In India, numerous species of the genus *Rhus* are known to exist (Watt's Dictionary, Economic Products of India), and again in Algeria the *R. pentaphylla* (Desf.) is used by the Arabs for tanning goat skins. Finally, the *Anaphrenium argenteum* (E. Mey.) (*R. Thunbergii*) (Cape of Good Hope), 28 p.c. of tannin (bark), probably of the catechol class (Procter), and the *Rhodosphaera rhodanthema* (Engl.) (*Rhus rhodanthema*) (New South Wales), 9·5 p.c. of tannin (leaves), resembling gallotannin, are worthy of mention. The latter plant, also known as the 'yellow cedar,' closely resembles the *R. cotinus*, and it is interesting to note that although the wood of this tree contains fisetin $C_{15}H_4O_2(OH)_4$, the colouring matter of the leaves is quercetin $C_{15}H_3O_2(OH)_5$ (Perkin, Chem. Soc. Trans. 1898, 73, 1017).

French sumach is derived from the *Coriaria myrtifolia* (Linn.), a low deciduous shrub, native of Southern Europe, and has been referred to above as an adulterant of Silician sumach. In addition to tannin (15·6 p.c., Procter), which consists probably of ordinary gallotannin together with a little ellagitannin, it contains the poisonous glucoside *coriamyrtin* (Riban, Chem. Zeit. 1867, 663) and a trace of quercetin (Perkin, Chem. Soc. Trans. 1900, 77, 428). According to Procter, the colour of leather tanned by these leaves is very satisfactory and practically equal to that produced by genuine sumach (*R. coriaria*). It is also employed in black dyeing.

Cape sumach consists of the leaves of the *Colpoon compressum* (Berg.) (*Osyris compressa, Fusanus compressus, Thesium colpoon*), and is much used in South Africa under the name of 'Pruimbast.' The bush is found in the mountains, where it grows to the height of about 6 ft., and only the younger leaves are gathered. These leaves contain about 23 p.c. of tannin (Procter) which has been isolated as a hygroscopic transparent glassy mass and is probably a catechol tannin glucoside. With boiling dilute acid, a reddish-brown phlobophane is gradually separated, and on fusion with alkali protocatechuic acid is produced (Perkin, Chem. Soc. Trans. 1897, 71, 1135). In addition to tannin there is also present a considerable quantity of the quercetin glucoside *Rutin* (Osyritrin) (Chem. Soc. Trans. 1910, 98, 1776). According to Procter, this material forms a useful substitute for Sicilian sumach.

In lieu of the *Colpoon compressum*, a tanning agent known as 'broach leaves' (botanical origin lacking) appears to be considerably employed in South Africa. It contains about 19·9 p.c. of tannin of the so-called 'catechol' variety, together with traces of both quercetin and myricetin (Chem. Soc. Trans. 1898, 73, 384).

Russian sumach consists of the leaves of the *Arctostaphylos Uva-ursi* (Spreng.) (Bearberry), and is said to contain about 14 p.c. of tannin, which, according to Perkin (Chem. Soc. Trans. 1900, 77, 424), consists of a gallotannin together with traces of an ellagitannin. Minute amounts of both quercetin and myricetin have been isolated from this material.

Considerable quantities of 'sumach extract' are now manufactured for dyeing and tanning purposes from genuine Sicilian sumach, and this is usually found on the market as a brown treacly liquid of about 52Tw. So-called *decolourised* extracts are also prepared to compete with ordinary tannic acid, and for this purpose the addition of blood albumen to the dilute extract at about 48°, then raising the temperature to 70°, and subsequently filter-pressing, gives the most satisfactory results. Sulphurous acid again is employed to brighten the colour of extracts and acts partly as a weak acid in decomposing the inorganic salts of the tannin or colouring matter and partly as a reducing agent. In this case it is usual to pass sulphur dioxide through the liquor before concentration (Procter). A. G. P.

SUNFLOWER, *Helianthus annuus* (Linn.). A Mexican plant, now grown in many warm countries for the oil contained in its seeds. The seeds, which differ greatly in size, according to the variety (3000 to 6000 seeds weighing 1 lb.), consist of a hard woody envelope and an oily kernel.

Average composition of the seeds (König):—

	Water	Protein	Fat	N-free extract	Fibre	Ash
Whole seed	8·6	13·7	31·3	18·0	25·4	3·0
Kernels .	6·7	26·3	44·3	16·4	2·8	3·5

According to Wiley (Bull. 60, 1901, U.S. Dept. of Agric., Div. of Chem.), the following represents the average composition of the products of American grown sunflowers:—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Seeds .	4·4	15·0	27·1	20·9	29·2	3·4
Seed shells	6·2	3·0	1·7	23·2	63·8	2·2
Kernels .	4·9	26·9	45·2	16·1	2·7	4·3

Hungarian grown sunflowers apparently yield more oil; Windisch (Landw. Versuchs-Stat. 1902, 57, 305) found the following:—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Whole seeds	6·9	15·2	28·9	17·4	28·5	3·2
Husks .	10·1	6·9	7·9	20·8	51·6	2·7
Kernels .	4·0	24·9	50·4	12·8	3·1	4·0

The principal proteid occurring in the seed is edestin (Osborne and Campbell, J. Amer. Chem. Soc. 1896, 18, 609; 1897, 19, 487) associated with heliantho-tannic acid. The edestin from sunflower seeds contains: C, 51·54 p.c.; H, 6·99 p.c.; N, 18·58 p.c.; S, 1·00 p.c.; O, 21·71 p.c.

Sunflowers are largely grown in Russia, the seeds being used to some extent as human food in cold weather, as food for poultry and cattle, but chiefly as a source of oil (*v.* OILS, FIXED, AND FATS). The leaves are sometimes used as food for farm animals, being often dried, powdered and mixed with meal for cattle. The stalks are used as manure, being rich in potash and lime, or sometimes, as fuel.

The plant requires much sunshine and prefers rich, dark soil. Excessive nitrogenous manuring is to be avoided, or the growth of stems and leaves is favoured at the expense of the seeds. About a ton of seeds per acre is the average yield in Europe.

