom, sides, and ends).

The different chambers of a set are sometimes arranged so that each is a few inches higher than the preceding one in order to enable the weaker acid produced in the last chamber to be run back into the stronger first chamber, and to get rid of traces of nitre which it usually contains. If the chambers are on the same level injectors are used for this purpose.

The connections between the chambers may be circular or rectangular in section, and are usually constructed of 10–12 lb. lead, those of the latter shape being supported by a wooden frame-work, whilst the round pipes are held in position by means of iron hoops with wood laggings. Considerable difference of opinion exists as to where they should leave and enter the chambers, some being of opinion that the gases should leave each chamber near the top and enter the next near the bottom, while others prefer the reverse arrangement. According to Lunge and Naef's experiments, it is a matter of indifference where the connecting tubes are placed, but Porter (J. Soc. Chem. Ind. 1902, 476), after describing some experiments with a glass model to show the path which gases travel in the chamber, recommends that they should enter near the bottom and leave near the top of each chamber.

There is a certain definite relationship between the total cubic capacity of a set of chambers and the quantity of acid produced in a specified time. The number of cubic feet of chamber space required for condensing the acid from 1 lb. of sulphur burnt in 24 hours (the form in which it is usually expressed in England [1]) will depend on a number of different factors. It will be less for brimstone than for pyrites, owing to the difference in the composition of the burner gas; it will be less for rich pyrites than for poor for a similar reason; other things being equal it will depend on the proportion of nitre used, a larger consumption compensating for a smaller chamber space; it will also depend on the presence or absence of Glover and Gay-Lussac towers, and likewise on the size and efficiency of those towers. It will be less in winter than in summer, owing to the lower temperature and increased density of the gases in the colder season, and it can be reduced by a number of different arrangements for cooling the gases and the chambers, which will be referred to later.

Generally speaking, where Glover and Gay-Lussac towers are not used, 25–30 cb. ft. of chamber space per lb. of sulphur burnt per 24 hours will be required. If moderate-sized towers are used 16–20 cb. ft. will be sufficient, and by increasing the size of these towers it may be reduced to 10–11 cb. ft., as in the intensive system, but in the latter case the wear and tear of the chambers will be very considerable, unless steps are taken to keep the temperature in them from rising too high. The working of the process also requires more supervision. These figures are for pyrites; for brimstone the chamber space need only be about 75 p.c. of the above figures.

Opinions differ among manufacturers as to how long it is possible to work a chamber economically. Generally speaking after 10 years' work the repairs required to keep a chamber in good working order are very considerable, and many are of opinion that it should then be rebuilt, losses through leakages, injury to the frame work, and cost of patching will more than counterbalance the cost of re-erection. On the other hand, where chambers are well constructed and the process is well controlled and not forced, they have been known to last 20 or even 30 years, with occasional stoppages for repairs after the first 8 or 10 years.

Burgemeister (Chem. Zeit. 13, 1633; also J. Soc. Chem. Ind. 1890, 66) has made various measurements of the rate of diminution in thickness of the lead in a set of two chambers, one of which had lost 26·8 p.c. after working 210 months, and the other 17·65 p.c. of its thickness after 120 working months. The latter was a small chamber placed between the Glover and the large chamber first mentioned, and kept at a higher temperature.

Arrangements for supplying steam or water to the chambers. When no Gay-Lussac and Glover towers are used all the water ultimately transformed into chamber acid must be supplied in the form of steam or water spray. If the strength of the chamber acid is 120°Tw.=68·7 p.c. H_2SO_4, 1·96 parts water will be required for

---

[1] On the Continent the number of kilogrammes of H_2SO_4 produced per cubic metre per 24 hours is the form in which the chamber space is expressed.

each part of sulphur burnt; if towers are employed, and the average strength of the acid obtained is 145°Tw.=79·25 p.c. H_2SO_4, the water required will be equal to 1·44 times the sulphur burnt.

This is usually introduced into the chambers in the form of steam generated in an ordinary steam boiler. At one time this was sometimes mounted on the burners so as to utilise the heat of combustion of the pyrites, but this arrangement has been given up everywhere since the introduction of the Glover tower. The pressure required need not be more than sufficient to carry the jets of steam well into the chamber, say 5–10 lbs. per square inch, but is very important for the regular working of the process that it should be kept uniform; to ensure this, automatic regulators are employed in some works to keep a uniform pressure in the steam main, no matter what the boiler pressure may be. The exhaust steam of engines may be utilised for supplying the chambers, provided that they are worked in such a way as to leave a definite pressure in the exhaust. Fig. 6 represents a steam jet, the tube CC passing into the chamber through the wall EE by a stuffing box DD, B being the regulating cock, A the connection with the steam main, and FG a mercurial gauge affixed by means of T-joint H so as to indicate the pressure of the entering steam.

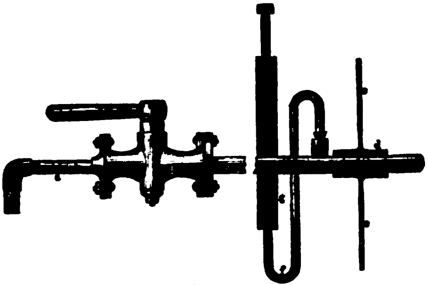

FIG. 6.

Practice differs considerably in different countries, and amongst different manufacturers, as to the method adopted for introducing the steam so as to mix uniformly with the burner gases. In England frequently only one jet is employed for each chamber, placed somewhere near the inlet pipe or a little above the centre of the chamber end, but on the Continent the practice is to employ a number of jets at right angles to the direction of the gaseous current either in the long chamber sides near the top, or through the roof of the chamber. The regulation is certainly much simpler and easier in the former method, but the distribution of the steam cannot be so well controlled as in the latter. Where a Glover tower is used the first part of the first chamber requires little or no additional steam to that entering with the gases, and therefore the first steam jet should be some distance from the front end of the chamber. Jets introduced at the far end in opposition to the direction of the gaseous current are sometimes employed, but tend to impede the draught.

In 1873 Sprengel patented the employment of pulverised water, *i.e.* water reduced to a mist-like spray by blowing a jet of steam at about 2 atmospheres pressure through a platinum nozzle in the centre of a water jet; with a properly proportioned compound jet, 4 parts by weight of water can be converted into fine spray by 1 of steam. The spray does not carry as far as a steam jet, wherefore in a large chamber a number of jets are necessary, and are placed in the sides about 40 ft. apart, and supplied with water from a tank fixed at some height above. The advantages claimed for the use of spray instead of steam are, that not only is fuel saved, but the temperature of the chamber is lowered so that more acid can be produced in a given chamber space. Sprengel's apparatus was worked for a number of years at Barking, but was given up on the introduction of Glover and Gay-Lussac towers there, and has practically gone out of use.

On the other hand, pulverised or atomised water (produced by the mechanical action of a fine stream issuing under a pressure of 2 atmospheres from a platinum nozzle on to a platinum button) has been successfully applied for a considerable number of years at Griesheim (Lunge), and has lately come into more general use where the intensive system of sulphuric manufacture is worked. Two rows of water jets, 20 ft. apart, are introduced through tubes in the chamber tops, and the water has to be specially filtered to avoid blocking up the fine jets used. For narrow chambers only one row of jets is employed. Where the intensive system is worked the use of atomised water has been of great service in keeping down the temperature of the chambers, and so preventing rapid wear and tear and excessive nitre consumption. Kestner (J. Soc. Chem. Ind. 1903, 334) gives the following calculations showing the effect of replacing steam by water sprays—

Heat of formation of $H_2SO_4+3H_2O$ (approx. chamber acid) . . =65,500 Cal.
Heat given up by condensation of steam at 120° to 60° . . =41,976 „
Total heat . . =107,476 „

If the steam is replaced by water at 15°—

Heat of formation of $H_2SO_4+3H_2O$=65,500 Cal.
Heat absorbed by water raised from 15° to 60° . . . . =3,240 „
Total heat . . =62,260 „

The difference in the two cases is thus, 45,216 calories.

If the average strength of the acid produced is represented by $H_2SO_4,2H_2O$, which will more nearly represent the correct strength when the Glover tower acid is taken into consideration, the difference in the heat of the reaction will be=33,910 calories. Water sprays cannot entirely replace steam, which is usually required in the last chamber, and also in the other chambers in very cold weather in order to prevent the temperature falling below a certain minimum, which Benker considers should be 60–65° for the first chamber (Kestner, J. Soc. Chem. Ind. 1903, 334). For this reason water spraying is of very little use in non-intensive working, except in very hot weather.

A special platinum jet for converting water or acid liquids into spray has been constructed by Benker in which the distance between the nozzle and the disc is adjustable, the disc being moved backwards and forwards by a rod at the end of which is cut a fine thread which works in a similar nut above. The jet is easily cleaned.

Korting Bros. have introduced a spray producer which gives the liquid a rotating movement, so that, issuing from the jet, it is projected in a conical spray. The nozzle is of platinum usually, but it can be replaced by a glass jet fitted into a hard lead nozzle by a small indiarubber washer. These spray producers have proved very successful, and have been used for a number of years in Continental factories (Lunge).

Guttmann (Eng. Pat. 18927, 1906) has patented the spraying of acid from the back chambers into the first and second chambers instead of steam or water; stronger chamber acid is obtained, and no harm is done if the spraying apparatus is defective.

Raschig (J. Soc. Chem. Ind. 1911, 172) has also suggested the spraying of weak sulphuric acid into the chambers instead of water, so as to avoid the possible reduction of the higher oxides of nitrogen to nitrogen monoxide or nitrogen.

The quantity of steam or water spray introduced into the chamber is regulated so as to produce an acid of a definite strength; and drips or tell-tales consisting of earthenware or leaden trays are placed inside the chambers to catch a certain amount of the condensing acid which runs through a tube into a lead or glass cylinder outside the chamber, and can there be tested from time to time; or samples can be obtained of the acid condensing in the connections between the chambers and tested at intervals in the same way.

In order to draw off acid from a chamber, a small leaden box is placed on the floor close by, open at the top, and of the same height as the upstand of the chamber bottom, and is connected at or near the bottom with the chamber by means of a pipe. In the bottom of this box is a seating of regulus metal (a hard alloy of lead and antimony) closed by a plug; on lifting this plug the acid in the box runs away through a pipe attached to the seating, and at the same time more acid levels into the box from the chamber. By allowing the acid to enter the box through a seating which can be closed by a plug, the same box may be used for two or more chambers. Another method is to siphon the acid from the chamber into the box by a siphon with a cup attached at each end in order to keep it always full when not in use, so that it starts to act as soon as one limb is put into the acid.

Arrangements for production of draught. The draught necessary for moving the acid gases through a set of chambers may be produced in several ways. In the first place, the hot burner gases are lighter, bulk for bulk, than air at the ordinary temperature, and consequently tend to rise and produce an indraught at the burners and a pressure in the chambers. The hotter the gases, and the higher they have to rise before they enter the Glover tower or chambers, the greater will be the draught due to this cause. At the end of the system the outlet pipe is usually connected with a chimney which assists in drawing the gases through the chambers, or else the outlet consists of a vertical pipe from the last chamber or tower; this has a slight aspirating action, owing to the exit gases being lighter than the air, which may be increased by means of a simple jet of steam, or better, by a Korting's injector. The formation of sulphuric acid itself in the chambers also acts as a cause of draught, the volume of the gases being reduced by the amount of condensation taking place.

For the regulation of the draught dampers are usually provided between the burners and the chambers, and in the outlet pipe at the end of the system.

Where a chimney is employed, any great variations in the draught from this may be corrected by a damper or throttle valve, which is automatically worked from a lever, on the other end of which hangs a bell standing in an annular lute containing water or other suitable liquid. The air in the bell is connected with the exit pipe beyond the damper, so that, when the draught from the chimney increases the bell descends in the lute, thus causing the other end of the lever to rise, partially closing the damper; the reverse happens when the draught decreases. Latterly the employment of fans for producing the necessary draught by mechanical means has very largely increased. These are usually made of iron covered with lead, of antimonial lead or of stoneware, and are generally placed between the last chamber and the Gay-Lussac tower, or if there are two of the latter towers, between them (Kestner, J. Soc. Chem. Ind. 1903, 334; Benker, Zeitsch. angew. Chem. 1903, 861). They have also been placed between the Glover tower and the first chamber, but lead or antimonial lead is rapidly corroded there (Niedenführ and Lüty, *ibid.* 1902). Falding employs two fans, one behind the Glover tower to regulate the draught of the burners, and the other in front of the Gay-Lussac (Min. Ind. vii. 672).

Mühlhaüser (Zeitsch. angew. Chem. 1902, 672) describes the history of introduction of fan; *see* also Rabe (*ibid.* 1905, 1735), and Schliebs (*ibid.* 1905, 1900).

O'Brien places a cast-iron fan immediately behind the burners before the nitre oven and Glover tower. The temperature inside the fan is 540°, and it is covered with a 1-in. coat of asbestos cement; water is used as a lubricant instead of oil (Falding, Min. Ind. ix. 621). The actual volume of gas passing through the chamber system may be determined by measuring the speed of the gaseous current in the connecting pipes or exit pipe by means of Fletcher's or Swan's anemometer.

Gay-Lussac and Glover towers. In 1827 Gay-Lussac proposed the use of a coke tower for absorbing the escaping nitrous fumes in strong sulphuric acid, but it was not until 1842 that the idea was put into practice, and it was not until some time after the invention of the Glover tower in 1860 that the Gay-Lussac came into general use. This delay was due to the fact that up to that date, all the acid used in the latter tower had to be concentrated, and the nitrous vitriol obtained could only be denitrated by dilution with water, so that the saving in nitre was partly counterbalanced by the cost of the fuel required for reconcentrating the acid. But the introduction of the Glover tower rendered this expense unnecessary, and at the present day there are very few sulphuric acid manufacturers who do not make use of these appliances.

The Gay-Lussac tower consists of a tall column, the walls of which are of lead, packed with some material, such as coke, which presents a large surface so as to bring the gas passing up through the tower into intimate contact with a stream of sulphuric acid entering at the top and passing down the tower. It is connected with the exit from the last chamber of a set, and receives all the gas leaving that chamber; this gas contains a large amount of nitrous vapours, which are absorbed by the descending sulphuric acid and again introduced into the process.

The tower is usually built on a solid block of brickwork or on strong brick piers, surmounted by an arch, or cast-iron columns may be employed, carrying a platform of iron bearers or rails. The brickwork or iron is protected from possible acid drops or leaks by sheet lead. The tower itself is constructed of sheet lead, supported by a wooden frame-work in the same manner as the chambers. Sometimes angle iron is used instead of timber for the frame. Square-sectioned towers are usually preferred, as being somewhat simpler to construct than round ones, but the latter have the advantage that for a given capacity less lead is required, and the gaseous current is more uniformly distributed within the tower. The sides are usually made of 8 or 10 lb. lead, and the bottom, which is turned up at the edges to form the upstand, of 12–18 lb. lead. The sides are not 'burnt' to the bottom, but dip into the acid, which forms a lute as in the chambers. The lower portion is usually lined with acid-proof blue bricks, put in dry without mortar or cement in order to protect the lead from being damaged by the packing. 1-in. splits are sometimes used to economise space.

The width varies from 4 to 10 ft., and the height from 30 to 50 ft., the dimensions depending on the capacity of the set of chambers.

The cubical contents should be at least equal to 1 p.c. of the chamber space, and may with advantage be increased to 2 p.c. when working with a normal chamber capacity of 16–20 cb. ft. per lb. of sulphur burnt per 24 hours. But when the chamber space is reduced to 10 or 11 cb. ft. per lb. sulphur, as in intensive working, the capacity of the Gay-Lussac tower is frequently increased to about 4 p.c. of the total capacity of the chambers. Two towers are usually employed in this case, and also with large sets in non-intensive working.

Sometimes the gases from a number of different sets of chambers, after leaving the Gay-Lussac towers, are passed through a large final absorbing tower in order to reduce the loss of nitrous vapours due to non-absorption to a minimum.

The pipe bringing the gases from the last chamber enters the side of the tower near the bottom, and just above is fixed the grating which carries the packing. This grating may consist of iron bars covered with lead, carried by the brick lining, or it may be of blue bricks on a series of parallel brick arches or of specially shaped acid-proof stoneware blocks. The packing itself used at one time almost universally to consist of hard-burnt furnace coke, and the latter is still used to a very considerable extent, but owing to the fact that it is apt to disintegrate in the tower which it gradually blocks, and that it also has a slight reducing action on the higher oxides of nitrogen, it has been, to a certain extent, replaced by cylinders of acid-proof stoneware, specially-shaped bricks, Guttmann stoneware balls, or Bettenhausen cones. When coke is used large lumps 12 or 14 ins. long are placed on the grating in regular layers, and the size of the fragments is gradually reduced as the packing goes on, until in the upper part pieces 3–4 ins. in size are employed. The top of the tower consists of sheet lead supported from above by iron bars covered with lead, and a large number of inlet holes for the acid are spaced over the whole area. Each hole has an upstanding rim, which is covered with a leaden cap which allows the acid to pass into the tower, but no gas to escape. The acid is conveyed to these lutes by leaden pipes from the bottom of a leaden box divided by radial partitions into sections which are continuously fed with acid by means of a reaction wheel or rotating distributor working on the principle of the Barker's mill. Another method of distribution is by means of an intermittent siphon, which at regular intervals flushes an intermediate leaden box from the bottom of which numerous pipes run to the lutes. The reaction wheel or siphon is fed with acid from an overhead tank, and the quantity passing down the tower is regulated by a tap. As it is of the utmost importance to the working of the process that this stream should be as uniform as possible, and since any variations in the level of the acid in the tank above will cause similar variations in the quantity the regulating tap will pass, various contrivances are employed for ensuring a uniform pressure of acid at the point of delivery. The most efficient of these is the balancing apparatus described by Lunge (Sulphuric Acid, vol. i. 599), in which the acid flows from the bottom of the tank into a smaller intermediate vessel on the same level in which a hollow leaden ball is suspended from the end of a lever. The entering acid presses the ball upwards, the other end of the lever descends and closes the outlet from the tank until sufficient acid has run out of the intermediate vessel to allow the ball to move down and open the outlet valve again. Thus the level of the acid in the small vessel will be independent of that in the main tank.