The cake left after the expression of the oil from the seeds forms a valuable food for cattle. Kellner gives as its average composition—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
9·2	39·4	12·6	20·7	11·8	6·3

32·4 of the total 39·4 is digestible protein.

If the seeds are not husked or decorticated before the oil is expressed, the resulting cake is richer in crude fibre (up to 30 p.c.) and correspondingly poorer in albuminoids and fat.

The ash of sunflower seeds and of other parts of the plant was examined by American investigators (Wiley, Bull. 60, 1901, U.S. Dept. of Agric.; Div. of Chem.), who found it to contain—

	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
Whole seeds .	29·0	1·1	9·4	17·9	0·5	38·4	2·9	0·4	0·5
Stems . .	38·9	3·8	24·1	19·9	1·2	1·5	3·5	1·3	7·3
Leaves . .	8·0	0·9	44·0	21·5	2·8	3·3	4·5	13·8	1·5
Kernels of seed	25·5	0·8	6·6	14·7	0·4	50·8	1·0	0·2	0·0
Shells of seed .	47·4	1·0	20·9	15·9	1·1	6·8	5·0	0·8	1·5
Husks of seed .	55·7	1·7	20·1	9·5	0·9	3·7	2·9	2·0	4·6

Sunflowers are therefore an exhausting crop, making great demands on the nitrogen, potash, and phosphoric acid of the soil. H. I.

SUNSTONE *v.* FELSPAR.

SUPRARENINE *v.* ADRENALINE.

SUPERPHOSPHATES *v.* FERTILISERS.

SYENITE *v.* GRANITE.

SYLVANITE. A native telluride of gold and silver, $AuAgTe_4$ (Au, 24·2 p.c.; Ag, 13·3 p.c.; Te, 62·5 p.c.), of importance at certain localities as an ore of gold. It has long been known from Transylvania (hence the name 'sylvanite'), where it occurs on joint surfaces in porphyry as slender rod-like crystals aggregated, by twinning, into branching forms suggesting a resemblance to written characters (hence the old names 'graphic gold' and 'graphic tellurium,' Ger. *Schrifterz*). The crystals are monoclinic and possess a perfect cleavage in one direction, parallel to the plane of symmetry: this cleavage is of assistance in recognising the mineral. The colour is silver-white with a brilliant metallic lustre, but on exposure to light the crystals become dull; sp.gr. 8·2. It is found at Offenbánya and Nagyág in Transylvania, and at several places in Boulder Co. in Colorado, and Calaveras Co. in California. At Kalgoorlie in Western Australia it is found as large cleavable masses (L. J. Spencer, Min. Mag. 1903, 13, 271). L. J. S.

SYLVITE or *Sylvine*. Native potassium chloride (KCl). It crystallises as cubes or cubo-octahedra with perfect cubic cleavage, but, as proved by etching experiments, these possess a lower degree of symmetry (plagiohedral-cubic) than crystals of rock-salt (halite). The crystals are colourless or sometimes bright blue, and they are indistinguishable in appearance from crystals of rock-salt. The two minerals may, however, be readily distinguished by the colour they impart to the Bunsen-flame, by their sp.gr. (1·99 for sylvite, 2·15 for rock-salt), and refractive index (1·491 and 1·547 respectively for sodium-light). Good crystals are found amongst the abraum-salts at Stassfurt in Prussia and at Kalusz in Poland. As a granular incrustation intermingled with sodium chloride and other salts it has long been known on Vesuvian lava, and small cubes were found after the 1906 eruption. The latter are intimately associated with cubes of rock-salt, but without forming mixed crystals. L. J. S.

SYMPHOROL *v.* SYNTHETIC DRUGS.

SYNGENITE *v.* CALCIUM.

SYNTHETIC DRUGS or **MEDICINAL PRODUCTS.** The employment of synthetic coal-tar products in internal medication may be said to date from the introduction of 'kairin,' a synthetic substitute for quinine, discovered by O. Fischer in 1882. The unsatisfactory results attending the administration of this preparation and the difficulties encountered in synthetic work in this direction, caused a lapse of interest until the accidental discovery of the antipyretic properties of antipyrine in 1885 and acetanilide in 1888. The simplicity of the structure of the latter, with its valuable medicinal properties attracted the attention of pharmacologists, who undertook a thorough investigation into the relationship between structure and physiological action of acetanilide and phenacetin which was discovered shortly afterwards. As a result, new and valuable products began to follow in quick succession, attracting the attention of the medical profession and of capitalists, until to-day the preparation of synthetic drugs forms one of the most important branches of the coal-tar industry. From the enormous amount of study on the part of pharmacologists and chemists, much valuable data have been collected bearing on the relation existing between chemical structure and physiological action, so that the medicinal action of certain nuclei may, in a measure, be modified to suit the demands of modern medicine. In tracing such relationships, one is struck by the fact that several entirely different nuclei possess the same medicinal properties. for example, the derivatives of aniline (acetanilide, phenacetin), pyrazolone (antipyrine), hydrazine (pyrodine), quinoline (analgene) and salicylic acid (aspirin). That is, these nuclei become antipyretics when suitable side chains are associated with them; under other conditions they become antiseptics. Although the action of substituting groups is in general influenced by their nuclei, yet certain side chains develop latent activities in one direction and others in another, or they may either harm or destroy medicinal action entirely. One should not assume from this that the relationship between structure and physiological action is such that it may be formulated into definite laws, or that definite pharmacophore groups exist analogous to the chromophores of the colours.

The groups that favour or develop the physiological action of a nucleus are chiefly the amino, alkyl, hydroxyl, carbonyl, and halogens. If the physiological action of a nucleus be excessively intensified through, for example, an amino group (aniline), this may be controlled through the introduction of an organic acid radicle (as in acetanilide), avoiding carboxylic and sulphonic acid groups which produce weak or inert compounds. Of primary importance is the deportment of these organic compounds in the human organism, for no inference, as to the manner in which they may split up, can be drawn from laboratory experiments. For example, of two substances differing but slightly in structure, one readily splits up whilst the other is eliminated unchanged. Readily oxidisable bodies like uric acid and creatinine pass through the organism unaltered, whilst succinic acid, not changed by concentrated nitric acid, is consumed to carbon dioxide and water. Through the alkalinity of the intestinal canal as well as of the body fluids, ingested chemicals of this class split up, and their physiological action depends upon the resulting decomposition products. It is upon this fact that the synthetic chemist must base his theories relative to action desired. Sometimes unexpected decomposition takes place in the acid secretions of the stomach and unanticipated effects result; as, for example, malarin, a condensation-product of acetophenone and *p*-phenetidine was theoretically an ideal remedy for migraine, but because of its decomposition in the stomach an unexpected systematic toxic effect from liberated *p*-phenetidine resulted. Many of the modern organic synthetic medicinals possess secondary undesirable or toxic effects, hence it is the aim of the chemist and pharmacologist to so alter the structure of such drugs that they can be placed in the hands of the medical profession and even of the general public. While severe criticisms have been offered on the secondary effects of synthetic drugs, it must not be forgotten that medical authorities frequently subject them to more severe tests than our older and better known remedies can withstand. Caution must always be exercised with remedies involving idiosyncrasies and cumulative effects. A great stimulus to this search after new remedies has been the success attending the study of the structure (chemical and pharmacological) of the alkaloids, which has resulted in the production of compounds from which the objectionable features of the natural products have been, in many cases, eliminated. For examples we have the many local anæsthetics as cocaine substitutes; and the codeine succedaneums as heroin and dionin. The study of the structure of caffeine has given us theophylline and its derivatives; the sedative effects of valerian led to its study and the production of a variety of such compounds as validol, quietol, &c.; the undesirable effects of salicylic acid have given us the aspirin class of derivatives, and so on.

Various methods of classification (chemical and physiological) of the synthetic drugs have been attempted, but none of them is entirely satisfactory. One method classifies the aliphatic derivatives under hypnotics and anæsthetics, and those of the aromatic series under antipyretics and antiseptics; another classification takes up the pharmacology of the various groups, for example, the aliphatic hydroxyls as narcotics, the aromatic phenols as antiseptics, the aromatic amino derivatives as antipyretics, &c. Since the structure and nature of the various nuclei influence largely the pharmacology of these radicles, this method is open to objection. The physiological classification is objectionable to the chemist, since compounds of entirely different structure are arranged under the same heading. In this article the method adopted consists in arranging the compounds into general groups according to their medicinal action; as, for example, antipyretics, hypnotics, antiseptics, &c., the compounds under these groups being classified chemically as far as possible. The object has been to give prominence to the presence of certain nuclei and groupings which occur in each of these classes, and to the influence exerted by the introduction of new radicles or structural changes; in other words, to show, wherever possible, the relationship between chemical constitution and physiological action in comprehensive form. For a more detailed *exposé* of this subject, the following works may be consulted:—

Hydrocarbons. The aliphatic hydrocarbons possess in general a narcotic action, influencing the central nervous system in gradually paralysing in turn the functions of the brain, spinal cord and medulla oblongata, affecting first the sensibilities as regards external impressions and stimulation. The physiological intensity of these narcotics increases with their carbon content, and the unsaturated hydrocarbons are more active than the saturated compounds of same carbon content. Branched chains, where a number of alkyl groups are linked with a carbon atom, favour narcotic action. This effect is intensified through the introduction of hydroxyls and also halogens in some instances, while in others it is entirely lost. Thus whilst methane is practically free from narcotic effect, the introduction of chlorine develops this action, the intensity increasing with the number of atoms introduced, reaching a maximum in CCl_4. The same holds for the higher homologues, but with the increase in carbon content their relative volatility and absorption possibilities, so essential for inhalation anæsthesia, decrease. The bromine substitution products deport themselves similar to the chlorine derivatives, but are less intense in action owing to lower degree of volatility, whilst the chief iodine derivative (iodoform) is only valuable for local application. The aromatic hydrocarbons, on the other hand, possess but very feeble narcotic properties, their action being chiefly convulsive and paralytic in connection with a well-marked lowering of temperature. Through the influence of substituting groups, their untoward action may be almost entirely eliminated, as exemplified among the antipyretics. The higher homologues of benzene, according to the number and kind of substituting alkyl groups, possess varying toxic action, methyl and ethyl benzene are more toxic whilst methyl *iso*propyl benzene (cymene) is less so than benzene. In general, relative toxicity decreases with the number of alkyl groups introduced, whilst the positions of the substituting groups bear an important part in physiological action. Pharmacologically, the halogens exert very little influence upon the aromatic nuclei.

Hydroxyl groups. The hydroxyl group develops the hypnotic characters of the hydrocarbons, increasing in intensity from the primary to the secondary and tertiary, and with the length of the unbranched chain. While the odour of the lower alcohols is feeble, that of the higher unsaturated alcohols is frequently marked (linalool). With increase in number of hydroxyls, the narcotic effect and odour are replaced by sweet taste. Physiologically, the introduction of the hydroxyl group in the aromatic hydrocarbons develops the property of causing a local caustic action, as seen in the phenols. While benzene affects the brain first and then the spinal cord, the action of phenol is restricted to the latter, exciting the motor centres of the spinal cord, the convulsive action diminishing with the number of hydroxyl groups. Intensity in physiological action depends upon the relative position of the substituting groups, thus with dihydroxybenzenes toxic action increases from the para- to meta- and ortho-derivatives.[1] Through introduction of alkyls in phenol, intensity of antiseptic action increases, while its caustic and convulsive effects diminish (guaiacol), although in cases where other substituting groups are present the alkyloxy group introduces hypnotic characters (phenetidine derivatives). In veratrole (dimethyl ether of pyrocatechol) the undesirable secondary effects of guaiacol are absent, also its desirable effects, because of too great stability; hence the presence of one free hydroxyl group is physiologically desirable (as in guaiacol), or if covered by an acid radicle (duotal, benzosol), practically the same effects are attained with a minimum of secondary action. The closing of the hydroxyl causing an alteration to a complete disappearance of the primary medicinal action of a substance may be illustrated among the tannins, benzyloxy tannin being devoid of astringent properties; less marked yet characteristic are eugenol, anisole, phenetole, pyrogallol methyl ether, resorcinol diethyl ether: compare *Synthetic morphine derivatives.* The alkyl ethers are physiologically hypnotics; this extends to many other compounds containing the ethoxyl group as ethoxycaffeine, phenacetine, &c. The introduction of alkyl groups in the nucleus of phenols increases their antiseptic powers. The same is true of the halogens but to a greater degree, the effect increasing with the number of halogen atoms; this applies to phenols or their ethers. Compounds containing two phenol groups linked together (as in diphenyl or dihydroxydiphenyl methane) exhibit intensified antiseptic properties. If, however, the linking groups be —CO or —SO_2, this action is considerably decreased.