The acid is usually forced up to the top of the tower by means of compressed air from a strong cast-iron vessel which is sometimes lined with lead, but this is unnecessary, as acid of the strength used has very little action on cast iron. These acid eggs, as they are called, hold several tons of acid. Latterly they have been replaced in some works by automatic elevators or pulsometers, which were first introduced by Harrison Blair, and have been considerably improved by Laurent and Kestner. They work continuously, and the rate of supply of acid to the towers can be regulated by the air-inlet cock below, so that no regulating arrangement or large storage tank is required on the top. When the tower is very high and the air pressure available is not sufficient to force the acid up to the top in a continuous stream, a modification of the automatic elevator, known as an *Emulseur*, may be employed, in which a certain amount of air is allowed to mix with the acid as it is forced up, the emulsion of acid and air requiring less pressure to elevate it than the acid by itself.

T. Meyer (Zeitsch. angew. Chem. 1910, 972) recommends the use of multistage turbine centrifugal pumps of hard lead connected to an electric motor, which he states have an efficiency of 19·4 p.c. of the total energy supplied as against 3½ p.c. when compressed air is used.

Working the Gay-Lussac tower. The acid used for absorption should be at least 144°Tw., and it will be more efficient if it is 150°–152°Tw.; it may readily be obtained of the latter strength from the Glover tower. It should also be as cool as possible, not above 30°C. Hot acid absorbs badly, and where coke is used for packing some of the higher nitrogen oxides may be reduced to nitric oxide. The quantity used per 24 hours should be at least equal to one-half the daily production of acid, and in many cases a quantity equal to the total daily make is used; in intensive working at least twice the daily production has to pass through the Gay-Lussac towers in order to prevent excessive loss of nitre.

The nitrous vitriol running off from the bottom of the tower usually contains from 1 to 2 p.c. N_2O_3; it is a solution of nitrosulphonic acid or nitrososulphuric acid (chamber crystals) $SO_2(OH)(NO_2)$ in sulphuric acid, and it is decomposed on dilution with water, the N_2O_3 being liberated. The percentage of N_2O_3 depends on the quantity of acid run down the tower; if it contains above 2 p.c. N_2O_3 there is danger of loss from incomplete absorption. When the process is working regularly it is almost colourless, but when the exit gases contain an excessive amount of unoxidised SO_2 it turns dark purple owing to the reduction of the $SO_2(OH)(NO_2)$ to $SO_2(OH)N(OH)O$, called by Raschig nitrosisulphonic acid, and appears full of bubbles of NO. It has been stated that some nitric acid is usually present in the nitrous vitriol, but Lunge holds that this is never the case under normal conditions of working. If such an excess of nitre be used that N_2O_4 exists in the gases leaving the last chamber, some nitric acid will probably be formed, but if the tower is packed with coke the latter will prevent this formation, and only where some non-reducing packing is employed is it likely that the formation of nitric acid will take place (J. Soc. Chem. Ind. 1885, 31). Lunge also controverts the statements of Benker and Lasne that when sulphur dioxide is practically absent from the gases entering the Gay-Lussac tower, the N_2O_4 present is not readily absorbed by the acid in the tower. To avoid this loss they proposed to introduce into the gases leaving the last chamber, a certain quantity of burner gas by means of a steam jet in order to reduce the N_2O_4 to N_2O_3, which is more readily absorbed (D. R. P. 17154, 1881). Benker modified this at a later date (D. R. PP. 88368, 91260) by taking a small quantity of gas from the first chamber and injecting it into the last or into a special chamber between this and the Gay-Lussac tower.

Petersen (D. R. P. 226793, 1909) states that ferrous sulphate in the Glover tower acid hinders the absorption of nitrous acid in the Gay-Lussac tower, and recommends that the ferrous sulphate should be oxidised by the addition of a little nitrous vitriol to the absorbing acid for the last tower.

The quantity of N_2O_3 in the nitrous vitriol may be estimated by means of potassium permanganate. 50 c.c. of N/2 $KMnO_4$ solution are taken, diluted with five times the volume of water, and the nitrous vitriol is run in from a burette with constant stirring until the colour just vanishes. 1 c.c. N/2 $KMnO_4$=0·0095 grms. N_2O_3.

If nitric acid is present it is not estimated by this method, but the total nitrogen compounds present may be determined by means of Lunge's nitrometer, in which they are converted into NO by shaking with mercury and the volume of gas produced can be measured. The following table represents the quantities of various nitrogen compounds in milligrams corresponding with 1 c.c. of NO at 0°C. and 760 mm.

NO	N	NO	N_2O_3	N_2O_5	HNO_3	KNO_3	$NaNO_3$

The Glover tower. Before the invention of the Glover tower the methods used for decomposing the nitrous vitriol obtained from the Gay-Lussac tower in order to reintroduce the nitrous compounds into the process were dependent on the use of hot water or steam, or else sulphur dioxide, dilution of the acid being necessary in both cases. The wear and tear of the apparatus employed was always very considerable, and as only dilute acid was obtained, additional expense was incurred in concentrating the acid again for supplying the Gay-Lussac tower. This was sometimes done by means of evaporating pans placed on top of the pyrites, or sulphur burners, but owing to danger of leakages this method did not come into general use. The advantages of the use of the Glover tower over any other system of denitration are that the heat of the burner gases is utilised for restoring the nitrous vapours uniformly to the chambers, and also for supplying them with steam, and that the burner gas is cooled down to such a temperature that no cooling pipes are required, and the wear and tear on the first chamber is considerably reduced.

Owing to the higher temperature of the gases Glover towers (Fig. 7) must be far more strongly built than Gay-Lussac towers, which in other respects they greatly resemble. The sides are usually of 14–18 lb. lead, and the bottom of 35 lb. lead, and the tower is lined with firebricks capable of resisting both heat and strong acid, or with volvic lava; this lining, which is put in dry without mortar of any kind, is about 2 ft.

3 ins. thick at the bottom, and decreases from 18 ins. above the grating carrying the packing to 4½ ins. at the top. The packing usually consists of flint, picked from the chalk, and washed with hydrochloric acid. This material has the advantage of being absolutely acid resisting, but it is very heavy, does not possess much surface, and is readily blocked up by dust. Acid-proof fireclay cylinders or bricks, either plain or dished and perforated, are frequently used instead, more particularly where pyrites dust burners are employed. They do not block up so readily, and also allow more free space in the tower for the reactions (Lüty, Zeitsch. angew. Chem. 1896, 645). Sometimes coke is used in the upper portion, but there is always danger of the coke firing should the acid feed be stopped for any reason. In America Herreshoff uses a particular kind of quartz rock, not only for the packing itself, but also for the grating supporting the packing, and for the lining; as the lumps of quartz are not obtained in very regular shape the space next the lead is packed with a thick layer of quartz sand; the lead is protected outside by iron plates (J. Soc. Chem. Ind. 1908, 269).

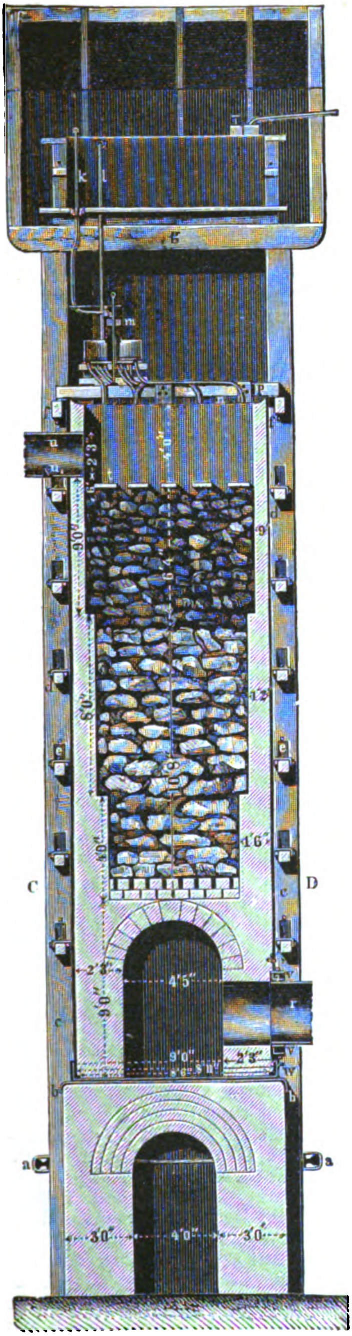

Fig. 7.

Volvic lava is largely used on the Continent both for lining and for packing Glover towers. In some cases the tower itself is made of this material without any leaden shell. The segments are held together by iron hoops covered with lead. There are no tanks on the top, as the tower is fed by means of automatic elevators from below.

The height of the Glover tower is generally much less than that of the Gay-Lussac tower, from 20 to 30 ft., while the width is proportionately greater, so that the cubic capacities of the two do not widely differ. A tower 9–10 ft. square and 25–30 ft. high containing 2025–3000 cb. ft. will suffice for a set of chambers containing 140,000–200,000 cb. ft. From 550 to 600 cb. ft. per ton of sulphur burnt daily is a proportion frequently employed; these figures refer to the total cubic capacity inside the lead, the actual working space being only about one-half this amount.

The gases enter the tower from the burners usually by a cast-iron pipe, and pass upwards through a grating of fireclay slabs or groined arches which carries the packing. Niedenführ recommends the construction of a second arch and grating a little higher up the tower so that the lower portion may be cleaned or replaced without disturbing the main body of the packing (Lüty, Zeitsch. angew. Chem. 1905, 1253). At the top similar arrangements are employed for distributing the acid as in the Gay-Lussac tower. There are two storage tanks on the top, one containing nitrous vitriol and the other chamber acid, and the two streams usually mix in the distributing box before entering the tower. When the additional nitre required for the process is introduced as liquid nitric acid, it is either mixed with the nitrous vitriol in the storage tank or else run into the centre of the top of the tower in a regular stream by means of a glass tube from a Mariotte's bottle, as previously described.

The hot concentrated acid leaves the saucer below by a lip, and is cooled by passing through a leaden trough in which leaden coils or pipes are placed, through which cold water is kept running. Usually Gay-Lussac and Glover towers are built side by side, the latter standing on a higher foundation so that the tops are on the same level. The inspection and control of the two towers is thus much facilitated.

If the Glover tower is fed with nitrous vitriol alone, the latter will not be completely denitrated when it reaches the bottom, but will contain about 0·2 p.c. of N_2O_3. It is usual, therefore, to mix it with a certain amount of chamber acid of from 110° to 120°Tw. in order to produce a mixture of from 130° to 136°Tw., from which the nitrous compounds will be completely removed by the hot burner gases by the time it arrives at the bottom of the tower. If more or weaker chamber acid is used, and a mixture is obtained below 130°Tw., there is danger of loss of nitric oxide from the decomposition of the nitrous vitriol outside the tower; at the same time, instead of obtaining an acid of 150°Tw. or thereabouts, running off at the bottom, the latter may only be 140°Tw., at which strength it is not nearly so efficient for absorbing the nitrous vapours in the Gay-Lussac tower. It is possible, by keeping the acid in the chambers up to at least 120°Tw., to pass the whole of the chamber acid made down the Glover tower with the nitrous vitriol, to completely denitrate the latter and to obtain the whole of this acid at 145°–150°Tw.

The temperature of the burner gas leaving the pyrites kilns will be about 500°C., and if there is no dust chamber employed the gas will enter the Glover tower at from 400° to 450°C., and will leave it at between 50° and 80°C. A dust chamber will probably cool the gas another 100°C. before it enters the tower; it will then not be possible to concentrate so much chamber acid in the latter, but perfect denitration can be obtained, the acid running off at the bottom being 140°–148°Tw. Niedenführ recommends the dividing of the Glover function between two apparatus; after the dust chamber comes a concentrating tower, then a hard lead fan, and then the denitrating tower. Acid of 130°Tw. leaving the second tower is concentrated to 142°Tw. in the first (Lüty, Zeitsch. angew. Chem. 1905, 1253).

Petersen, in order to deal with the large amount of absorbing acid used in working on the intensive system, also recommends the use of two Glover towers, together with two Gay-Lussac towers, the first Glover and the last Gay-Lussac towers working together with acid of 1·7 sp.gr., whilst for the inner towers 1·6–1·65 acid is employed (Zeitsch. angew. Chem. 1907, 1101).

In other cases, where there are several sets of chambers each working with a single Glover tower, some are worked to make strong acid (which need not be denitrated completely) for the Gay-Lussac towers, while the others produce a larger quantity of a weaker acid quite free from nitrous compounds and ready for sale or use.

Where two towers are employed in series the first removes many impurities from the gases, so that the acid concentrated in the second is much purer than that running from the first.

The concentration of the acid in the Glover tower is not due solely to the evaporation of water; it is also very largely due to the production of sulphuric acid in the tower itself, partly from the sulphur trioxide in the burner gas, and partly from oxidation of sulphur dioxide by the nitrous vitriol. Scheurer Kestner found by actual measurement that 17–19 p.c. of the total acid made was produced in the Glover tower, of which about 3·5 p.c. was due to sulphur trioxide in the gases (Bull. Soc. chim. [ii.] 44, 98).

Meyer (Zeitsch. angew. Chem. 1909, 1841) obtained in two cases only 10·8 and 7·3 p.c. of the total make; and Raschig, by estimating the sulphur dioxide in the gases entering and leaving the tower, found that about 14–16 p.c. of the daily production was formed there. Sorel (Bull. Soc. Ind. Mulhouse, 1889, 240; also J. Soc. Chem. Ind. 1890, 175) explains this formation in the following way: The nitrous vitriol is denitrated in the lower part of the tower, and some of the nitric oxide liberated is oxidised as it ascends, and is reabsorbed by the fresh acid entering at the top and brought down again to be once more denitrated by the sulphur dioxide. In this way a comparatively small amount of nitrogen oxides converts a comparatively large amount of sulphur dioxide into sulphuric acid in the same way as in the chambers subsequently, except that in the tower, the reactions are intensified by the constant subdivision and mixing of the gases, and the contact with a large amount of surface wetted with nitrous vitriol. The heat developed by the intensive reactions in the tower is expended again in evaporating water from the weak entering acid. If the top part of the tower gets too cold, either through the tower being too high or from the large amount of weak acid entering, the denitration will take place in a comparatively small zone near the top, and less acid formation will take place in the tower. Lunge calculates that with 250 cb. ft. of active Glover tower space per ton of sulphur, and a chamber space of 20 cb. ft. per lb. of sulphur burnt per 24 hours, if $\frac{1}{8}$ of the oxidation takes place in the tower and $\frac{7}{8}$ in the chambers, the denitrating zone of the Glover tower makes 224 times more acid than an equal cube of chamber space (Sulphuric Acid, vol. i. 671).

THE CHAMBER PROCESS.

Before starting a set of chambers the saucer should be luted with acid of at least 90°–100°Tw.; if the sides are 'burnt' to the bottom this is not necessary; but water must on no account be used, as it will dissolve the nitrous vapours with the formation of nitric acid which will rapidly attack the lead of the chamber bottom. The dampers are then opened at the end of the system and before the Glover tower, a stream of acid is started running down the latter, the kilns are charged and the hot burner gases are allowed to enter; at the same time three or four times the quantity of nitre required for normal working is charged in the nitre oven or introduced as liquid nitric acid in the Glover tower. As soon as the drips show that sulphuric acid is condensing in the chambers steam is introduced, the quantity admitted being regulated from time to time according to the strength of the drips. Excess of nitre is used until the gas in the last chamber shows a reddish-yellow colour, when the acid feed on the Gay-Lussac tower is started, and as the nitrous vitriol from the latter becomes available for use in the Glover tower, the quantity of fresh nitre is reduced until the minimum required for the regular working of the process is reached.

The strength of the chamber acid. In England the acid in the first chamber is generally kept at from 120° to 125°Tw., and the steam or water admitted is regulated by the strength of the drips, which usually are 5°–10°Tw. higher than the bottom acid. If the strength exceeds 125°Tw. the quantity of nitrous fumes dissolved in the acid begins to increase very considerably, and the wear and tear of the chamber through corrosion of the lead is notably increased. On the Continent it is more usual to keep the first chamber weaker, from 106° to 110°Tw. The subsequent chambers are all worked a little weaker than the first, the last chamber being usually kept at from 90° to 100°Tw., except in the now very exceptional case where there is no Guy-Lussac tower, when it is reduced to 50°–60°Tw.