Aldehydes and ketones. Among these compounds, the narcotic effects of the hydrocarbon nuclei increase like those of the alcohols. Owing to the reactive characters of the aldehydes, a great variety of condensation-products have been produced, and only those that readily yield chloral (as chloralamid, chloralose, dormiol, &c.) possess sufficient hypnotic action to be of value. The ketones possess in general, hypnotic properties. Dimethyl ketone (acetone) causes intoxication-hypnosis with accelerated pulse, diethyl ketone and its higher homologues have no such action. Aromatic radicles diminish hypnotic action materially. More profound hypnotics are the ketoximes, in which the duration of sleep increases with the molecular weight of the alkyl group; unfortunately, undesirable secondary effects prevent their use. The influence of the introduction of hydroxyls in the branched carbon chains is the same as with the alcohols, causing complete disappearance of hypnotic action as exemplified in the sugars. The aromatic aldehydes are not particularly toxic when their local irritant action is eliminated: this is due to their rapid oxidation. These bodies play an important part in synthetic perfumery; for example, cinnamic aldehyde, anisic aldehyde, benzaldehyde, phenylacetaldehyde (hyacinth), vanillin, piperonal, citral, &c.

Acids and esters. The introduction of the carboxylic or sulphonic group into compounds of well-defined toxic properties, results in a marked diminution of this action: thus benzene and its derivatives, aniline, naphthalene, phenol, pyridine and quinoline, are far more toxic to the organism than their respective carboxylic derivatives benzoic acid, salicylic acid, naphthalene, pyridine and quinoline carboxylic acids; pyrogallol is far more toxic than gallic acid: the same is true of the corresponding sulphonic acids. Thus symphoral (caffeine sulphonic acid) is purely diuretic; sulphanilic acid is indifferent, and morphine sulphonic acid may be given in large doses without effect.

The first-named poisonous class of aromatic bodies on entering the system, readily submit to oxidation and reduction, giving rise to toxic action, but the relative stability of the carboxyl and sulphonic acid groups and their resistance to processes of oxidation serve to protect the derivatives from further chemical change. Further, the aromatic nitro derivatives lose their toxic effects through introduction of sulphonic or carboxylic groups. The lower aliphatic acids seem to accelerate metabolic processes, particularly intestinal peristaltis. Since they are consumed in the body to carbonic acid, they serve to increase the

---

[1] Of the trihydroxybenzenes, phloroglucinol is but slightly toxic and caustic, while pyrogallol is very toxic.

alkalinity of the body fluids, hence are of value in gout and similar disturbances resulting from faulty metabolism. The carboxyl group, *per se*, is not toxic but may become so when combined with another atomic complex; thus glyoxalic acid

$$(\mathrm{OHC{-}COOH})$$

yields oxalic acid in the urine and is toxic; ethylene glycol which likewise yields oxalic acid yet is non-toxic; glyoxal

$$(\mathrm{OHC{-}CHO})$$

which is eliminated unchanged, is very toxic; oxalic acid occurs in urine after ingestion of large amounts of grape sugar. The toxicity of oxalic acid diminishes quickly if methylene groups are inserted between the two carboxyls as in malonic and succinic acids. For further influence of carboxylic groups, see under *Antipyretics*, also *Local Anæsthetics*.

The esterification of the carboxyl group changes it physically and physiologically, usually developing narcotic action in the case of the aliphatic acids. Among these products we find many odorous principles such as the 'fruit essences,' also innumerable synthetic perfumes which also possess a distinct narcotic action, moreover such sedatives as validol and bornyval belong to this class. Particularly odoriferous are the esters of the aromatic acids, as methyl salicylate, anthranilic methyl ester, benzyl benzoate, &c. In addition, these esters play an important part in the development of local anæsthetic action in cocaine, eucaine, orthoform, &c. (*see Local anæsthetics*).

Organic ammonia derivatives. *Aliphatic amines.* The exciting influence of ammonium hydroxide upon the functions of the spinal cord manifests itself in cessation of breathing, convulsion, and finally paralysis of these centres, The intensity of this action is diminished according to the number of alkyl groups introduced (amines), increasing, however, with their molecular weight. With the disappearance of the typical characteristics of ammonia through alkylation, we find another distinctive action developed, especially among the quartenary amines, namely the curari effect. While the narcotic characters of the hydrocarbons disappear when combined with ammonia, we find through introduction of acid radicles (acid amides), this effect reappears, feeble in case of the monobasic acids, increasing in intensity with molecular weight. This action is intensified through the well-known action of halogens, for example, diethyl-, dipropyl-, and ethylpropyl bromacetamide. Notable is the effect of the introduction of alkyl amines (dimethylamine) in antipyrine (pyramidon), which not only intensifies its specific action but also eliminates largely its secondary effects. Of special significance is carbonic acid, considered as formic acid, in which a hydrogen is replaced by OH, this forms two amides, carbamic acid and urea. As may be expected, the alkyl esters of carbamic acid (urethanes) are hypnotics, the intensity of their action increasing with the molecular weight of the alkyl group, any toxic effects being overcome, as is customary, through the introduction of an acetyl radicle in the amino group. The alkylisation of urea does not develop any marked hypnotic action until combined with a dibasic acid radicle, as in barbituric acid (veronal, proponal). The aromatic amines possess such marked antipyretic properties that all possible precautions must be taken to modify their excessive and toxic effects, such as acetylation and alkylation (*see Antipyretics*).