The colour of the gases in the chambers requires continuous inspection in order to see if the correct amount of nitre is being used. For this purpose glass windows are let into the sides of the chambers and into the exit pipes from them, the gas being viewed either horizontally through opposite windows or diagonally upwards towards a light in the roof consisting of a bell-jar placed in a hydraulic lute. The first chamber, owing to the fact that it is full of sulphuric acid mist, will not show any decided colour, but the following chambers should appear distinctly reddish-yellow, the colour gradually deepening till in the last chamber it is dark-red, and even in the exit pipe to the Gay-Lussac it shows a decided colour. The smaller the chamber space employed the deeper this colour will have to be in order to prevent the escape of unoxidised sulphur dioxide, and also nitric oxide with the exit gases from the Gay-Lussac tower. After the latter the gases should show no colour whatever; if they do show a yellowish tint it means that an excess of nitre is being used in the process, or else that the absorbing capacity of the Gay-Lussac tower is insufficient for the nitrous gases present.

Whenever the gases in the last chamber are pale in colour it means that something is wrong; it may be due simply to a shortage of nitre, or it may be caused by too little or too much steam being present; if too little steam is being used the condensing acid will be too strong and will contain much nitrous acid, whilst if too much is being introduced the condensing acid will be weak and will contain nitric acid. Another cause of pale gases is shortage of oxygen due to insufficient draught; analysis of the burner gas or a determination of the percentage of oxygen in the exit gas will at once show whether this is the cause or not. Whatever may be the cause, pale chamber gases mean unoxidised sulphur dioxide and an excess of nitric oxide in the gases entering the Gay-Lussac tower, and as the acid running down the latter will not absorb either of these gases they pass away and are lost. In any case, extra nitre must be introduced at once into the process to replace this loss, and the cause of the disturbance determined and corrected as soon as possible. If too much nitre is being employed the acid condensing in the chambers and in the drips will show the presence of an excessive amount of nitrous acid if tested with ferrous sulphate solution. The bottom acid in the first chamber should give no coloration by this test, and the drip acid only a faint indication. The middle chambers should not give more than a faint indication in the bottom acid and a stronger one in the drips. The last chamber usually gives a decided reaction in the bottom acid and a strong one in the drips.

The regular observation of *the temperatures of the gases* in the chambers by means of thermometers with their bulbs several inches inside the walls is very useful in controlling the working of the process. These temperatures depend chiefly on the intensity of the reactions taking place in the chambers; if the outside atmospheric conditions do not vary much, they should be fairly constant when the process is working well. The loss of heat by radiation will vary according to the external temperature, the force of the wind, &c., more particularly when the chambers are not enclosed in buildings, but the differences between the temperatures of the chambers and the external air should not vary much. The first chamber will be the hottest, and the last the coolest, and different parts of the same chamber will show slight variations, the upper part being a little warmer than the bottom, and the exit cooler than the entrance. There is considerable difference of opinion as to the best temperature for the chamber process. With moderate chamber space the first chamber should not exceed 60°–70°C., the later chambers being, of course, cooler, the last showing a reading of 25°–35°C. In intensive working with only 11 or 12 cb. ft. chamber space the temperatures will be some 20° higher unless means are taken to obtain additional cooling of the gases to that due solely to radiation from the chamber walls. These high temperatures certainly mean additional corrosion, and wear and tear of the lead, and in all probability increased destruction of the available oxides of nitrogen by secondary reactions giving rise to the formation of nitrous oxide and nitrogen. With regard to the lower limit of temperature there is some difference of opinion. Meyer (Zeitsch. angew. Chem. 1901, 1245) states that the temperature for best working is probably above 50°C., but Lunge is of opinion that the process always works better and with a greater economy of nitre in cold weather than in hot, provided that the temperature does not fall so low that ice is formed in the chambers. On the other hand, since the introduction of water sprays instead of steam, experience seems to show that in very cold weather some steam has to be used, more particularly in the back chambers, in order to obtain the best results.

The pressure of the gases in the different chambers will not be uniform throughout; where only natural draught is employed there is usually a slight outward pressure in the first chamber, in the intermediate chambers the gas is practically in equilibrium with the outside air, while in the last there is a slight suction. These pressures are regulated by means of the dampers between the burners and the chambers, and at the end of the system; where no chimney is employed, and the production of the draught depends chiefly on the upward pressure of the hot gas column between the burners and the Glover tower there is frequently a pressure right through the system, gradually decreasing from first to last.

Where mechanical draught is employed the pressures will depend on the position of the fan. Niedenfuhr recommends working with a considerable pressure throughout the chambers by placing the fan between two Glover towers and throttling the gas behind the Gay-Lussac tower (Lüty, Zeitsch. angew. Chem. 1905, 1253). But fans are usually placed at the end of the system where they may produce a considerable suction in the chambers. In any case, the draught must be so regulated that the oxygen in the exit gases is not less than 5 p.c., nor greater than 8 p.c. Between these limits opinions differ as to what the excess should be, 6 p.c. being perhaps the most generally accepted figure.

The total quantity of nitre required depends chiefly on the chamber space. Working with pyrites and a chamber space of 24 cb. ft. per lb. of sulphur burnt per 24 hours, this will amount to about 10 p.c. on the sulphur. With less chamber space 15–20 p.c. nitre will be required, whilst for intensive work and a chamber space of 11 or 12 cb. ft. as much as 25 p.c. nitre will probably have to be used. The amount of fresh nitre to be introduced will depend chiefly on the quantity recovered in the nitrous vitriol from the Gay-Lussac tower, and will therefore vary with the efficiency of that apparatus. Generally 3–4 p.c. of fresh nitre has to be used with moderate tower capacity and chamber space; even where the absorbing capacity of the Gay-Lussac tower is very large, the quantity required is never less than 2 p.c., whilst any irregularity in the working of the process may cause a much greater loss of nitre from defective absorption, a correspondingly greater quantity of fresh nitre being required to replace this loss.

Widely different views have been held by different experimenters as to the relative functions of different parts of the same chamber —*i.e.* the lower middle and upper zones, and the portions adjoining the sides and top as compared with the interior.

Mactear (J. Soc. Chem. Ind. 1884, 228), as the result of a series of experiments in which the acid condensing in different parts of the chamber was collected by a number of trays each 1 ft. square, came to the conclusion that most chemical action takes place in the upper part of the chamber, and least near the bottom. Lunge and Naef (J. Soc. Chem. Ind. 1884, 663), on the other hand, deduced from their experiments that the acid formation is greatest near the top, bottom, and sides, and least in the central portion, while Hasenclever concluded that the acid condensed is practically the same per given amount of space in all parts of the interior of a given chamber. There is no doubt that the cooling influence of the external air, together with the surface action of the walls and top, cause a greater condensation of liquid acid along the roof and sides, and Lunge's and Naef's analyses appear to show that there is always more sulphur dioxide in the central part of the chamber than near the outside, pointing to a stronger formation of acid near the chamber walls. They also give a certain amount of support to Abrahams' theory concerning the path taken by the gases within the chambers (Dingl. poly. J. 1882, 416). He is of opinion that the cooling action of the walls and top causes the gas to rise in the centre of the longitudinal section and to descend along the sides of the chamber; so that the gases travel in vertical layers at right angles to the length of the chamber, from front to back, but each single gaseous molecule describes a spiral line, whose axis is parallel to the length of the chamber.

Lunge and Naef have also shown that the conversion of sulphur dioxide into sulphuric acid goes on rapidly in the first half of the first chamber, then slackens very much, but is suddenly revived when the gases pass into the next chamber. This has been confirmed by Schertel (Chem. Ind. 1889, 80), Retter (Zeitsch. angew. Chem. 1891, 4), and others, and is due partly to the better mixing of the gases in passing through the connecting pipe and partly to the cooling and condensing effect of the latter.

The relative amounts of acid formed in a series of chambers have been stated by Hurter (J. Soc. Chem. Ind. 1882, 8) to decrease approximately in geometric progression from the first chamber to the last. Thus with a series of four chambers of equal size, if $\frac{2}{3}$ of the production takes place in the first, $\frac{2}{9}$ will be formed in the second, $\frac{2}{27}$ in the third, and $\frac{2}{81}$ in the fourth. Lunge and Naef have shown that this is only approximately correct.

The examination of the exit gases passing away from the Gay-Lussac tower is a most important part of the control operations requisite for carrying on the process efficiently. Samples may be taken at intervals during each day, or an average sample may be drawn every 24 hours by aspirating a slow stream at a definite rate through a series of absorption bottles containing caustic soda in order to absorb the acid gases. According to the Alkali Works Regulation Act, in England the total quantity of sulphur acids escaping from the exits of sulphuric acid works must not exceed 4 grns. per cb. ft. calculated as sulphur trioxide. This is usually determined by shaking a definite volume of the gas, taken by means of a flexible bellows aspirator, with a solution of hydrogen peroxide and titrating with standard caustic soda solution, using methyl orange as indicator. According to the Alkali Works Inspectors' reports the average acid escapes in England during 1908, 1909 and 1910 were 1·163, 1·162, and 1·178 grains SO_3 per cb. ft. But this test takes no account of the oxides of nitrogen escaping with the gases. Hurter and Lunge (Alkali Makers' Handbook, 98) recommend the following arrangements for estimating the different acids in the exit gases. These agree in the main with those published by the British Alkali-Makers Association in 1878. About 24 cb. ft. of the gases are drawn in 24 hours through four absorption bottles, the first three containing normal caustic soda solution, and the fourth distilled water. The contents are mixed together and divided into three equal parts. One is tested with normal sulphuric acid solution to determine the total acidity. The second is poured into a warm solution of potassium permanganate, strongly acidified with sulphuric acid to oxidise all the nitrogen acids to nitric acid, any considerable excess of permanganate being reduced by sulphur dioxide solution until the colour is a faint pink. It is next mixed in a flask with 25 c.c. of a solution of ferrous sulphate (containing 100 grms. $FeSO_4,7H_2O$ and 100 grms. H_2SO_4 per litre), to which 20–25 c.c. H_2SO_4 has been also added, all air being first expelled by a current of carbon dioxide. The flask is boiled to expel nitric oxide, and the solution is of a light yellow colour, and the unoxidised ferrous sulphate is determined by titrating with N/2 permanganate solution. If V be the volume of air aspirated after reduction to 0°C. and 760 mm., x the number of c.c. of normal sulphuric acid used in the first titration, y that of the permanganate used during the second test, and z the quantity of permanganate equivalent to the 25 c.c. iron solution, then the

Grms. per cubic metre

$$\text{Total acidity } SO_3 = \frac{0{\cdot}12(100-x)}{V}$$

$$\text{Sulphur } S = \frac{0{\cdot}008(600-6x-z+y)}{V}$$

$$\text{Nitrogen } N = \frac{0{\cdot}007(z-y)}{V}$$

Grains per cubic foot

$$\text{Total acidity } SO_3 = \frac{1{\cdot}852(100-x)}{V}$$

$$\text{Sulphur } S = \frac{0{\cdot}12346(600-6x-z+y)}{V}$$

$$\text{Nitrogen } N = \frac{0{\cdot}10803(z-y)}{V}$$

Nitric oxide is estimated by passing the gases after leaving the first four bottles through a tube containing 30 c.c. N/2 permanganate and 1 c.c. sulphuric acid, sp.gr. 1·25. Excess of standard ferrous sulphate solution is added, and the excess is titrated back by N/2 permanganate solution. Then the nitrogen present as—

$$NO = \frac{0{\cdot}007 \times A}{3V} \text{ grms. per cubic metre}$$

$$= \frac{0{\cdot}10803 \times A}{3V} \text{ grains per cubic foot}$$

where A = number of c.c. of N/2 permanganate reduced by the NO.

Fig. 8 shows the best form of absorbing apparatus for estimating the nitric oxide according to Lunge.

The oxygen is determined in the residual gas after the acid gases have been all removed.

Carpenter and Linder (J. Soc. Chem. Ind. 1902, 1490) have investigated the methods employed for estimating the acidity of the gases escaping from the chamber process, and find that when soda is used to absorb the acid gases reactions arise with formation of condensation products or sulphazotised bodies whose titre is less than that of the constituents separately, and recommend the use of neutral or alkaline hydrogen peroxide for this purpose.

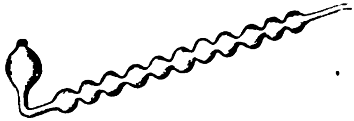

FIG. 8.

Proposals for diminishing chamber space. A number of proposals have been made from time to time for the purpose of increasing the rapidity of the acid formation in the chambers, and thereby reducing the chamber space necessary for the production of a definite quantity of acid.

Additional surface has been provided by means of lead partitions in the chambers, but these quickly corrode, while partitions of glass soon collapse. Walter and Boenig (Eng. Pat. 14944, 1891) employ double walls of acid-proof material arranged across the whole width of the chambers; the main portion of the gas has to traverse the spaces between these, entering at the bottom and leaving at the top, while the remainder passes through numerous small holes in these partitions.

Richter (D. R. P. 15252) aspirates the gases from the lower part of the chamber and introduces them again near the top, and Boult (Eng. Pat. 10757, 1899) brings the gases back from the rear of the apparatus to the front again to obtain a better admixture and circulation.

Rabe (Zeitsch. angew. Chem. 1910, 8 and 1115) suggests methods to facilitate the circulation of gases in rectangular chambers spirally (Abraham's theory) by introducing the gases in the direction of the Abraham currents, by gradually reducing the height of the chamber from front to back or by introducing lead curtains hanging down at intervals a certain distance from the roof, parallel with the ends of the chamber, or the introduction of acid sprays in the direction of the currents. He also criticises Porter's experiments with regard to the movements of the gases in the chambers.

But mixing the gases alone is not sufficient, and arrangements for this purpose have not had any great success. Hartmann (Chem. Zeit. 1897, 877) employs a number of shafts 5 or 6 ft. wide from top to bottom of the chamber, luted at the bottom so that a continuous current of cooling air passes up them, and states that he has obtained an increased production of 20 p.c. by this means. Meyer (Zeitsch. angew. Chem. 1900, 74; 1901, 1245) has introduced into the first of his circular chambers a system of cooling pipes, reaching down into the chamber about 8 or 10 ft., and cooled by water which enters the pipes by means of narrower ones reaching nearly to the bottom of the wider ones. By this means he removes 15–20 p.c. of the heat of the reaction, and obtains a corresponding increase in the production. The greatest success, however, in increasing the output of vitriol has been obtained by the employment of mixing and cooling towers between the chambers. Lunge (Zeitsch. angew. Chem. 1899, 385; J. Soc. Chem. Ind. 1889, 774) was the first to introduce these successfully; his plate towers consist of columns of perforated stoneware plates contained in a lead-lined tower into which the gases enter at the bottom and leave at the top. They are fed with a stream of water or dilute sulphuric acid at such a rate that by the vaporisation of water the temperature does not rise above 70° or 80°C. Fig. 9 shows a Lunge tower packed with plates, and Figs. 10 and 11 represent the plates in sectional elevation and plan, from which it will be seen that there is always a thin layer of liquid on each plate, and they are so arranged that the openings in consecutive layers are not in the same vertical line. By this means a very intimate contact between the gas and liquid is obtained. According to Lunge, these towers do from 10 to 20 times as much work as an ordinary coke-packed Gay-Lussac tower of the same cubic capacity, in place of which they are sometimes used. But it is as intermediate towers between the chambers that they are mostly employed. By feeding them with acid above 1·3 sp.gr. the possible formation of nitrous oxide is avoided (Lunge, Ber. 1881, 2200). The heat of reaction in the formation of chamber acid furnishes enough heat to evaporate 100 parts of water at 100°C. during the production of 98 parts H_2SO_4, a quantity 25 p.c. in excess of the requirements of the process; but most of this excess of heat will be dissipated by radiation from the tower walls (Lunge, Sulphuric Acid, vol. i. 487). Lunge towers have come into considerable use on the Continent; their chief drawback is due to amount of obstruction of draught they cause, but where fans are employed this is easily overcome. Niedenführ (Chem. Zeit. 1896, 31; J. Soc. Chem. Ind. 1896, 541) describes a number of chamber systems where they have been introduced with very satisfactory results. *See* also Lüty (Zeitsch. angew. Chem. 1897, 484); and Niedenführ (Chem. Zeit. 1897, 20); Lütz and Niedenführ (Zeitsch. angew. Chem. 1902, 242; 1905, 1253).

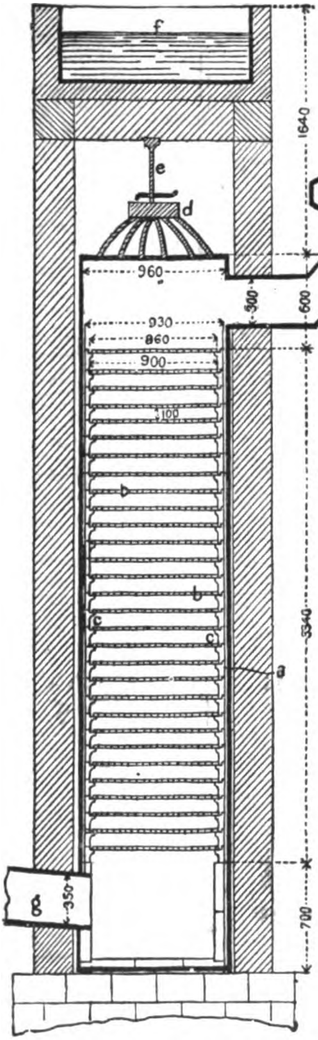

FIG. 9.

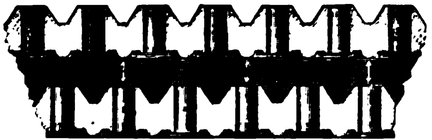

FIG. 10.

Other apparatus based on the same principle as the plate towers have been introduced by other inventors. Gilchrist (J. Soc. Chem. Ind. 1894, 1142; 1899, 461) employs pipe columns between the chambers; these are lead towers through which pass from side to side a large number of horizontal pipes cooled by drawing air through them, while the towers are fed with water or acid. Winsloe and Hart (Eng. Pat. 20142, 1901) employ vertical air-cooling pipes set in the connecting trunks between the chambers. Benker (Fr. Pat. 238872) places leaden towers between the chambers 5 ft. wide and 20–25 ft. high, filled with stoneware cylinders; they are fed with nitrous vitriol and steam enters at the bottom with the gases. Guttmann (D. R. P. 91815) recommends hollow balls for packing reaction towers. Hart and Bailey (J. Soc. Chem. Ind. 1903, 473) employ towers between the chambers also provided with vertical tubes through which cooling air passes, and the gases pass down from top to bottom. Petersen introduces an additional tower called the 'chamber-regulator' between the last chamber and the Gay-Lussac towers; nitrous vitriol of 1·6 sp.gr. is continuously circulated through this and he claims that he obtains a more regular working of the process by this means, and considerable economy in nitre consumption (Chem. Zeit. 1909, 409).

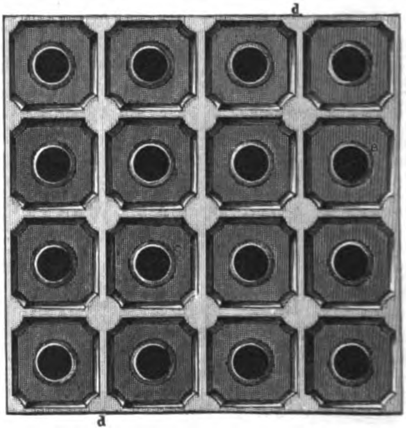

FIG. 11.

The increase in the size and number of Gay-Lussac and Glover towers, and the introduction of intermediate reaction towers, led Niedenführ (Zeitsch. angew. Chem. 1902, 242) to propose the employment of a system of towers only, without chambers, for the manufacture of sulphuric acid. Two processes have been introduced for this purpose, viz. that of Opl of Hruschau (Eng. Pat. 20171, 1908), and the

Griesheim Elektron process (Eng. Pat. 20407, 1909). Opl's process with its 8 towers in series works in a similar way to the chamber process, the nitrous vitriol from the towers 8, 7, 6, and 5 being denitrated in towers 1, 2, 3, and 4 respectively, compressed burner gases being used for elevating the acids.

At Griesheim nitric acid is used in place of nitrous vitriol, and has to be completely regenerated after the formation of sulphuric acid. But neither process has yet reached such a stage of development as to allow a definite opinion to be formed upon it (Hasenclever, J. Soc. Chem. Ind. 1911, 1292).

Hartmann (Zeitsch. angew. Chem. 1911, 2302) gives further details of the Opl process, which has now been at work four years at Hruschau. Six towers are employed like ordinary Glover and Gay-Lussac towers, and are fed by automatic elevators; the pipes leading to towers 3, 4, 5, and 6 are cooled by water; the surplus acid from 2, 3, 4, and 5 is mixed with the whole of that from 6, and finally passed through 1, which it leaves at 1·7 sp.gr. The fan is placed behind 6, and then there is a coke box to remove acid mist so that the exit acidity is only 0·22 grains SO_3 per cb. ft. 18 tons 1·7 acid are produced daily with a reaction space equal to 2 cb. ft. per lb. of sulphur burnt and a nitre consumption equal to 2·25 p.c. on the sulphur. Towers 1, 2, and 3 produce, 20, 30, and 50 p.c. of the acid, the others being simply denitrators.

THEORY OF THE CHAMBER PROCESS.

A large number of different views as to the nature of the normal chemical changes taking place in the vitriol chamber (as well as of those occurring under abnormal conditions) have been from time to time put forth by different observers. The basis on which all these views are founded is the fact that the higher oxides of nitrogen in one way or another bring about the oxidation of the sulphur dioxide in presence of water or steam to sulphuric acid, being reduced to lower oxides which take up oxygen again and then continue the cycle of changes as before.

The theories of Weber and Berzelius were very simple, and may be represented by the following equations—

(1) $3SO_2+2HNO_3+2H_2O=3H_2SO_4+2NO$.
(2) $4NO+O_2=2N_2O_3$.
(3) $2NO+O_2=N_2O_4$.
(4) $SO_2+N_2O_3+H_2O=H_2SO_4+2NO$.
(5) $2SO_2+N_2O_4+2H_2O=2H_2SO_4+2NO$.

Weber believed that equations (2) and (4) represented the chief reactions occurring, N_2O_3 or nitrous acid being the active agent, whilst Berzelius was of opinion that N_2O_4 also played an active part in the process.

The steam, oxides of nitrogen, and sulphur dioxide react, producing a fine mist of dilute sulphuric acid.

If sufficient water be not present crystals separate of the composition $SO_2(OH)(NO_2)$, a substance known as *nitrosylsulphuric acid*, *nitrososulphuric acid*, *nitrosulphonic acid*, or *chamber crystals;* but these are decomposed again into sulphuric acid and nitrous acid by excess of water or steam.

Davy and Winkler were of opinion that this substance was a temporary intermediate product in the process, and their views were represented by the following equations—

(6) $4SO_2+3N_2O_4+2H_2O=4SO_2(OH)(NO_2)+2NO$
(7) $4SO_2(OH)(NO_2)+2H_2O=4H_2SO_4+N_2O_4+2NO$
(8) $2NO+O_2=N_2O_4$.

Lunge's earlier ideas were similar only that he represented N_2O_3 as the active substance, and not NO, and his views are thus represented—

(9) $2SO_2+N_2O_3+O_2+H_2O$
$=2SO_2(OH)(ONO)$ nitrososulphuric acid.
(10) $2SO_2(OH)(ONO)+H_2O=2H_2SO_4+N_2O_3$.

By N_2O_3 here is meant the equivalent mixture of NO and NO_2. Lunge believed that this represented the chief cycle of reactions in the process, but stated that they must be modified in the first part of the chambers where there is present a large excess of NO above the proportion $NO+NO_2$. Here the following reactions may take place—

(11) $SO_2+N_2O_3+H_2O=H_2SO_4+2NO$.
(12) $2SO_2+2NO+3O+H_2O=2SO_2(OH)(ONO)$.
(13) $2SO_2(OH)(ONO)+SO_2+2H_2O$
$=3H_2SO_4+2NO$.

The last reaction represents what takes place in the Glover tower, the conditions being identical in both cases.

During the last few years a number of different views have been put forward by Lunge, Raschig, Divers, Wentzki, and others, of the reactions taking place in the chambers, which differ from each other chiefly in conceptions as to the nature of the intermediate substance or substances which are formed by the interaction of sulphur dioxide, the oxides of nitrogen and water, and which afterwards split up, yielding sulphuric acid and a lower oxide of nitrogen.

Lunge's latest ideas are given in an article published by him in conjunction with Berl (Zeitsch. angew. Chem. 1906, 19, 807–819, 857–869, 881–894). The following equations represent these—

(1) $SO_2+NO_2+H_2O=O:N(OH)SO_3H$ (Raschig's nitrosisulphonic acid or Trautz blue compound).

(2*a*) $2ON(OH)SO_3H+O=H_2O+2ONOSO_3H$ nitrososulphuric acid.

(2*b*) $2ON(OH)SO_3H+NO_2$
$=NO+H_2O+2ONOSO_3H$ nitrososulphuric acid.

(3*a*) $2ONOSO_3H+H_2O$
$=2SO_2(OH)_2+NO+NO_2$.

(3*b*) $2ONOSO_3H+SO_2+2H_2O$
$=H_2SO_4+ON(OH)SO_3H$.

(3*c*) $ON(OH)SO_3H=NO+H_2SO_4$.

(4) $2NO+O_2=N_2O_4$.

Equations (1), (2*a*), and (3*a*) represent the chief cycle of reactions which takes place, whilst (1), (2*b*), (3*b*), (3*c*), and (4) most likely represent the reactions occurring in the first chamber where there is an excess of sulphur dioxide and much nitric oxide.

Raschig's theory of the nature of the changes by which sulphur dioxide passes into sulphuric acid was first published in 1887 (Annalen, 1887, 241, 161), but it has been several times considerably modified since then. His latest ideas were published in Zeitsch. angew. Chem. 1907, 20, 694, and further elaborated and explained in a paper read before the Society of Chemical Industry in 1911 (J. Soc. Chem. Ind. 1911, 4, 166).

He represents the following reactions as taking place—

(1) $HNO_2+SO_2=ONSO_2H$, *nitrososulphonic acid*, a purely hypothetical substance which has not been isolated.

(2) $ONSO_2H+HNO_2=ON<^{OH}_{SO_3H}+NO$,

nitrosisulphonic acid, which he believes to be identical with the blue compound formed when excess of sulphur dioxide is passed through a solution of nitrosulphonic acid $O_2N{\cdot}SO_3H$ in concentrated sulphuric acid, and to be the cause also of the purple colour of Gay-Lussac acid when sulphur dioxide is in excess in the exit gases from the chambers—

(3) $ON<^{OH}_{SO_3H}=NO+H_2SO_4$.

(4) $2NO+O+H_2O=2HNO_2$.

Divers (J. Soc. Chem. Ind. 1911, 10, 594) has again modified Raschig's theory. He believes that this transitory substance, identical with the compound which gives the colour to purple acid, has the composition $H_2N_2SO_6$, which he calls *nitroxysulphuric acid*, and that it is the only intermediate substance formed in the reaction.

His views are represented as follows—

(1) $2HNO_2+SO_2=H_2N_2SO_6$.
(2) $H_2N_2SO_6=2NO+H_2SO_4$.
(3) $2NO+O+H_2O=2HNO_2$.

Wentzki (Zeitsch. angew. Chem. 1910, 1707; 1911, 392) criticises Raschig's and Lunge and Berl's views, and is of opinion that neither nitrosylsulphuric acid (chamber crystals) nor the blue compound can exist in the chamber when excess of sulphur dioxide is present, and that sulphuric acid may be produced from sulphur dioxide, nitrous gases, and water without the formation of any intermediate compounds, as in Weber and Berzelius' early theory.

The blue compound he calls *nitrosylous sulphuric acid*, and he gives it the constitution

$HO{\cdot}SO_2{\cdot}\underset{\underset{O}{\vee}}{ON{\cdot}NO}{\cdot}SO_2{\cdot}OH$.

Jurisch (Chem. Zeit. 1910, 1065) and Manchot (Zeitsch. angew. Chem. 1910, 2113, and 1912, 1055) criticise Raschig's formulæ for the composition of chamber crystals and purple acid.

Reynolds and Taylor (J. Soc. Chem. Ind. 1912, 367) also unfavourably criticise Raschig's conclusions, and support the early simpler theory.

Whichever of these various views of the nature of the chemical reactions taking place be regarded as most probable, and it is impossible to enter here into the details of the experimental evidence in favour of each, no doubt whatever can be entertained that none of them accounts for the whole of the chamber phenomena; for even with the best-designed and most perfectly working system of nitre recovery, there is always a loss to be accounted for, which amounts to at least 2 parts of nitre per 100 parts sulphur burned as pyrites, the average loss being 3–4 parts.

Considerable difference of opinion exists as to what proportion of this is lost by incomplete absorption in the Gay-Lussac tower either as NO or N_2O_3 and N_2O_4; but this cannot account for the whole of the loss; there remains a very considerable proportion which can only be put down to other chemical reactions taking place in the chambers and causing reduction of the higher oxides of nitrogen to nitrous oxide, nitrogen, or other nitrogenous compounds, or even to ammonia.

The loss through incomplete absorption may be called mechanical loss. Figures have been obtained by Lunge, Davis, Jackson, Mactear, and others, indicating amounts of escape equivalent to from 1 to 1·75 parts of nitre per 100 of sulphur burnt as usual proportions; whilst Hurter, Eschellmann, and others consider 0·25–0·5 as more nearly the amount thus lost on the average with efficient plant in good working order. From the results obtained in a variety of works Hurter concluded (Chem. News, 39, 170) that the total loss of nitre from mechanical sources (*i.e.* defective absorption, formation of nitric oxide, leakages, and solution in chamber acid jointly) does not amount to as much as 25 p.c. of the nitre charged, at least 75 p.c. being lost by chemical secondary changes. E. K. Muspratt states (J. Soc. Chem. Ind. 1884, 137) that the result of experiments made in ten different works by a committee of the Alkali Makers Association was that the total loss by non-absorption in the Gay-Lussac tower averaged close to 20 p.c. of the nitre used, that being 4 parts per 100 of sulphur burnt. Eschellman found (*ibid.* 1884, 134) that out of 2·75 parts of nitre per 100 of sulphur burnt, 0·33 part (12 p.c.) was accounted for by non-absorption in the Gay-Lussac tower of soluble nitrogen oxides, and 0·19 part more (7 p.c.) by the formation of nitric oxide, representing a total of 0·52 part (19 p.c.) of loss due to available nitrogen oxides of all kinds; to which 0·08 part (3 p.c.) must be added for leakages and retention in the acid; thus leaving 2·15 parts (78 p.c.) not accounted for by mechanical losses, but destroyed by secondary chemical changes.

On the other hand, Lunge, Benker, Sorel, and others are of opinion that the greater proportion of the loss is due to incomplete absorption, owing to the fact that the coefficient of solubility of N_2O_3 in sulphuric acid is immensely reduced by its enormous dilution in the exit gases with oxygen and nitrogen, and that, therefore, its complete absorption is an impossibility. Sorel has attempted to prove in a special instance (Zeitsch. angew. Chem. 1889, 279) that the exit gases were bound to carry away N_2O_3 equivalent to 3·09 parts nitre per 100 sulphur burnt, and Lunge states (Sulphuric Acid and Alkali, vol. i. pt. ii. 954) that it is extremely difficult by ordinary analytical methods to estimate the quantities of N_2O_3 or N_2O_4 passing away into the exit gases, whilst the escaping NO is still more difficult to determine accurately.

Considerable support has been given to the view that the mechanical losses constitute the greater proportion of the total loss by some experiments made by Inglis at Silvertown (J. Soc. Chem. Ind. 1907, 668). He condensed a number of samples of the exit gases by means of liquid air, and afterwards separated the various constituents by fractionation. He was able to account for between 50 and 60 p.c. of the loss as due to incomplete absorption, partly as N_2O_3, and partly as NO, the total loss being 2·58 parts nitre per 100 parts of sulphur burnt. However, even his figures leave some 40 p.c. loss of nitre to be accounted for as chemical losses. At one time the Glover tower was blamed, it being supposed that considerable reduction of the nitrous gases to nitrous oxide by the excess of sulphur dioxide present took place there, but this has been practically disproved by the fact that quite as good results are obtained when nitric acid is run through the tower as when it is introduced into the chambers direct; whilst the quantity of available nitrogen oxides contained in the gases passing out of the tower can be shown analytically to correspond practically with the quantity contained in the nitrous vitriol run into the tower. It has also been suggested that there is some loss in the Gay-Lussac tower owing to the reducing action of arsenious oxide in the acid, or to the coke packing, but this is again disproved by the fact that with brimstone acid, where there is no arsenic present, the same loss occurs, and also with towers packed with other materials than coke.

Hence any material chemical loss must be confined to the chambers themselves in virtue of secondary reactions.

It has long been known from the experiments of Pelouze and Weber, more recently repeated and amplified by Lunge, that in contact with water or highly dilute sulphuric acid, higher oxides of nitrogen are slowly acted on by sulphur dioxide, with formation of nitrous oxide, thus—

$$N_2O_4+3SO_2+3H_2O=N_2O+3H_2SO_4$$
$$N_2O_3+2SO_2+2H_2O=N_2O+2H_2SO_4$$
$$2NO+SO_2+H_2O=N_2O+H_2SO_4$$

but in contact with stronger acid these actions take place either not at all or only extremely slowly. Consequently this action is only likely to take place where water or aqueous vapour is in excess, and that will be only in the immediate vicinity of the entering steam. That this reduction does take place is now generally admitted, but to what extent and what proportion of the loss is due to it there is considerable difference of opinion. Inglis, in the experiments alluded to above, could only account for about 10 p.c. of the loss as nitrous oxide in the exit gases, but Hempel and Heymann (Zeitsch. Elektrochem. 1906, 600) state that they obtained nitrous oxide in the exit gases from several works varying from 0·063 to 0·25 p.c. where 0·1 p.c. nitrous oxide would be equivalent to a loss of 4·3 parts nitre per 100 parts sulphur burnt.

A further reduction to nitrogen may also take place, but no proof of this is possible, whilst Raschig is of opinion that even ammonia may be formed by secondary reactions, but, in general, this would probably at once react with nitrous acid to give nitrogen and water. In some cases, however, where the chamber acid contains free sulphurous acid he has found traces of ammonia present in the acid (J. Soc. Chem. Ind. 1911, 172).