The basicity imparted by the amino acids is employed in preparing soluble compounds of otherwise insoluble derivatives (as phenocoll).

The pharmacodynamic actions of other groups are discussed under the special divisions, *v. Suprarenal preparations.*

ANTIPYRETICS, ANTIRHEUMATICS AND ANTINEURALGICS.

Apart from their medicinal value the organic compounds belonging to this class offer many interesting points in tracing the relationship between chemical structure and pharmacodynamic action. That a number of these substances possess antipyretic, antirheumatic and antineuralgic properties in common may be explained by the close relationship of these diseases, that is, they arise from fundamentally infectious, toxic, or auto-toxic conditions. The majority of the enumerated preparations are derivatives of nuclei possessing a decided toxic action, but by a careful study of the influence of groupings, elimination products and pharmacological structure, primary and secondary toxic effects are more or less eliminated. These latter form the chief difficulties encountered to-day in the preparation of synthetic drugs, for not only must individual idiosyncrasies be considered, but also prolonged medication and possible cumulative effects. Unforeseen difficulties may arise in that a product, which from a chemico-pharmacological standpoint is ideal, may either undergo a too rapid decomposition or an unanticipated splitting up, or prove to be too stable in the human organism, and thereby fail to accomplish its purpose. With this class of remedies, it is desirable, from a pharmaceutical standpoint, to present them in a soluble form. Very few are soluble in water. Attempts to render them soluble through sulphonating or carboxylating usually result in comparatively inert products. The use of amino- acids has not proved successful commercially. One of the best examples of this is phenacetin. A consideration of the many derivatives of *p*-phenetidine serves to show the futility of such attempts. The various groups of antipyretics owe their action to essentially different nuclei, but the general principles governing the action of the side chains remain the same. They may be classed as follows:—

Acetylated amines. With the introduction of alkyl groups into the ammonia molecule, the convulsive action of the latter materially decreases whilst the narcotic effect of the alkyl disappears in a measure, both components neutralising one another. Quite different is the result of the introduction of the convulsive excitant aromatic alkyls: aniline (phenylamine) influences chiefly the motor centres of the midbrain (mesocephalon), producing paralysis of its functions, resulting in vertigo, sleep, and finally collapse. Further, aniline and its homologues destroy the hæmoglobin. Apart from these undesirable symptoms, the aromatic amines produce a marked lowering of the temperature, hence are of value in combating fevers, provided the toxic effects can be sufficiently eliminated. The higher homologues of aniline possess like toxic properties, modified, however, by the position of the substituting group; thus metatoluidine behaves like aniline, whilst the ortho- and paratoluidines are much milder. With an alkyl group, as in benzylamine ($C_6H_5{\cdot}CH_2{\cdot}NH_2$), the anti-pyretic action almost disappears. To eliminate, as far as possible, the accompanying toxic symptoms of the substituted aromatic amines, we usually resort to the introduction of acid radicles, the substitution taking place in the amino group. As a result of the acetylation of the aromatic amines, more stable bodies are produced which are far more resistive to the influences of the circulation. The relative degree of stability increases with the molecular weight of the substituting acid: thus formanilide is more toxic than acetanilide, because of its ready decomposition, while benzanilide is but mildly antipyretic, and valerylanilide inert, being eliminated unchanged from the system. The effect of these anilides are those of aniline, protracted, depending on the relative slowness of their decomposition. If a hydrogen of the methyl group in acetanilide be replaced by COOH, an insoluble, inert, malonanilic acid results. The introduction of a hydroxyl group in the methyl of acetanilide (hydroxyacetanilide), results in no material influence in therapeutic effect. The introduction of a sulphonic acid group in the acetyl group (sulphoacetanilide) or the nucleus (acetyl sulphanilic acid, cosaprin), while giving a more soluble product, results, as previously stated, in diminished potency. If acetanilide's nitrogen be methylated (exalgin $C_6H_5{\cdot}N(CH_3)CO{\cdot}CH_3$), a diminished antipyretic and increased toxic action results. The reverse is the case if the alkyl enters the acid group as in phenylurethane (euphorin $C_6H_5NH{\cdot}CO{\cdot}OC_2H_5$). The popularity of acetanilide may be ascribed more to its use in combination with an alkali bicarbonate with or without caffeine, sold extensively as 'headache powders.'

Acetanilide. Acetyl amino benzene
$C_6H_5NH{\cdot}COCH_3$ m.p. 112°.
Benzanilide. Benzoyl amino benzene
$C_6H_5NH{\cdot}COC_6H_5$ m.p. 160°–162°.
Benzacetine. Acetamino ethoxy salicylate
$C_6H_3(OC_2H_5)(NH{\cdot}COCH_3)COOH$ m.p. 190°.
Cosaprin. Acet-*p*-sulphanilate of sodium
$C_6H_4(NH{\cdot}COCH_3)SO_3Na[1:4]$. La Roche.
Exalgin. Methyl acetanilide
$C_6H_5N(CH_3)CO{\cdot}CH_3$ m.p. 101°. Merck.
Methacetin. Acetanisidine
$C_6H_4(OCH_3)NH{\cdot}COCH_3$ m.p. 127°.