PURIFICATION.

All pyrites acid contains more or less iron, arsenic, and other substances derived from the ore employed, the contamination being considerably greater in the case of acid from the Glover tower than in that from the chambers. For many purposes these impurities are of no great importance, but for others, a purer acid is required, and various processes have been devised for removing these impurities, more especially from the chamber acid.

The chief impurities are arsenic, antimony, selenium, lead, iron, nitrous acid, and organic matter. The lead is almost entirely precipitated on diluting the acid; the iron largely separates during concentration, especially in the platinum still, organic substances being oxidised at the same time.

The most serious impurity is arsenic, which is nearly always accompanied by antimony and selenium, and nitrous acid.

Arsenic. Pyrites chamber acid made from Spanish pyrites usually contains from 0·05 to 0·2 p.c. arsenic, as arsenious oxide, whilst the Glover tower acid may contain as much as 1 p.c. or more, partly as As_4O_6 and partly as As_2O_5.

There are two methods employed on a considerable scale for the removal of arsenic. The first is by precipitation as arsenic sulphide by sulphuretted hydrogen. The latter is generated usually from ferrous sulphide by the action of weak sulphuric acid in wooden vessels lined with lead, and the gas passes into a tower packed with rows of horizontal wooden bars of triangular section covered with lead. A stream of chamber acid, from 100° to 110°Tw., is fed into the tower by a distributing arrangement at the top. Usually several generators are employed, so that, by charging them alternately a fairly uniform current of gas can be obtained, and the arsenic should be completely precipitated by the time the acid arrives at the bottom of the tower, from which it is run or blown into settlers. From these it runs on to sand filters, which it leaves practically free from arsenic; it should not contain more than 1 part in 500,000 parts acid. When alkali waste is available, the sulphuretted hydrogen is frequently obtained from that source. Nitrous acid, antimony, selenium, lead, &c., are removed also by this method, and except for the presence of a small quantity of iron the acid is practically as pure as brimstone acid.

The second method employed on a manufacturing scale for the removal of arsenic depends on the conversion of the arsenic into trichloride by treatment with hydrochloric acid, and the removal of the latter by heat. Common salt and barium chloride have been tried instead of hydrogen chloride, but they have not been successfully used on a practical scale. It is necessary that any arsenic oxide in the acid should first be reduced to arsenious oxide. The United Alkali Co. have patented a process for treating Glover tower acid with hydrogen chloride at 100°, and removing the liquid arsenic chloride which separates by blowing air through it; any arsenic oxide present is reduced by treatment with charcoal or sulphur (Eng. Pats. 7916, 16929, 16930, 1905; 23139, 1906).

The arsenic chloride may also be removed by treatment of the acid with certain mineral oils or oil from lignite tar (Hasenbach, U.S. Pat. 836034, 1906; and Vereiso, Chem. Fabrik. Mannheim. Fr. Pat. 368452, 1906).

Nitrous compounds or nitric acid are removed from sulphuric acid by heating with a small quantity of ammonium sulphate, whereby nitrite or nitrate ammonium is formed and at once decomposed with evolution of nitrogen or nitrous oxide. This is especially necessary where the acid is to be concentrated in platinum vessels in order to prevent serious corrosion of that metal.

Non-volatile impurities can only be completely removed by distillation of the concentrated acid. This is usually carried out in glass retorts, and is a troublesome operation owing to the liability of the retorts to crack: as the impurities accumulate in the retort they cause serious bumping. Scraps of platinum or quartz, &c., are frequently introduced to prevent this, or a slow current of air is passed through the boiling acid.

Iron is practically insoluble in 100 p.c. sulphuric acid, so that by bringing the acid up to that strength by mixing with fuming acid, and allowing to stand for some months, practically all the iron separates out.

CONCENTRATION.

Before the invention of the Glover tower chamber acid of 110°–120°Tw. was always evaporated down in leaden pans until the sp.gr. rose to about 140°–145°Tw., when the action on the lead became too great for further concentration to be thus possible. Such pans are still in use to a considerable extent; when contamination by fuel gases is immaterial they are heated by passing the flame over the liquid (top-firing); in which case the concentration may be carried to 150°Tw.; a certain amount of acid is always carried away in the current of fire gases when this method is employed. It escapes as a vesicular mist, which can only be condensed by filtration through fine granular material.

In other cases the pans are heated from below, the lead being protected from direct contact with the flame by iron plates. Waste heat from various sources is often used for heating the pans; sometimes they are mounted on the top of the kilns or on the burner gas flue, so as to partly utilise the heat of combustion of the sulphur burnt. Glover at one time employed a large platinum dish, placed inside the gas flue from his brimstone burner for concentrating chamber acid up to 140°Tw. High pressure steam passing through lead coils has also been used instead of directly fired pans.

For the further concentration up to from 93 to 98 p.c. H_2SO_4, glass or platinum stills were at one time chiefly used, but the great losses through breakages of the former and the great rise in the price of the latter, have led to their being displaced by other materials and methods of concentration, of which the Kessler and Gaillard processes have been most successful.

Glass stills, as first introduced by Chance Brothers at Oldbury, were worked separately, each being filled up with acid from the lead pans and heated until sufficiently concentrated, when the heat was withdrawn and the acid siphoned off into carboys through a platinum or lead siphon cooled by water. They were set in sand-baths and it was very important that they should be protected from cold draughts, especially towards the close of the operation, otherwise great losses were incurred through breakages. The continuous system of Gridley was a great improvement, a series of retorts being arranged at slightly different levels, each being connected with the next lower one by a siphon, so that when a slow stream of weak acid is run into the top one, entering at its highest part, the partly concentrated heavier acid passes through the siphon to the next, and so throughout the series, while concentrated O.V. is continuously discharged from the lowest. The acid vapours pass from each retort into a common pipe by which they are conveyed to a leaden coke tower and condensed by water. In the latest arrangement four retorts are enclosed in a glass case to protect them from draughts, and each is heated by a separate burner, coal gas being used as the heating agent, breakages being in this way reduced to a minimum. The acid is cooled by first passing through a platinum tube and then into a leaden vessel, both water-cooled. The strength of the acid obtained in these glasses does not usually exceed 93 p.c. H_2SO_4.

G. Veitch has patented (J. Soc. Chem. Ind. 1889, 983) the use of a series of flat-bottomed glass retorts arranged one above another on a stepped terrace within a common fire flue, the fire being placed at the lowest end, the flue narrowing upwards. The acid passes continuously through the whole series, leaving the lowest as concentrated acid.

Negrier (*ibid.* 1891, 46) patented a similar arrangement, using porcelain dishes instead of glass retorts, the lip of one dish projecting over the next below in the series. Two series of dishes are mounted side by side, fed from the same cistern, each dish resting on asbestos tissue and surrounded by sand up to the level of the upper rim; the supporting shelves are of iron.

Benker has improved the Negrier system by enclosing the porcelain dishes in a chamber of volvic lava. The flue gases are kept separate from the acid vapours, which are condensed in a lead-lined box filled with granular stoneware or silica. The dishes are covered with a thin layer of asbestos and silicate of soda cement, and the acid may be concentrated up to 97–98 p.c. H_2SO_4 (Zeitsch. angew. Chem. 1903, 1150). The porcelain dishes have, with advantage, been replaced latterly by vessels made of fused silica or metillure.

Webb uses a series of beakers arranged terracewise, the acid overflowing from one beaker and passing to the bottom of the next; they were at first made of glass, but later of porcelain. They can be worked without lead pans, 14–16 vessels in each series, but the fire gases and acid vapours are not separated, and a considerable amount of white fumes escape to the chimney (Eng. Pats. 2343, 17407, 18891, 1891). Other patents of Webb's showing modifications of the above are Eng. Pats. 1515, 1516, 1901; and D. R. P. 135886.

Levinstein (Eng. Pats. 19213, 1892; 2476, 2835, 1893) and Guttmann (Eng. Pat. 16220, 1898) have patented different arrangements of glass or porcelain beakers somewhat similar to Webb's.

Platinum stills have been considerably modified since their first introduction. Long, narrow, and shallow stills are now employed, sometimes with the bottom corrugated to increase the heating surface (Prentice system). In the Delplace system two shallow stills about 6 ft. long and 18 ins. wide are combined in series, the first receiving acid of about 144°Tw. from the lead pans; the vapours from each are condensed in a water-cooled platinum tube, the distillate from the second one being returned to the pans. The acid may be concentrated up to 98 p.c. in this way, and is cooled in a bottle-shaped platinum cooler, and afterwards in lead. Desmoutis puts concentric partitions in the stills, but any saving in fuel is counterbalanced by a greater loss of platinum. In the Faure and Kessler system platinum dishes are employed, provided with water-cooled leaden hoods; the condensed vapours run down the leaden covers to a lute. Platinum stills are appreciably attacked by concentrated sulphuric acid, the action being considerable when traces of nitrous acid are present. Platinum-iridium containing 10 p.c. iridium and upwards is much less readily affected than pure platinum. The loss of platinum by corrosion has been variously estimated at from 0·5–5·0 or even 10·0 grms. per ton of acid concentrated, according to the purity of the acid and the degree of concentration required. W. C. Heraeus (Chem. Zeit. Rep. 15, 36; also J. Soc. Chem. Ind. 1891, 460) found that platinum-iridium alloys containing respectively 0·01, 0·5, 5·0, and 10·0 p.c. iridium, are affected by hot sulphuric acid in the relative proportions 100, 90, 73, and 58 when sheets of these alloys are allowed to remain 40 days in a concentration apparatus, making 98 p.c. acid. With pure gold the relative proportion is only 13, or only one-seventh that of commercial platinum (0·5 p.c. iridium). Heraeus has, therefore, patented a process for covering the surface of platinum vessels with a compact adhesive layer of gold (Eng. Pat. 2499, 1891). Even when the price of gold was considerably higher than that of platinum the diminution of corrosion during use offered considerable pecuniary advantage, more particularly for 97–98 p.c. acid, and Heraeus stills have been adopted in several large German works (Lunge, J. Soc. Chem. Ind. 1892, 522). The acid to be concentrated must be very pure as crusts from impure acid damage the gold lining. Glover tower acid is seldom concentrated in platinum vessels owing to the hard crusts which separate.

Conroy (*ibid.* 1903, 465) has investigated the influence of various impurities in the acid, and the effect of temperature also on the corrosion of platinum vessels.

Cast-iron vessels have come into considerable use for the production of acid of high strength up to 98 p.c. H_2SO_4. Usually the acid is brought up to 93 or 94 p.c. in glass or platinum, and then to the highest strength in cast iron. There is a certain amount of action on the iron even at these strengths, but the contamination of the acid is not serious, as the sulphate mostly separates as an insoluble precipitate as the acid becomes fully concentrated. Sometimes cast-iron pans are employed with leaden covers, as in Faure and Kessler's system. If iron covers are used they must be kept hot so that no weak acid can condense on them. Cast-iron vessels seldom last more than 4–8 months. Weak acid can be concentrated in a deep cast-iron pan by running it on the surface of the heated acid, which is not allowed to drop below 90–93 p.c. H_2SO_4, the strong acid being at the same time withdrawn from the bottom. Cast-iron vessels are largely used for concentrating waste acids and impure Glover tower acid where the separation of impurities would render concentration in glass or platinum apparatus practically impossible. Hartmann (Chem. Zeit. 1899, 147) describes their use for concentrating waste acid from nitrating processes. Cast-iron dishes made of the so-called "neutral iron" by the A. G. für Bergbau und Eisen Luttenbetrieb at Kattowitz, Silesia, are now used by Hartmann and Benker for concentrating on the Benker system, and the acid comes out water white and not distinguishable from acid concentrated in platinum (Lunge's Sulphuric Acid, vol. i. 1176).

Dyson (Eng. Pats. 17699, 1893; 27769, 1896) employs a double row of stepped retorts made of iron and lined with a special acid-proof enamel for concentrating sulphuric acid from 100° to 168°Tw.

Zanner (Eng. Pat. 7999, 1901) places cast-iron pans lined with acid-proof stoneware slabs jointed with asbestos cement in the flue between the kilns and the Glover tower, and concentrates acid from 60°Bé. up to 66°Bé. by means of the hot gases. The pans are covered with earthenware slabs to keep the flue dust from falling into them and holes are provided for the escape of the distillate (Meyer, J. Soc. Chem. Ind. 1903, 781).

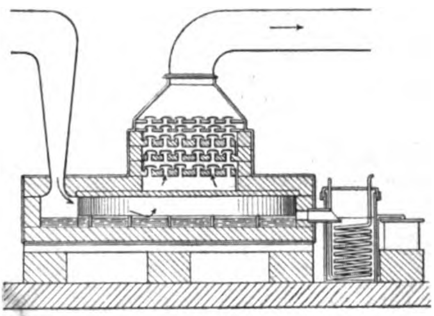

FIG. 12.

The Kessler process for the concentration of sulphuric acid by means of hot gases (Eng. Pats. 19215, 1891; 26169, 1898; 21376, 1900) has proved one of the most successful of the processes for this purpose. The hot gases from a producer charged with coke are drawn by means of a steam exhauster over the surface of the acid in a large shallow trough of volvic lava with a thick lead jacket, called the *saturex*, and then through a column, the *recuperator*, the lower section of which is of lava and the upper one of lead, where they come into intimate contact with a descending stream of weak acid which retains most of the acid vapours, but allows the steam to pass on to a large lead-lined condenser filled with coke crushed to the size of rice grains. This filters out the remainder of the acid vapour, and allows only aqueous vapour to escape. Fig. 12 gives a sectional elevation of the saturex and recuperator. The steam exhauster is placed in the connection between the recuperator and the condenser, and the steam and acid vapours pass downwards through the latter. A recent improvement has been made by replacing the steam exhauster by a compressed air jet; this has considerably reduced the amount of weak acid passing back from the condenser to be reconcentrated.

The concentrated acid is not so pure as that obtained in Benker's process, and seldom exceeds 95–96 p.c. H_2SO_4. A much larger condenser or filter is also required, owing to the dilution of the acid vapours with the fuel gases.

In the Gaillard process (Eng. Pat. 12538, 1906; Chem. Zeit. 1910, 173) the concentration is also brought about by means of hot gases. The dilute acid is sprayed by means of atomisers into the top of a cylindrical tower of volvic lava, in which it meets the hot products of combustion from a generator fed with coke. The hot gases enter near the bottom and leave at the top, from which they pass to a number of leaden boxes containing fine coke to remove the acid vapours. The acid arrives at the bottom of the tower in a concentrated state. This process has proved particularly useful for concentrating very impure chamber acid, and also for waste acids from petroleum refining. Stolzenwald (Zeitsch. angew. Chem. 1910, 175) and Duron (*ibid.* 1910, 2307) compare concentration up to 98 p.c. H_2SO_4 in Gaillard and Kessler plants with concentration in cast-iron boilers and pans.

Sulphuric acid of 100 p.c H_2SO_4 is usually obtained by adding fuming acid to ordinary oil of vitriol; this was formerly a very expensive process, and Lunge worked out a method for freezing out the acid from ordinary concentrated sulphuric acid by suitably cooling it, separating the crystals from the fluid portion and melting the former (Eng. Pats. 96, 1883; 4430, 1887). It was worked for a number of years in England at Widnes, and on the Continent at Petit-Quevilly and Griesheim, but it has been given up owing to the cheapening of fuming acid. It is described by Lunge (Sulphuric Acid, vol. i. 918) and by Osterberger and Capella (Bull. Ind. Soc. Rouen, 1889, 307).

PRACTICAL YIELD OF SULPHURIC ACID AND LOSSES DURING MANUFACTURE.

100 parts of sulphur charged into the kilns as brimstone or pyrites should theoretically yield 306·25 parts H_2SO_4. This yield is never obtained in practice, the chief sources of loss being—

(1) Sulphur is left in the ashes or cinders as sulphide, sulphate, &c. In the case of brimstone this is usually negligible, but with pyrites the sulphur left in the burnt ore may vary from 1 p.c. in the case of certain non-cupreous ores, practically free also from lead and zinc, to 2·5–3 p.c. in ordinary cupreous Spanish ores (Rio Tinto, Tharsis, Esperanza, &c.), and may reach 7 or 8 p.c. in the case of inferior ores containing much lead or zinc, or with good ores owing to faulty construction or working of the burners.

(2) Sulphur may sublime, when it will condense in the flues or in the acid itself and is lost.

(3) Loss occurs by leakages of gas during charging and working the kilns, potting nitre, and through cracks and holes in the chamber walls due to corrosion if they are not kept in good repair; and by leakages of liquid acid from chambers, siphons, tanks, &c.

(4) Sulphur escapes in the exit gases either through incomplete conversion of sulphur dioxide into sulphuric acid, or by incomplete condensation of the suspended vesicles of the latter substance.

Loss by incomplete conversion mainly depends in the first place whether Gay-Lussac towers are used or not; if they are used the sulphur dioxide escaping cannot amount to more than 2 p.c. of that equivalent to the sulphur burnt without causing a great loss of nitre through the formation of much nitric oxide, and it may be kept below 1 p.c. if the chamber space is ample (18–20 feet per lb. of sulphur burnt), the Gay-Lussac tower is well-proportioned and carefully packed, and the working of the whole process is under skilled supervision.