II. **Amino phenols.** Phenacetin, the most popular of all antipyretics in medical practice, owes its introduction to the observation that acetanilide undergoes oxidation in the human organism, whereby a hydroxyl group enters the ring in the para- position to the amino group. *p*-Aminophenol was found to be a powerful antipyretic, much less toxic than aniline yet attacking the blood corpuscles with formation of methaemoglobin. The introduction of an acetyl group (acetyl-*p*-amino phenol) diminished this objectionable feature through greater molecular stability, but not sufficiently until the phenol hydroxyl was covered by an alkyl (ethyl). The chemico-pharmacological structure of phenacetin is such that as yet no improvement has been effected. The methyl derivative (methacetin), possessing a maximum antipyretic effect, is less satisfactory, while the introduction of higher alkyls in the hydroxyl group of acetyl amino phenol produce weak or inert derivatives owing to excessive stability and failure to split off amino phenol. The same may be said of aliphatic groups containing COOH (*e.g.* acetaminophenoxyl acetic acid,

$$C_6H_4(OH)(COOC_6H_4{\cdot}NHCOCH_3).$$

If, on the other hand, an hydroxy acid radicle of the aromatic series replaces the carboxyl hydrogen as in salophen

$$C_6H_4(OH)(COOC_6H_4{\cdot}NH{\cdot}CO{\cdot}CH_3),$$

salicylic acid and aminophenol appear in the urine, hence the anticipated antipyretic action. The toxicity of aniline increases through the introduction of an alkyl radicle in the amoni group, but diminishes if an aryl radicle is introduced, or there be two alkyl groups.[1] Further, the acid radicle entering the amino group and thus diminishing toxicity must not split off through the action of the gastric secretions, or the undesirable effects of *p*-phenetidine will follow; while, on the other hand, the acid radicle should not be too firmly linked or an inert product will result. Formylphenetidine, quite unstable, is irritating; while pyrantin (succinimid phenetidine $C_6H_4(OC_2H_5){\cdot}N[COCH_2]_2$) is inert because of excessive stability; the same applies to *iso*-propyl and *iso*-butyl phenetidine. Only such derivatives of *p*-phenetidine possess an antipyretic action as give the indophenol reaction in the urine, depending on the formation of a red colour upon the addition of nitrous acid followed by beta-napthol. That is, active derivatives of this class must split up into bodies containing a free amino group (phenetidine or amino phenol), the intensity of action depending upon the rapidity of decomposition. The employment of aromatic acids in place of acetic (for the amino group) either diminishes or totally destroys antipyretic action. The urea derivatives of phenetidine possess antipyretic properties, dulcin (ethoxy-phenyl carbamide), an intensely sweet chemical, belongs to this group. Attempts to render phenacetin or derivatives of *p*-phenetidine soluble, through sulphonating (Phesin) and carboxylating [Benzacetine

$$C_6H_3(OC_2H_5)(NH{\cdot}COCH_3)(COOH)$$

the nuclei were unsuccessful medicinally because of their excessive stability. More successful results were attained through the use of the amino acetyl group (phenocoll).

Amygdophenin. Mandelic *p*-phenetidine
$C_6H_4(OC_2H_5){\cdot}NH{\cdot}CO{\cdot}CH(OH)C_6H_5$
m.p. 140·5° Hoechst.
Apolysin. Aconitic monophenetidine
$C_6H_7O_6{\cdot}NH{\cdot}C_6H_4OC_2H_5$
m.p. 72° (D. R. P. 87428) Heyden.
Citrophen. Monophenitidine citrate. m.p. 188°.
Eupyrine. Vanillin-ethyl carbonate-*p*-phenetidine
$C_6H_4(O{\cdot}C_2H_5)N:CH{\cdot}C_6H_3(O{\cdot}CO{\cdot}OC_2H_5)OCH_3$
m.p. 87° (U.S. Pat. 658446) Zimmer.

---

[1] If the hydrogen of the amino group in *p*-acetamino-phenetole be replaced by an alkyl, a narcotic is obtained; as, for example, methyl phenacetin

$$(C_6H_4(OC_2H_5)N(CH_3)COCH_3).$$

If an ethyl group enters, a diminished narcotic effect results.

Kyrofin. Methyl glycolic-*p*-phenetidine $CH_3{\cdot}OCH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}OC_2H_5$ m.p. 98°, Basel, C. F.

Lactophenin. Lactyl-*p*-phenetidine $C_6H_4(OC_2H_5)NH{\cdot}CO{\cdot}CH(OH)CH_3$ m.p. 118° (U.S. Pat. 503743) Boehringer.

Malakin. Salicyl *p*-phenetidine $C_6H_4(OC_2H_5)NH{\cdot}CO{\cdot}C_6H_4{\cdot}OH+H_2O$ m.p. 92°, G. C. I. Basel.

Malarin. Acetophenone-*p*-phenetidine $C_6H_5C(CH_3){:}N{\cdot}C_6H_4{\cdot}OC_2H_5$ m.p. 88° (D. R. P. 98840) Valentiner.

Phenacetin. Acet-*p*-phenetidine m.p. 134° (U.S. Pat. 400086), Bayer.

Phenocoll. Amino-acet-*p*-phenetidine $(C_6H_4(OC_2H_5)NH{\cdot}CO{\cdot}CH_2NH_2)HCl$ m.p. 95°. Anhydrous base 100·5° (U.S. Pat. 543214) Schering.

Phenosol. Salicyloacetate of *p*-phenetidine m.p. 182°, Hofmann.

Pyrantin. *p*-Ethoxy-phenyl-succinimid $[CH_2{\cdot}CO]_2N{\cdot}C_6H_4{\cdot}OC_2H_5$ m.p. 155°, Hoechst.

Salophen. Acetyl *p*-aminophenol salicylate $C_6H_4(OH)(COOC_6H_4{\cdot}NH{\cdot}CO{\cdot}CH_3)$ m.p. 188° (D. R. PP. 62533, 62289) Bayer.

Thermodin. Phenacetin urethane $C_6H_4(OC_2H_5){\cdot}N(COOC_2H_5){\cdot}COCH_3$ m.p. 86°–88°, Merck.

Triphenin. Propionyl *p*-phenetidine $C_6H_4(OC_2H_5)NH(CO{\cdot}CH_2{\cdot}CH_3)$ m.p. 120° (U. S. Pat. 535846) Merck.

Valerydin. Valeryl *p*-phenetidine $C_6H_4(OC_2H_5)NH{\cdot}C_5H_9O$ Erdmann.

Vinopyrin. *p*-Phenetidine tartrate m.p. 168°, Fischer.

III. **Salicylic acid derivatives** (*for internal use*). As is well known, the introduction of a COOH group into compounds of well-defined toxic or antiseptic properties results in a marked diminution of these properties. Particularly is this the case with the phenol acids (salicylic), the ortho-derivative being more toxic and antiseptic than benzoic acid and much less so than phenol. To-day, salicylic acid is one of the most important of our medicinal chemicals. Owing, however, to its irritant action and consequent gastric disturbances with frequent tinnitis, we find that the majority of the newer derivatives consist of compounds designed to split up in the intestinal tract only. This is usually accomplished through acylation of the OH group or esterification of the COOH group as typified in aspirin and glycosal. Some of the combinations are more especially designed for intestinal disinfection as alphol, salacetol, cordol, &c.

Alphol. *a*-Naphthyl salicylate $C_6H_4(OH)COOC_{10}H_7$ m.p. 83°.

Aspirin. Acetyl salicylic acid $CH_3{\cdot}COO{\cdot}C_6H_4{\cdot}COOH$ m.p. 135° (U. S. Pat. 644077) Bayer.

Aspirin, soluble. The calcium salt of aspirin; readily soluble and produces no gastric disturbances.

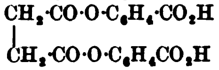
Benzosalin. Benzoyl salicylic methyl ester $C_6H_5COO{\cdot}C_6H_4{\cdot}COOCH_3$ m.p. 85° (D. R. P. 169247), La Roche.

Betol. *β*-Naphthyl salicylate $C_6H_4(OH)COOC_{10}H_7$ m.p. 95°.

Benzacetin. Acetamino-ethyl salicylic acid $C_2H_5O{\cdot}C_6H_3(NHCOCH_3)COOH$ m.p. 205°.

Cordol. Tribromosalol $C_6H_4(OH)COO{\cdot}C_6H_2Br_3$ m.p. 195°.

Diaspirin. Succinyl salicylic acid



$$\begin{array}{l} CH_2{\cdot}CO{\cdot}O{\cdot}C_6H_4{\cdot}CO_2H \\ | \\ CH_2{\cdot}CO{\cdot}O{\cdot}C_6H_4CO_2H \end{array}$$

m.p. 176°–180° (D. R. P. 196634), Bayer.

Diplosal. Salicylo-salicylic acid $OH{\cdot}C_6H_4{\cdot}COO{\cdot}C_6H_4COOH$ m.p. 147°, Boehringer.

Glycosal. Monosalicylic glyceryl ester $C_6H_4(OH)COO{\cdot}C_3H_5(OH)_2$ m.p. 71° (D. R. P. 127139), Merck.

Indoform. Salicylic methylene acetate m.p. 108°, Schulz.

Methylaspirin. Methyl acetylsalicylate $CH_3{\cdot}CO{\cdot}O{\cdot}C_6H_4{\cdot}COOCH_3$ m.p. 54°, Merck.

Novaspirin. Methylene citro-salicylic acid (D. R. P. 185800), m.p. 150° Bayer.

Salacetol. Acetonyl salicylate $C_6H_4(OH)COO{\cdot}CH_2{\cdot}CO{\cdot}CH_3$ m.p. 71°, Schoetensack.

Salibromin. Dibromsalicylic methyl ester $C_6H_2Br_2(OH)COOCH_3$ Heyden.

Salicreol. Creosote salicylate

Salol. Phenyl salicylate $HO{\cdot}C_6H_4{\cdot}COOC_6H_5$ m.p. 43°

Vesipyrin. Phenyl acetylsalicylate $C_6H_4(OCOCH_3)COOC_6H_5$ Reiherstieg.

For external use. Another method for the employment of salicylic acid, either alone or in conjunction with its internal use, consists in the local application of its various esters. These must be either in fluid form or, if solid, soluble in fats, so that absorption by the skin may readily take place. Owing to the objectionable odour of oil of wintergreen, various other inodorous esters of the aliphatic series have come into use.

Mesotan (ericin). Salicylic methoxymethyl ester $C_6H_4(OH)COOCH_2{\cdot}OCH_3$ b.p. 162° (42 mm.) (D. R. P. 137585) Bayer.

Protosal. Salicylic glycerol formal ester b.p. 200° (12 mm.) (D. R. P. 163518) Schering.

Saligallol. Pyrogallol disalicylate m.p. 141°, Knoll.

Salimenthol. Menthyl salicylate (D. R. P. 171453), Bibus.

Salit. Borneol salicylate $C_{10}H_{17}O{\cdot}CO{\cdot}C_6H_4{\cdot}OH$ (D. R. P. 175097), Heyden.

Spirosal. Salicylic monoglycol ester $C_6H_4(OH){\cdot}COO{\cdot}CH_2{\cdot}CH_2OH$ b.p. 170° (12 mm.) (D. R. P. 164128), Bayer.

IV. **Quinine derivatives.** Quinine will always retain its popularity as an antifebrile, chiefly because of the total absence of any depressing action upon the heart. Its bitter taste and what few secondary effects it may produce, as tinnitis and quinine intoxication, have been largely overcome in a number of new derivatives of real merit. These are esters in which the hydroxyl hydrogen of quinine has been replaced by carbonic acid (aristochin), phenyl carbonic acid (euchinin), salicylic acid (salichinin), &c.

Aristochin. Diquinine carbonic ester $CO(O{\cdot}C_{20}H_{23}N_2O)_2$ m.p. 189° (U.S. Pat. 625075), Bayer.

Bromochinol. Acid dibromsalicylate of quinine $C_{20}H_{24}N_2O_2{\cdot}2[C_6H_2Br_2(OH)COOH]$ m.p. 198°, Zimmer

Chinaphenin. Phenetidine quinine carbonic ester $CO(NH\cdot C_6H_4\cdot OC_2H_5)(C_{20}H_{23}N_2O_2)$ (D. R. P. 109259), Bayer.

Chinaphthol. Quinine beta-naphtholmonosulphonate $(C_{20}H_{24}N_2O_2)(C_{10}H_6(OH)SO_3H)_2$ m.p. 185°, Merck.