Under such conditions 100 parts of sulphur (as pyrites) charged into the kilns may be accounted for thus—

Left unburnt in 'cinders' . . .	5–6 parts.
Losses through leakages and incomplete conversion . . .	2–3 „
Total losses . . .	7–9 „

leaving 93–91 parts obtained as sulphuric acid, which is equivalent to 285–278 parts H_2SO_4 per 100 sulphur charged.

Even where only 11–12 cb. ft. chamber space per lb. sulphur burnt is employed, as good a yield may be obtained, provided that the capacity of the absorbing towers is considerably increased.

From brimstone 295–300 parts may be obtained per 100 sulphur charged, losses from incomplete burning being usually insignificant.

Where no Gay-Lussac tower is used the loss from incomplete conversion and condensation may be much greater, even when 25–30 cb. ft. chamber space per lb. sulphur is employed.

Consumption of nitre. As regards loss of nitre both with and without Gay-Lussac towers, the figures obtained in different factories vary very considerably; but, in general, the nitre used per 100 parts of sulphur burnt varies between 2·5 and 4 p.c.,[1] where Gay-Lussac towers are employed, and averages about 10 p.c. when they are absent. The more recent improvements of the chamber process have resulted in a great increase in the capacity of the chamber plant in many instances without any serious increase in nitre consumption.

Guttmann (J. Soc. Chem. Ind. 1903, 1332) states that Meyer, for his circular chamber system, guarantees a maximum consumption of 2·7 p.c. nitre, using 11·6 cb. ft. chamber space per lb. of sulphur burnt; with intermediate towers, fans and atomised water in place of steam, this may be reduced to 1·8 p.c. nitre.

Lüty (Zeitsch. angew. Chem. 1905, 1253), in describing Niedenführ's system, states that with 7–9 cb. ft. chamber space only 2·2–2·45 p.c. nitre is required.

The Alkali Works Report for 1906 gives particulars of a chamber system in which steam has been completely replaced by atomised water, whereby the chamber space has been

---

[1] On the Continent the consumption of nitre is stated in a number of different ways. Usually the percentage is calculated on the acid made either in the form of chamber acid, acid of 1·7 sp.gr. or 100 p.c. H_2SO_4. Frequently it is stated in terms of nitric acid of 1·33 sp.gr., instead of sodium nitrate

reduced from 16·2–10·33 cb. ft. per lb. sulphur, and the nitre consumption from 4·23–2·87 p.c.

Littmann (Zeitsch. angew. Chem. 1906, 1177) claims that by allowing the gas from the Glover tower to enter the first chamber by six inlets at intervals along the top instead of by one at one end, he was able to reduce the chamber space from 14·5–12·9 cb. ft., and the nitre consumption from 3·6–2·9 p.c.

Falding (Eng. and Mining J. 1909, 441), in describing his system in which he combines one large chamber of considerable height compared with its length or breadth, with a cooling tower before the Gay-Lussac tower (U.S. Pat. 932771, 1909), states that with a chamber space of 7 cb. ft. per lb. of sulphur burnt, he only uses 2·8 p.c. nitre, and later (J. Ind. Eng. Chem. 1913, 223) he states that the chambers can be worked with only 1 to 1·5 per cent. nitre, using the same chamber space. On the other hand, Nemes (Zeitsch. angew. Chem. 1911, 387) adversely criticises the intensive system of working, and contends that the nitre consumption invariably rises with, and much more rapidly than, the yield per cubic metre; more supervision is required, and the cost of production of the acid is increased. He gives figures which differ considerably from the results quoted above.

Petersen (Zeitsch. angew. Chem. 1911, 877) replies to Nemes, giving the results obtained by Falding's and Meyer's systems in order to refute his statements.

Hasenclever (J. Soc. Chem. Ind. 1911, 1291), in the Hürter memorial lecture, gives it as his opinion that 11 cb. ft. per lb. of sulphur burnt is about the limit for chamber space without unduly increasing the cost of chamber repairs.

The nitre consumption in the Opl tower process as worked at Hurschau is given by Hartmann (Zeitsch. angew. Chem. 1911, 2302) as equal to 2·25 p.c. on the sulphur burnt, whilst the reaction space of the system is 0·53 cb. ft. per lb. 1·7 acid (approx. 2 cb. ft. per lb. sulphur).

Petersen (Zeitsch. angew. Chem. 1912, 762) compares the tower system with Falding's to the advantage of the latter.

MANUFACTURE OF FUMING ACID.

The various processes for the production of fuming acid, which have been at different times patented and put more or less in actual operation, may conveniently be grouped in two divisions—namely: (1) those depending on the action of heat on some metallic sulphate, whereby decomposition is brought about with evolution of sulphur trioxide, more or less further decomposed into sulphur dioxide and oxygen according to the temperature employed; (2) those in which the essential action is the surface or catalytic action of certain solids in bringing about union between sulphur dioxide and oxygen.

(1) Processes of Distillation of Sulphates.

The substance most largely employed, before the development of the contact process, as a source of fuming acid, was sulphate of iron, formerly in the form of 'copperas' or 'green vitriol' (ferrous sulphate), carefully dried so as to deprive it of most of its water of crystallisation and partially peroxidised during the process; latterly in the form of crude ferric sulphate prepared by long continued weathering of certain slaty minerals containing iron sulphide disseminated throughout them, lixiviation of the mass, evaporation of the mixed ferrous, ferric and aluminium sulphates dissolved out, and gently roasting so as to dehydrate the mass and completely peroxidise the iron present. The product thus obtained was heated in a series of clay retorts mounted together in a large 'galley' furnace, the sulphur trioxide was expelled and condensed in receivers previously charged either with a small quantity of water or preferably with oil of vitriol or weak fuming acid from a previous operation. Several successive charges were worked off into the same set of receivers, each retort holding not more than 3 kilos of 'vitriol-stone;' the residuum of impure ferric oxide, more or less brightly tinted, left in the retort constituted as important a product as the fuming acid itself, especially in the case of certain shades in the production of which so high a temperature was requisite that much of the anhydride was lost by splitting up into sulphur dioxide and oxygen; by the use of various subsidiary processes the residue was converted into pigments of different shades and considerable value. By redistilling at a gentle heat the fuming acid thus prepared, almost pure sulphur trioxide could be obtained or fuming acid of any strength required. This process was worked in Bohemia from about the year 1790 until 1900, when it was given up, as it could not compete with the 'catalytic' or 'contact' process. R. Schubert proposed to effect the distillation under greatly diminished pressure in order to reduce the loss from decomposition of SO_3, and passed the vapours evolved over heated platinised asbestos to bring about the reunion of any SO_2 and O formed. Sonstadt (1875) proposed magnesium sulphate for use in place of ferric sulphate, but the high temperature required to decompose it causes much loss by conversion into sulphur dioxide and oxygen. Sodium pyrosulphate obtained by carefully heating sodium hydrogen sulphate, was proposed by Prelier in 1847, and repatented by Wallace in 1876; the reactions here are

$$Na_2SO_4+H_2SO_4=2NaHSO_4$$
$$2NaHSO_4=H_2O+Na_2S_2O_7$$
$$Na_2S_2O_7=Na_2SO_4+SO_3$$

so that the process is a continuous one, the neutral sodium sulphate resulting from the distillation being converted into sodium hydrogen sulphate by treatment with sulphuric acid, and so on, over and over again. Wolters mixed magnesium sulphate with the pyrosulphate, stating that the sulphur trioxide was given off at a lower temperature than with pyrosulphate alone. None of these processes appears to have met with much commercial success, but a method due to Wolters is said by Lunge to have been actually at work in several factories; sodium pyrosulphate was treated with sulphuric acid, when sulphur trioxide was formed, together with sodium hydrogen sulphate, thus:

$$Na_2S_2O_7+H_2SO_4=2NaHSO_4+SO_3.$$

The residual sodium hydrogen sulphate was heated to 300°–320°C. in a retort furnished with an agitator and connected with an air-pump, and converted into pyrosulphate again.

Winkler suggested applying the continuous principle to the ferric sulphate distillation process by heating the residue with sulphuric acid so as to reproduce the sulphate of iron. Scheurer-Kestner found that by heating to a bright red heat a mixture of 2 parts calcium sulphate and 1 of ferric oxide, much sulphur trioxide was evolved, comparatively little being broken up into sulphur dioxide and oxygen, until the latter part of the heating; addition of a little calcium chloride or fluoride to the mixture considerably retarded the decomposition. Cummings (Eng. Pat. 7355, 1886) heated bricks made of gypsum and clay in a kiln, whereby silicate of lime and alumina were formed, suitable for hydraulic cement, while sulphur trioxide was evolved, more or less decomposed into sulphur dioxide and oxygen.

(2) Catalytic or Contact Process.

It has long been known that when a mixture of sulphur dioxide and oxygen is passed through a tube containing heated platinum, combination is induced, and sulphur trioxide formed; Peregrine Phillips, a vinegar maker, of Bristol, was the first to utilise the reaction in vitriol-making, and so to dispense with the use of nitre; in 1831 he patented a process of this kind (Eng. Pat. 6096, 1831), brimstone being burnt in excess of air, so that the gaseous mixture contained sufficient oxygen, and the gases were passed through heated tubes containing finely-divided platinum. The sulphuric acid formed was absorbed in a lead-lined tower filled with pebbles, down which water trickled. The process proved unable to compete with the chamber process at the time, and the demand for fuming acid had not yet arisen. Nevertheless, Phillips must be recognised as the real inventor of the contact process which has made such enormous progress during the last 30 years, having superseded all other processes for the manufacture of fuming acid, and is also largely employed for the production of high strength non-fuming acid in place of the lead chamber process.

Although several other attempts were made to utilise the catalytic action of platinum for this purpose no real progress was made until the year 1875, when two proposals were brought forward for manufacturing fuming acid by catalytic action. In that year Squire and Messel (Eng. Pat. 3278, Sept. 18, 1875) invented a process for the manufacture of sulphur trioxide and fuming acid, in which ordinary oil of vitriol was decomposed by heat into sulphur dioxide, oxygen, and steam, the latter was removed by condensation, as in Deville and Debray's process for the manufacture of oxygen from vitriol, except that the sulphur dioxide was not removed with the aqueous vapour, and the sulphur dioxide and oxygen were recombined by passing over heated platinised pumice (The Alkali Trade, C. J. Kingzett, p. 25). In 1875 also Winkler (Dingl. poly. J. Oct. 1875, 128) suggested a process based on much the same lines in which platinised asbestos (prepared by dipping asbestos successively into platinic chloride and sal-ammoniac solutions and igniting) was to be employed as the 'catalytic' agent. The principal difficulty in applying this process industrially was the rapid corrosive action exerted upon that part of the plant where the sulphuric acid was decomposed by heat. Squire and Messel's process was started at Silvertown in April, 1876, and was worked for a number of years until superseded by other processes mentioned later.

Fuming acid was made in Germany also by this or a similar method in 1877 by Clemm at Mannheim, and later by Jacob at Kreuznach, and in 1882 by Meister Lucius and Brüning at Höchst. In 1881 at the Thann Chemical Works in Alsace, a process introduced by Squire and worked out during 1879–1880 in conjunction with Chapman, Messel & Co. of Silvertown, was started for the manufacture of fuming acid from brimstone burner gases. The latter were treated with water under a pressure of 4 atmospheres. The sulphur dioxide was expelled by steam, mixed with air and passed over heated platinised asbestos. The sulphur trioxide formed was absorbed by concentrated sulphuric acid, and the exit gases containing some unoxidised sulphur dioxide were passed back into the process. Soon afterwards a similar plant was started at Silvertown.

In 1878 Winkler (D. R. P. 4566) patented the use of a variety of catalytic agents of high activity, more especially such substances as asbestos, slag wool, infusorial earth, &c., or even organic bodies like cellulose or cotton wool, impregnated with platinum black by soaking in platinum chloride solution and reducing with sodium formate. Messel (1878) patented the employment of sulphur dioxide and oxygen made by burning sulphur in excess of electrolytic oxygen prepared by a dynamo machine. A somewhat similar patent was taken out by Lunge in 1888, pure oxygen obtained by Brin's process being employed. Neale (Eng. Pat. 1103, 1876) heated anhydrous sulphates or bisulphates in earthenware retorts and passed the mixture of sulphur dioxide and oxygen thus obtained over heated platinised asbestos, spongy platinum, or the oxides of iron, chromium, or copper. In 1882 Rath took out a patent for the use of ordinary burner gases from sulphur or pyrites burnt in air, passed through purifiers for removing dust and aqueous vapour, and then through vertical iron tubes containing surface-acting materials at a temperature below a full and a red heat. And in 1887 Hänisch and Schröder (Eng. Pat. 9188) worked out a process in which 25 p.c. pure sulphur dioxide, obtained by treating burner gases with water in a coke tower and expelling the sulphur dioxide by heat, as in their process for the manufacture of liquid sulphur dioxide, with 75 p.c. air were passed over heated platinised asbestos while under a pressure of 2–3 atmospheres. According to Lunge, this process was at work for some years in several large factories until the development of the contract process dealing with ordinary pyrites gases made it unprofitable.

In 1898 patents were taken out almost simultaneously by the Badische Anilin und Sodafabrik, by Meister Lucius and Brüning of Höchst, and by the Mannheimer Verein Chemischer Fabriken, for the manufacture of sulphur trioxide from ordinary pyrites gases by the contact process. They have been followed from time to time by other patents, giving particulars of later developments of these processes.

The best-known of these is that of the Badische Anilin und Sodafabrik (Eng. Pats. 19547, 19548, 19549, 1898). These patents give a general description of the process, and more details have been furnished by Dr. Knietsch in a lecture before the German Chemical Society (Ber. 1901, 4069). The pyrites burner gases have first to be purified from all substances that can affect the activity of the platinum of the contact mass. Arsenic, phosphorus, and mercury are the most injurious and the most difficult to remove from the gases; other substances which may also do harm either by mechanically enveloping the platinum or by chemically affecting it, are iron, lead, copper, antimony, etc.

The gases are first treated with a jet of steam in the dust flue; this helps to oxidise any sulphur which has sublimed, by thoroughly mixing the gases, and at the same time it moistens them and prevents any condensation of concentrated sulphuric acid in the cast-iron cooling pipes, and therefore the possible formation of gaseous arsenical compounds, such as arsenuretted hydrogen, which cannot be eliminated when once formed, and which find their way into the contact mass, and in time seriously diminish its activity. The gases are then cooled to 100°C. by water in a tubular lead cooler, the steam again serving a useful purpose by preventing the formation of hard crusts in the cooler, and by diluting the condensing acid to such an extent that it has no serious action on the leaden tubes. The gases are next repeatedly washed with water or dilute sulphuric acid to free them from all traces of mist or dust, and are finally dried by means of concentrated sulphuric acid. Before passing to the contact apparatus they are examined optically, to see that they are free from dust and mist, by looking through a layer some yards in length illuminated at the further end, and chemically by allowing a stream of the gas to bubble through water for 24 hours, and then examining the liquid for arsenic by the Marsh test. The sulphuric acid mist must be completely removed, as it acts as a carrier for arsenic and other injurious substances.

The pure and dry gas, containing about 7 p.c. SO_2 is next forced by means of a mechanical mover through the contact apparatus (Fig. 13). This consists of a number of narrow vertical iron pipes containing the contact substance, in an outer casing also of iron. A portion of the gas enters this outer casing near the bottom, passes up between the contact tubes to a chamber at the top, where it meets and mixes with the remainder of the gas which enters the apparatus there. The temperature of this mixture is regulated by the relative proportions admitted at top and bottom, and should be high enough to start the reaction when it reaches the platinum contact material. The mixed gases pass down through the contact tubes, and the temperature rises quickly owing to the rapidity with which the combination of sulphur dioxide and oxygen takes place, but it is kept from rising too high by the stream of gas passing up between the tubes from below. When sulphur dioxide and oxygen combine to form sulphur trioxide, 32,200 calories are set free, and unless it is checked, the temperature rises so high that the reverse action sets in, the sulphur trioxide being decomposed again into sulphur dioxide and oxygen. A portion of the gas may also be admitted at different levels into the apparatus in order to get the best regulation of the temperatures. If necessary the gases are heated before entering the apparatus by their passage through the tubular heat-interchanger or regulator, through which a portion of the hot gases leaving the contact apparatus pass.

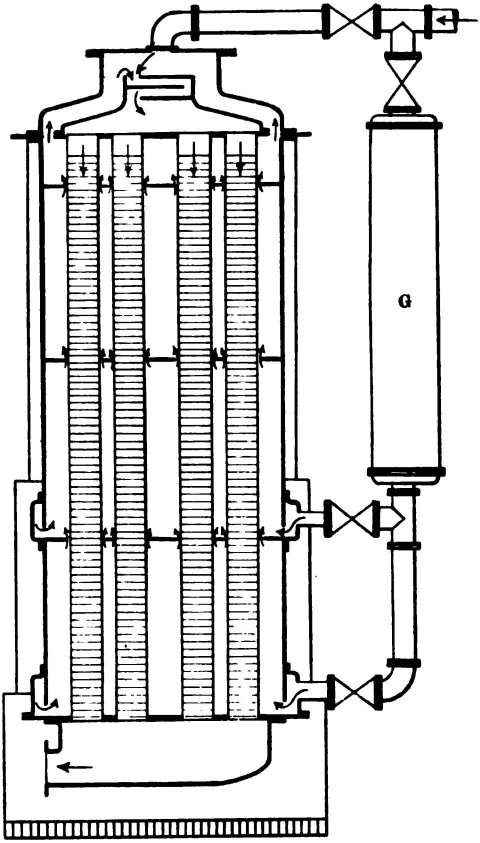

FIG. 13.—CONTACT APPARATUS.

The contact material consists of platinised asbestos containing about 10 p.c. platinum, and it is arranged in each vertical tube on perforated plates strung on a central rod, and separated from each other by short lengths of pipe in order that it should not get compressed and offer any considerable resistance to the passage of the gases.

The apparatus is first heated to above 300°C. in some convenient way, and the purified gases are then allowed to enter, the amounts, passing in at various levels, being regulated by the temperatures registered by thermometers at the top and bottom of the apparatus. The gases should reach the contact material at a temperature between 300° and 400°. The energetic action taking place at first causes a rapid rise to over 500°, followed by a gradual cooling, so that the gases leave the contact material at between 400° and 450°, at which temperatures a conversion of 96–98 p.c. may be obtained. The most suitable temperatures for maximum conversion will depend on a number of different factors, namely the quantity of gas passing through the apparatus, the percentage of sulphur dioxide and oxygen in the gases, the efficiency of the contact material, &c.

Other substances may be used instead of asbestos in combination with platinum as contact material. A mixture of salts consisting of a non-volatile base or salt of a non-volatile base which contains a radicle of a volatile acid, with a salt of a volatile base and non-volatile inorganic acid may be incorporated with platinum chloride and heated (Eng. Pat. 6828, 1901). Or oxides of iron, copper, or chromium may be used as foundations for the platinum (D. R. P. 140353, 1901). Two contact apparatus may be employed, 80–90 p.c. combination being obtained in the first, and the action completed in the second, the sulphur trioxide being removed from the gases before passing into the second apparatus. By this means the quantity of platinum employed may be considerably reduced (Eng. Pat. 12781, 1901).

The absorption of the sulphur trioxide takes place in iron vessels, wrought iron being used for making fuming acid, and cast iron for ordinary concentrated sulphuric acid (Eng. Pats. 1904, 1901, and 6829, 1901). Fuming acids containing more than 27 p.c. free sulphur trioxide have practically no action on wrought iron; by passing the gases through an absorber of this material, provided with a serrated hood dipping into acid of this strength or higher, and fed with dilute acid, fuming acid may be continuously obtained practically free from iron (containing less than 0·003 p.c.). To complete the absorption of the sulphur trioxide a similar absorber of cast iron is employed, also fed with dilute acid, but kept at a strength of between 97 and 98 p.c. H_2SO_4, at which strength almost perfect absorption may be obtained. If the attempt be made to absorb the sulphur trioxide with weaker acids or water, a considerable amount of white acid fume escapes from the apparatus, even although a number of absorbing vessels be employed.

Further details of the Badische process are given in U. S. Pats. 690062, 1901; 692018, 1902.

The processes worked out by Meister Lucius and Brünning and Höchst are described by Dr. Krauss and von Berneck in Lunge's Sulphuric Acid and Alkali, vol. i. 1374, and in various patent specifications. In their earlier process, the pyrites kiln gases were freed from impurities by washing with water, &c., dried by concentrated sulphuric acid and heated in a contact apparatus consisting of preliminary heating pipes and two contact retorts containing platinised asbestos. The gases left the contact apparatus at 400°–450°, and the sulphur trioxide was absorbed by concentrated sulphuric acid in cast-iron absorbers. After working in this way for some years, improvements were made by utilising the heat of the reaction for heating the incoming gases (Eng. Pat. 6057, 1898) and for regulating the temperature of the contact apparatus by the introduction of cold gases at various parts (Eng. Pat. 285, 1899). The greatly increased velocity of the reaction at high temperatures, up to a certain stage of the combination, next led to improvements for working the process, first at a high temperature, 530°, to obtain 75–80 p.c. conversion, and then at a lower temperature, 400°–450°, to complete it, either by working with two contact chambers kept at different temperatures, with cooling arrangements between, or by employing a long contact space, in which the gases enter at 530° and leave at about 430° (Eng. Pat. 1385, 1901). If two contact chambers are employed, a cheaper catalytist than platinum may be used in the first. The following list of active catalytic agents is given in this patent specification.

1. Platinum group metals.
2. Oxides and sulphates of Fe, Cr, Ni, Co, Mn, Ur, Cu.
3. Oxygen compounds of Al, Be, Zr, Ce, Di, La, Th, Ti, Si, and nearly all rare metals.
4. Mixtures of 1 with 2 and 3.
5. Mixtures of two or more substances of 2 and 3.

2, 3, and 5 can only be used at high temperatures, and hence may be used in the hot part of the contact apparatus.

The removal of the sulphur trioxide from the gases before passing into the second contact chamber and the more perfect utilisation of the heat of the reaction by means of heat interchangers in which the gases are cooled before the absorption of the sulphur trioxide and heated again for the completion of the reaction was the next improvement. Working in this way it is possible to use a cheaper catalytic than platinum in both contact chambers, which must be kept at the necessary high temperature, 80 per cent. conversion being obtained in the first, whilst 80 per cent. of the remaining 20 per cent. SO_2 is oxidised in the second, making 96 per cent. altogether; additional heat may also be obtained from the hot burner gas by passing the purified gas through a tubular economiser placed in the dust-chamber (Eng. Pat. 2368, 1901). Further particulars of the Hochst processes are given in Eng. Pats. 3161 and 4026, 1902; D. R. PP. 135887, and 169728, 1902.

In the process of The Mannheimer Verein Chemischer Fabriken (Eng. Pats. 17266, 1898; 1859, 3185, 24748, 1899; 18206, 1902; U. S. Pat. 690133, 1901) the air supplied to the pyrites furnaces is previously heated and dried, and the hot dry gases at about 700° pass at once into an iron-cased chamber containing ferric oxide (burnt ore) in pieces resting on a revolving grate. 60–65 p.c. of the sulphur dioxide is said to be here converted to sulphur trioxide, and at the same time the arsenic is retained by the oxide of iron. The latter is renewed from time to time as its catalytic activity diminishes. The gases pass on to an absorbing apparatus where the sulphur trioxide is removed, and are then forced by a fan-blast through filters of porous, granular, or fibrous substances to remove the last traces of impurities. They are now reheated before entering the final contact apparatus, which consists of a chamber containing removable iron frames supporting a net-work of platinised asbestos or other platinised fabric, in superposed compartments where the combination is completed.

The sulphur trioxide is then absorbed as before.

Copper oxide, chromium oxide, or manganese oxide or their sulphates may be used instead of ferric oxide as contact material for the hot gases (Eng. Pat. 4610, 1901).

Additional details of this process are given in a paper by Wilke (J. Soc. Chem. Ind. 1906, 4).

The chief features of the Schroeder-Grillos process (Eng. Pats. 25158, 1898; 17034, 1900; 10412, 1901) and its development are described in three papers read before the New York section of the Society of Chemical Industry (J. Soc. Chem. Ind. 1903, 348). The gases are purified by first cooling them to the ordinary temperature, passing them through scrubbers or washing towers fed with water or dilute acid, and finally through wet filters of large area containing a very fine coke packing or a fibrous material such as asbestos or cotton wool, and drying them by means of concentrated sulphuric acid. They are then preheated to 260°–280°, and passed into the bottom of a chamber set over a fireplace. In this chamber the contact mass is spread on perforated iron plates superposed one above the other, separated by partitions with central openings, by which means the gases are thoroughly mixed before passing from one layer to the next. The contact material is prepared by mixing solutions of a platinum salt with other soluble salts such as magnesium sulphate or a soluble phosphate, evaporating to dryness, and granulating. When heated in the contact apparatus the platinum separates and a very porous material is obtained, or platinum chloride may be mixed with a liquid or pasty material or a substance which melts in its own water of crystallisation, and the mixture dried in the contact apparatus by passing hot gases through it. The advantages claimed for this kind of contact material are that it is easily regenerated when its activity decreases by treating with water and regranulating, and that it offers little resistance to the passage of the gases. The heat is regulated so that the gases leave the contact apparatus at between 350° and 400°, and the sulphur trioxide is absorbed in a scrubbing tower after passing through suitable coolers.

At Freiberg (Lunge's Sulphuric acid, vol. i. 1409) the pyrites gases are purified exclusively by filtration (without any washing or drying apparatus) through a set of lead towers packed successively with coke, charcoal, wood shavings, and cotton wool. From the last tower the gases are aspirated by a fan-blast, and propelled into the contact apparatus, which consists of five horizontal retorts in a furnace heated by means of a gas producer. The contact material consists of platinised pumice or platinised unglazed porcelain containing 3–4 p.c. platinum. The temperature is kept between 440° and 460°, and the combination obtained varies between 45 and 90 p.c., depending on the percentage of sulphur dioxide in the gases. The sulphur trioxide is absorbed in towers fed with concentrated sulphuric acid and the uncombined gases are treated in vitrol chambers.

In Rabe's process Lunge's Sulphuric Acid, vol. i. 1415; Eng. Pat. 3327, 1901) the pyrites gases, after leaving the dust chamber, are sprayed with water in a porcelain-lined conduit, until the temperature is reduced to a point at which condensation of the fluid contents cannot yet take place, and then through a Glover tower fed with cold dilute sulphuric acid to cool them. They then pass through filter beds consisting of layers of granular coke of successively diminishing size, or through fibrous materials such as asbestos, the surface of which may be washed with water from time to time. The gases are thus obtained quite free from dust, and are further purified from non-neutral elements of a gaseous nature such as hydrogen chloride by means of bisulphites in granular form or in concentrated solution, and dried by concentrated sulphuric acid. The contact apparatus is a wide chamber containing platinised asbestos spread on sieves and the gases are heated up to the necessary temperature before entering it. The sulphur trioxide is absorbed in specially constructed reaction towers by concentrated sulphuric acid.

The Tentelen process as carried out at the Tentelen Chemical Works, St. Petersburg, is described in the British patents mentioned below. The burner gases after leaving the dust-chamber are cooled down to the ordinary temperature by passing down a circular tower built of lead surrounded by a water-jacket and cooled internally by means of a number of hollow vertical plates through which water continually flows (Eng. Pat. 14670, 1911). They next pass up through a filter of large area packed with coarse coke and then down through a similar filter containing very fine coke which removes all acid mist. The purification is completed by passing the gases through a series of washers containing an aqueous solution of an alkali or milk of lime or other alkaline earth to remove gaseous impurities as HCl, SiF_4, etc. (Eschellmann, Eng. Pat. 12213, 1907).

After drying, the pure gas passes through a heat interchanger or regulator to the contact apparatus. The first portion of the latter consists of a large empty vessel of considerable area, at the bottom of which is spread a layer of the contact material (platinised asbestos) on a perforated plate with projecting truncated pyramids which radiates its heat into the space above containing the incoming gases. By this means the temperature in the contact mass is not allowed to rise too high, and the conversion is completed in the lower narrower portion of the apparatus where the contact material is arranged in 25 thin layers on perforated plates and which is carefully protected against loss of heat (Eschellmann and Harmuth, Eng. Pats. 11969, 1902; 20952, 1904; 23419, 1909). After passing through the heat regulator again, and a small air cooler, the SO_3 is absorbed in a specially designed absorbing tower by concentrated sulphuric acid (Eschellmann and Harmuth, Eng. Pat. 22095, 1907).

A great many other patents have been taken out in recent years in connection with the contact process.

For purifying the burner gases Raynaud and Pierron (Eng. Pat. 16253, 1900) condense them in a porous material like kieselguhr, and after an interval expel them again by heat. The impurities are left behind. Eschellmann and Harmuth, U.S. Pats. 937147–937148, recommend the use of coke filters for removing lubricating oil from the purified gases before allowing them to enter the contact chamber.

Herreshoff (U.S. Pats. 940595, 950596, 955067, 969868, 1910) describes methods for cooling and purifying the burner gases by bringing them into intimate contact with weak acid in scrubbing towers and cooling pipes.

Messel (Eng. Pat. 22672, 1909) passes the burner gases over granulated coke or other carbonaceous material at a temperature above 300° in order to reduce any sulphur trioxide or sulphuric acid present to sulphur dioxide. In this way the acid mist which acts as a carrier for impurities is decomposed, and the whole of the sulphur dioxide and sulphur trioxide originally in the gases is obtained as sulphur trioxide and sulphuric acid in a pure condition.

Herreshoff (U. S. Pats. 719332 and 719333, 1903) employs two or more contact chambers with heat interchangers between. Ferguson (U. S. Pats. 723595, 723596, 1903) recommends the introduction of air into the gases in the interchangers to increase the content of oxygen, and (U. S. Pat. 857389, 1907) describes a long narrow contact apparatus furnished externally with ribs between which asbestos can be packed to regulate cooling by external air.

Raynaud and Pierron (Eng. Pat. 16254, 1900) suggest the use of different strengths of platinised asbestos in different parts of the contact apparatus in order to keep the temperature uniform. For absorption of sulphur trioxide, Herreshoff (U. S. Pats. 737233, 737626, 722981, 1903) describes apparatus suitable for this purpose.

Contact substances. The most important of these is platinised asbestos. It may be prepared of any strength up to 80 p.c. platinum by soaking asbestos in an alkaline solution of platinum chloride mixed with sufficient sodium formate to reduce the platinum, and heating to 70–80°. The platinum black is precipitated on the fibre, and the salts can be washed out with water without removing any of the platinum.

Another method of preparing it is by soaking the asbestos with a mixture of platinum chloride solution and methylated spirit, and setting fire to it.

Many other substances besides asbestos have been suggested as carriers for the platinum. Pumice, porcelain, oxides and sulphates of iron, copper, and chromium, soluble sulphates and phosphates have already been mentioned. Others are clay, glass, wool, kieselguhr, and sulphates of barium and calcium.

Revivification of inactive platinum contact masses. The Badische Anilin and Sodafabrik (D. R. P. 148196) treat the contact mass with dry sulphur dioxide or purified burner gas containing an excess of sulphur dioxide and little oxygen at the temperature of the contact process to remove arsenic and other impurities; or else with gases containing volatile compounds of chlorine.

D. R. P. 135887, 1902, recommends the admixture of steam with the purified gases for removing arsenic from the platinum contact material.

For catalytic bodies other than platinum, Eng. Pat. 1385, 1901, of Meister Lucius and Brüning already referred to, gives an extensive list.

THEORY OF THE CONTACT PROCESS.

The earlier workers of this process, Squire and Messel, Winkler, &c., were of opinion that a stoichiometrical mixture of sulphur dioxide and oxygen would give the best results, and endeavoured to work with these proportions, but never obtained anything like complete combination. In fact, complete conversion in one operation is theoretically impossible under these circumstances. This was first pointed out by Knietsch in the paper already referred to (Ber. 1901, 4093). From the results of a large number of experiments with mixtures of sulphur dioxide and oxygen, he showed that it is necessary to have an excess of one of the constituents present in order by mass action to eliminate the other completely, through its combining with the preponderating constituent to sulphur trioxide. The results of his experiments are illustrated by a series of curves (Figs. 14 and 15) showing the influence on the reaction of variations in temperature, composition of the gases, rate of flow for a definite amount of contact substance, and also of various contact substances. They show that it is necessary to have present an excess of oxygen, in order to obtain anything like complete combination of sulphur dioxide and oxygen to sulphur trioxide, and that if nitrogen is present it only acts as a diluent affecting the rate of combination, but not the percentage conversion.

Curves S, S′ and S″ show the course of the reaction using gases containing sulphur dioxide and oxygen in stoichiometrical proportions with which a quantitative conversion is not obtainable.

The formula of conversion should be written $2SO_2+nO_2=2SO_3+(n-1)O_2$, where n should not be less than 2.

Taking a technical burner gas containing 7 p.c. SO_2, 10 p.c. O, and 83 p.c. N, which is passed through a porcelain tube containing platinised asbestos heated to various temperatures, it is found that the first trace of sulphur trioxide appears at a little above 200°, and that the conversion is practically complete about 400°, and remains so up to 430°. Above this temperature the sulphur trioxide gradually dissociates more and more as the temperature rises, till it is all again reduced to sulphur dioxide and oxygen at 900°–1000° (curve 1, Fig. 14).

On increasing the rate of flow of the gas, or decreasing the amount of platinum employed, the maximum percentage conversion obtainable decreases, but at the same time the temperature of maximum conversion increases, but in all cases, there is the gradual reversion of the reaction which becomes complete at between 900° and 1000° as before (curves 2, 3, 4 and 5). Between 200° and 450° the reaction of formation preponderates, but above 450° the dissociation of sulphur trioxide comes very rapidly into play.

If the gases are passed through an empty porcelain tube some combination takes place, a maximum conversion of 30 p.c. being obtained at 600° (curve P), but if we start with almost completely converted gases and pass them through a heated empty tube, we find that decomposition only begins to take place as the temperature approaches 800°, and is not quite complete even at 1200°, thus showing that sulphur trioxide once formed, is very stable at high temperatures in the absence of an active contact substance (curve D). If the tube is filled with pieces of porcelain the decomposition begins earlier and increases more rapidly as the temperature rises (curve E), but not to the same extent as in the presence of platinum. Knietsch concludes from the results of his experiments that only those contact substances will be able to produce a quantitative reaction in one operation which exhibit their maximum of activity below 450°. All substances such as oxide of iron which develop their maximum power only beyond this temperature can never produce a quantitative conversion of sulphur dioxide into sulphur trioxide, no matter how long they remain in contact with the gases. Up to now there is only one catalytic substance which fulfils the beforementioned conditions, and that is platinum, and it cannot be replaced by any other metal of the Pt- group with even approximately equivalent results. On the other hand, above 450° the velocity of the reaction increases rapidly as the temperature rises, so that a large amount of sulphur dioxide may be converted to sulphur trioxide by a small amount of platinum when working at a high temperature, although the conversion may not be more than 90 p.c., and then the reaction may be completed at a lower temperature by using a larger amount of platinum. Fig. 15 represents this increase in velocity with temperature very clearly. Or a cheaper catalytic such as oxide of iron may be employed in the first stage of the operation.

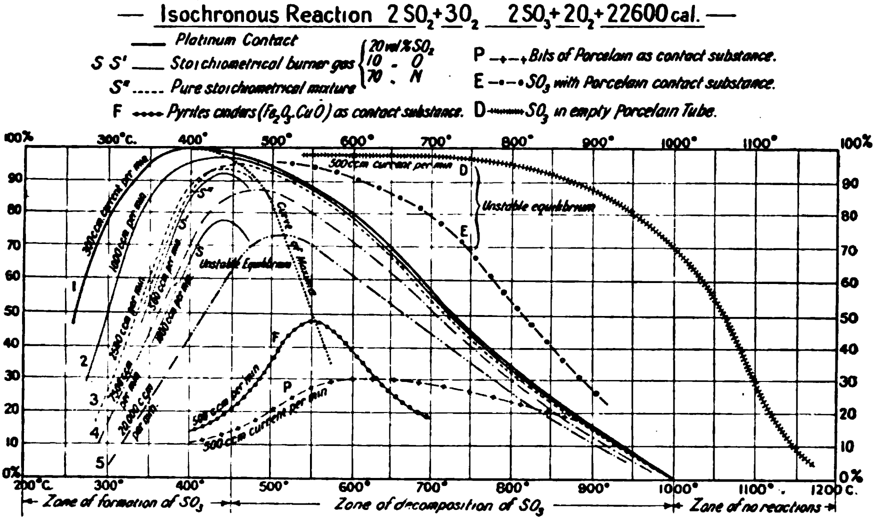

FIG. 14.

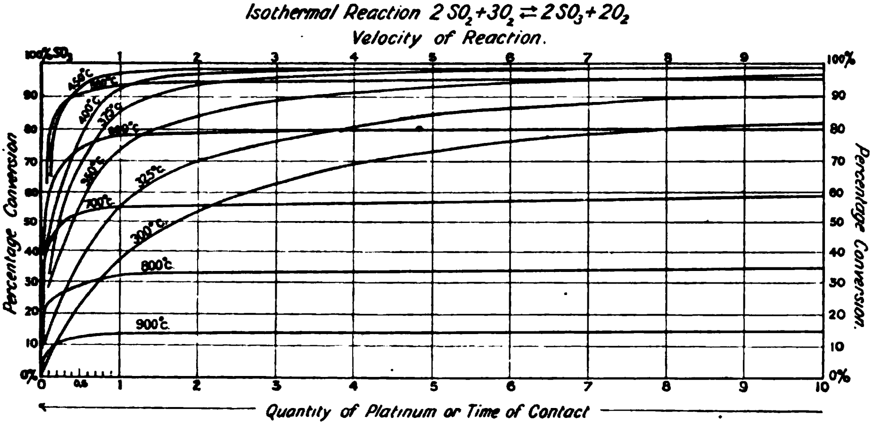

FIG. 15.

Brode (Zeitsch. angew. Chem. 1902, 1081) applies the laws of chemical equilibrium and velocity of reaction to the contact process and shows that to increase the reaction velocity and carry the reaction further towards completion, increase of sulphur dioxide and oxygen concentration and decrease of sulphur trioxide concentration are necessary.

The formula $K = \frac{C^2_{SO_3}}{C^2_{SO_2} \times C_{O_2}}$ shows that the ratio of sulphur trioxide to sulphur dioxide increases as the square root of the oxygen concentration. Also as the formation of sulphur trioxide lessens the volume, it must be favoured by increase of pressure.

Bodländer and Köppen (Zeitsch. Elektrochem. 1903, 559) state that in the reversible reaction $2SO_2+O_2 \rightleftharpoons 2SO_3$ equilibrium is represented by $\frac{(SO_2)^2\cdot(O_2)}{(SO_3)^2}=K$, and depends only on the relative concentrations of the reacting bodies, but the velocity depends on the absolute concentrations. Thus dilution with extra air retards the reaction at first, while it is rapid, but greatly accelerates it in the later stages.

By heating gaseous mixtures in a tube with platinum gauze, and measuring the diminution of pressure at constant volume, these chemists find that at temperatures between 182° and 341° the values of K approximate more nearly to $[(SO_2)^2\cdot(O_2)]$ than $[(SO_2)\cdot(O_2)]$ and that the velocity increases about 1·4 fold for each 10° rise in temperature. Also the concentration of the sulphur trioxide formed retards the reaction even at these low temperatures.

They also have determined the temperatures at which, with different gaseous mixtures of sulphur dioxide, oxygen, and nitrogen, definite percentages of the total possible amount of sulphur trioxide will be formed, when equilibrium is established. Above 650° the platinum absorbs oxygen.

Comp. of orig. mixture		Yield of SO_3						
SO_2	O_2	98 p.c.	96 p.c.	94 p.c.	92 p.c.	90 p.c.	80 p.c.	60 p.c.

10·0	8·04	503	538	558	576	589	639	703

Lucas (Zeitsch. Elektrochem. 1905, 457) repeated Bodländer and Köppen's experiments, and practically confirmed their results.

Bodenstein and Pohl (*ibid.* 1905, 373) adopted Knietsch's method of passing a stream of sulphur dioxide and air or oxygen over platinum in a quartz tube heated by an electric furnace, and determining the composition of the mixture before and after contact. They have also calculated from their results and tabulated the yields (percentage of SO_2 converted to SO_3) for different mixtures at different temperatures.

Bodenstein and Fink (Zeitsch. physikal. Chem. 1907, 1) describe further experiments dealing with the kinetics of the contact sulphuric acid process.

A large number of papers have also been published dealing more particularly with the ferric oxide contact process.

Keppeler (Zeitsch. angew. Chem. 1902, 809); Lunge and Pollit, J. Soc. Chem. Ind. 1902, 79; Lunge and Reinhardt (Zeitsch. angew. Chem. 1904, 1041; Kuster, *ibid.* 1904, 1512; Keppeler, *ibid.* 1908, 532, 577).

STATISTICS OF THE PRODUCTION OF SULPHURIC ACID.

The Chemische Industrie of Feb. 1, 1912, attempts to estimate the quantity of sulphuric acid produced in the chief countries of the world from the consumption of pyrites. Taking the years 1900–1910 it will be seen that in the four most important industrial countries England, France, Germany, and the United States, the consumption of pyrites in the last two countries during that period has steadily increased, while in England it has been practically stationary.

PYRITES CONSUMPTION IN 1000 TONS.

	England	France	Germany	United States	
1900	. 753	397	627	536	
1901	. 693	461	646	640	including brimstone.
1902	. 620	423	647	645	
1903	. 745	408	690	660	
1904	. 753	426	678	620	
1905	. 710	518	737	768	
1906	. 770	589	776	858	
1907	. 779	614	938	903	
1908	. 777	592	878	890	
1909	. 799	508	890	902	
1910	. 801	—	1008	1007	

Assuming a yield of 134 parts H_2SO_4 from 100 parts pyrites the sulphuric acid produced in 1910 would amount in tons to—

England	Germany	United States
1,073,000	1,350,000	1,349,000

To these figures must be added the amount of acid produced from brimstone, spent oxide, sulphuretted hydrogen, zinc blende, &c.

According to the 25th Alkali Report the quantity of brimstone burnt in England in 1883 was 17,295 tons equal to about 50,000 tons H_2SO_4, and it will, no doubt, be less now. For spent oxide no figures are at present available.

In 1910 the consumption of zinc blende in Germany was 430,000 tons, from which the greater part of the sulphur was utilised for sulphuric acid manufacture.

In France the production of sulphuric acid averaged about 900,000 tons during the last few years, and in Italy about 400,000 tons per annum.

In Russia in 1910 the production was 200,000 tons.

According to Wedge (Proc. 8th Int. Cong. Appl. Chem. 1912, 271, and J. Soc. Chem. Ind. 1912, 874) the production of sulphuric acid in the United States in the year 1911 amounted to 3,250,000 tons 50°Bé.=approx. 2,031,200 tons H_2SO_4.

Of this 2,665,000 tons were obtained from pyrites.
27,500 „ from copper sulphide ores.
285,000 „ „ zinc blende.
and only 25,000 „ „ brimstone. E. C. T.

SUMACH. True sumach consists of the dried and usually powdered leaves of the genus *Rhus* (order *Terebinthaceæ*), and is useful for tanning the finer kinds of leather, and also in dyeing and calico-printing on account of the tannin matter present in it.

Sicilian sumach, the variety most esteemed in this country and throughout Europe, consists of the leaves of the *Rhus Coriaria* (Linn.), a shrubby bush cultivated to a large extent in Sicily, where the sumach industry is of considerable importance. When the plant is about to flower the younger twigs are removed, dried in the sun, and subsequently beaten to remove the leaves and flower panicles. The sumach is imported sometimes in leaves, but more often in the form of powder, and should contain about 25 p.c. of tannin, although as much as from 27 to 32 p.c. may occasionally be found.

According to Löwe (Zeitsch. anal. Chem. 12, 128), the tannin matter present $C_{14}H_{10}O_9$, is ordinary gallotannin; indeed it is well known that when an aqueous extract of the sumach is boiled with dilute sulphuric acid, considerable quantities of gallic acid are produced. On the other hand, Strauss and Geschwender (Zeitsch. angew. Chem. 1906, 1121) who isolated the tannin according to Löwe's instructions, detected the presence of a methoxyl group, and suggest the formula $C_{32}H_{29}O_{11}\cdot OMe$.

Sicilian sumach contains also a trace of an ellagitannin and myricetin, $C_{15}H_{10}O_8$, to the extent of about 0·1173 p.c. (Perkin and Allen, Chem. Soc. Trans. 1896, 69, 1299), the latter colouring matter having been previously mistaken by Löwe (Zeitsch. anal. Chem. 1874, 12, 127) for quercetin.

Considerable quantities of sand and sometimes particles of magnetic iron ore, which cause black stains, are often to be found in sumach (Procter, Principles of Leather Manufacture, 1903, 271; compare also Trotman, J. Soc. Chem. Ind. 1904); and it is frequently highly adulterated in the ground condition with the leaves and twigs of various plants. Of these, the *Pistacia Lentiscus* (Linn.) ('schinia' or 'skeñs'), *Coriaria myrtifolia* (Linn.) (French sumach or 'stinco'), *Tamarix africana* (Poir.) (brusca), *Tamarix gallica* (Linn.), *Ailanthus glandulosa* (Desf.), *Ficus Carica* (Linn.), *Vitis vinifera* (Linn.), other species of the Rhus family, and also the ground branches ('gambuzza,' 'gammuzza') of the *R. coriaria* itself are known to be employed. These sumach adulterants also contain tannin matters, but for tanning and dyeing purposes are as a rule much inferior to sumach itself.

The *Pistacia Lentiscus* (Linn.) (mastic tree), a small tree about 20 ft. high with evergreen leaves, grows abundantly in Cyprus. The leaves of this plant constitute the most important sumach adulterant, and about 10,000 tons are said to be exported from Tunis to Sicily annually and re-exported thence (as sumach ?). According to Procter (*l.c.*) the leaves contain 12–19 p.c. of a catechol tannin. A good plump leather can be obtained from this material, but of a faintly reddish tint, the result being intermediate in character between those which are given by oak bark and sumach. Its presence in sumach is to be deprecated, and in many cases leads to injurious results. A considerable quantity, however, is consumed at Lyons in France as an assistant dyeing material for silk stuffs.

According to Perkin and Wood (Chem. Soc. Trans. 1898, 73, 374), these leaves contain a tannin closely allied to, if not identical with, ordinary gallotannic acid, as when an aqueous extract is boiled with dilute sulphuric acid a considerable quantity of gallic acid is produced. A second tannin or tannin glucoside is also present which, although possessing the general characteristics of the so-called 'catechol' tannins in that it yields a red phlobophane, and as noted by Procter, a reddish coloured leather, gives, by fusion with alkali, *gallic acid* and *phloroglucinol*.

In addition to these tannins, myricetin (probably as glucoside) $C_{15}H_{10}O_8$ is also present to the extent of about 0·15 p.c.

Tamarix africana (Poir.) is a small shrub or tree characterised by its twiggy branches and minute scale-like leaves. The small twigs are collected in Tunis and imported into Sicily for the adulteration of sumach (Procter).

According to Perkin and Wood (*l.c.*), the leaves contain a tannin probably identical with gallotannin, in addition to a small quantity of an ellagitannin. A trace of yellow colouring matter is also present and consists of a *quercetinmethylether* $C_{16}H_{12}O_7$.

The *Tamarix gallica* (Linn.) closely resembles in appearance the *T. africana* and flourishes in Cyprus, where the latter is not found. According to Procter, it contains 8·4 p.c. of tannin matter.

Ailanthus glandulosa (Desf.) is a tree of large size and handsome appearance, native of India and China but common on the Continent. The leaves contain 11·2 p.c. of tannin matter (Procter) and this resembles gallotannin, although a trace of an ellagitannin is also present (Perkin and Wood). Curiously enough, although so high a percentage of tannin is present, leather is scarcely tanned by an extract of these leaves, but is merely stained a dull dirty colour. This material is therefore of little use for tanning purposes, and as an adulterant of sumach exerts a deleterious influence. A small quantity of quercetin can be isolated from the leaves.

The leaves of the *Ficus carica* (Linn.) (common fig tree) contain 1·6 p.c. of tannin (Procter) and a trace of a yellow colouring matter (Perkin and Wood). Skin is untanned by an extract of these leaves, but acquires, during the process, a dirty olive tint.

Gambuzza consists of the small stalks branching from the main root of the *R. Coriaria* (Linn.) which are ground to powder and mixed with sumach. The material contains some quantity of a tannin resembling gallotannin, together with a trace of myricetin.

Attempts to detect the presence of these adulterants in sumach by chemical methods have not given satisfactory results, but should a prolonged boiling of the extract with dilute sulphuric acid cause the gradual precipitation of phlobophane, the presence of the leaves of the *Pistacia lentiscus* may be suspected.

More satisfactory results can be obtained by microscopical examination, and an elaborate work on this subject has been carried out by Andreasch (Sicilianischer Sumach und seiner Verfalschung, Wien, 1898); the book, however, is unsuitable for abstraction. A useful method, now generally adopted by leather trades chemists, has been devised by Lamb and Harrison (J. Soc. Dyers, 1899, 14, 60), and is based upon the behaviour of the leaf mixture with warm nitric acid. Under such treatment, the more delicate leaf structure of sumach itself is completely destroyed, whereas the strong cuticles of *Pistachia lentiscus, Coriaria myrtifolia, Tamarix africana* and *Ailanthus glandulosa* are unaffected and can then be readily recognised (compare also Lamb, *ibid.* 1904, 20, 265). Again, the leaves of the *R. coriaria* are very easily distinguished from those of other plants employed for their adulteration in that both upper and lower cuticles are covered with a dense growth of hairs (Priestman, J. Soc. Chem. Ind. 1905, 24, 231).

Venetian sumach or *Turkish sumach* consists of the leaves of the *Rhus Cotinus* (Linn.), a small tree the wood of which constitutes the yellow dyestuff known as 'Young Fustic.' The material contains about 17 p.c. of tannin, which resembles ordinary gallotannin, together with a trace of an ellagitannin. The presence of myricetin $C_{15}H_4O_2(OH)_6$ in these leaves is interesting, in view of the fact that in the wood itself, fisetin $C_{15}H_6O_2(OH)_4$ is present (Perkin, Chem. Soc. Trans. 1898, 73, 1016).

American sumach. The leaves of numerous varieties of *Rhus* are employed in the United States for tanning and dyeing purposes, and of these the *R. glabra* (Linn.) very largely takes the place of Sicilian sumach. It contains about 25 p.c. of a tannin closely resembling gallotannin, but produces a leather of very much darker colour than the Sicilian product.

Of the other varieties, *R. typhina* (Linn.) or 'Virginian sumach' (10–18 p.c.), *R. cotinoides* (Nutt.) (21 p.c.), *R. semialata* (Murr.) (5 p.c.), *R. aromatica* (Ait.) (13 p.c.) (Procter), *R. Metopium* (Linn.) (about 8·2 p.c. of tannin, probably gallotannin, together with traces of both quercetin and myricetin) (Perkin, Chem. Soc. Trans. 1900, 77, 427), *R. copallina* (Linn.), *R. pumila* (Michx.), and *R. Toxicodendron* (Linn.) are to be found in the States. Among these, *R. glabra* and *R. copallina* are considered to be worthy of extended cultivation.