Euchinin (euquinine). Quinine ethyl carbonate $C_2H_5O\cdot CO\cdot OC_{20}H_{23}N_2O$ m.p. 95° (U. S. Pat. 585068), Zimmer.

Insipin. Diglycollic ester of quinine sulphate $O(CH_2\cdot COO\cdot C_{20}H_{23}N_2O)_2\cdot H_2SO_4,3H_2O$ tasteless. Merck.

Quinine lygosinate. Dioxy-dibenzal-acetone quinine $CO(CH{:}CH\cdot C_6H_4\cdot C_{20}H_{24}N_2O_2)_2$ m.p. 114°, Zimmer.

Rheumatin. Salicylate of salochinin, m.p. 183°.

Salochinin. Quinine salicylic ester $C_6H_4\cdot OH\cdot COO(C_{20}H_{23}N_2O)$ m.p. 141° (U. S. Pat. 678401), Bayer.

V. **Quinoline derivatives.** The earlier attempts to determine the origin of the physiological action of quinine indicated that the quinoline nucleus (tetra hydroquinoline) was largely responsible. While this possesses an antiseptic and antipyretic action, the latter is much weaker and less reliable than that of quinine. In malaria quinoline is inert. The introduction of a methyl group increases its antiseptic effect and diminishes antipyretic action, whilst the methoxyl, as in *p*-methoxy tetrahydroquinoline (thalline), is markedly antipyretic. Owing to its injurious action upon the kidneys, the use of thalline was soon discontinued. A like course followed the introduction of the kairins, methyl and ethyl derivatives of orthohydroxyquinoline tetrahydride. The untoward effects of these remedies (toxic to red blood corpuscles) were not altered either through the introduction of other alkyls or acid radicles in the imido group. Quite different results were obtained by placing ethoxyl and acylamino groups in the positions 1 : 4 (analgene), analogous to phenacetin. More successful derivatives of the class of hydroxyquinolines are found among the antiseptics as loretin, $C_9NH_4I(OH)SO_3H$ diaptherin.

Analgene. *o*-Ethoxy-ana-benzoylamino-quinoline $C_9NH_5(OC_2H_5)NH\cdot COC_6H_5$ m.p. 208°, Bayer.

Chinosol. Hydroxyquinoline potassium sulphate $(C_9H_7ON)_2H_2SO_4$ m.p. 175°–177·5° (U. S. Pat. 906918), Fritsche.

Diaphtherin. Hydroxyquinaseptol $(C_9NH_6\cdot OH)_2C_6H_4(OH)SO_3H$ m.p. 85°, Hoechst.

Quite different results have been attained through the introduction of a carboxylic group into the nucleus or its methylated derivative; such compounds possess not only analgesic action but also are of particular value in uric acid diathesis.

Atophan. 2-Phenylquinoline-4-carboxylic acid $C_9NH_5(C_6H_5)COOH$ m.p. 208–209°, Schering.

Novatophan. Ethyl 6-methyl-2-phenylquinoline-4-carboxylate $C_6H_5\cdot C_9NH_4(CH_3)COOC_2H_5$ m.p. 76° (U. S. Pat. 1045, 759), Schering.

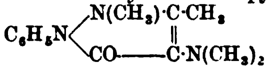
VI. **Pyrazolone derivatives.** Two erroneous assumptions led to the discovery of this group of antipyretics, namely, that quinine was a tetrahydroquinoline derivative and that what is now known as antipyrine was related to this same ring system. Knorr, in 1884, obtained a condensation-product of phenyl hydrazine (antipyretic but toxic) and aceto-acetic ester, the resulting phenyl methyl pyrazolone, was unsuited for therapeutic purposes. Utilising Filehne's previous experiences with substances of like physiological action derived from quinoline, namely kairine and kairoline, a methyl group was introduced which resulted in the formation of the well-known antipyrine. While this substance does not possess any of the antiperiodic properties of quinine, it has greater antipyretic and antineuralgic effects; in general, its action resembles that of salicylic acid. Phenyl monomethyl pyrazolone is only slightly antipyretic. The presence of an aromatic group (like tolyl in tolylpyrine) while not being absolutely essential increases the efficiency. A great improvement over antipyrine in intensity (3 times), mildness and duration of action was attained through the introduction of a dimethylamino group ($N(CH_3)_2$) in place of the only replaceable hydrogen of the nucleus (pyramidone). The success attending the introduction of pyramidone led to a variety of combinations with camphor, salicylic acid, &c., none of which offers any material advantages.

Acopyrin (acetopyrin). Antipyrine acetyl salicylate m.p. 63°/65°, Heyden.

Ferropyrin $(C_{11}H_{12}N_2O)_3(FeCl_3)_2$ (U. S. Pat. 548352), Knoll.

Melrubin. Sodium 1-phenyl 2 : 3-dimethylpyrazolone-4-aminomethane sulphonate $C_{11}H_{11}N_2O\cdot NH\cdot CH_2SO_3Na$ Hoechst.

Pyramidone. Dimethylamino antipyrine



$$C_6H_5N\left\langle\begin{array}{l}N(CH_3)\cdot C\cdot CH_3\\ \qquad\qquad\quad\|\\ CO\text{———}C\cdot N(CH_3)_2\end{array}\right.$$

m.p. 108° (U. S. Pat. 579412), Hoechst.

Pyramidone neutral camphorate, m.p. 80°–90° (U. S. Pat. 686998), Hoechst.

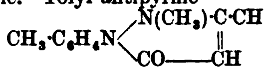
Pyramidone acid camphorate, m.p. 84°–94° (U. S. Pat. 686999), Hoechst.

Pyramidone salicylate camphorate, m.p. 68°–70° (U. S. Pat. 680278), Hoechst.

Pyrosal. Acid salicylo-aceto antipyrine, m.p. 150°, Hoffmann.

Salipyrine. Antipyrine salicylate m.p. 92° (U. S. Pat. 444004), Riedel.

Tolypyrine. Tolyl antipyrine



$$CH_3\cdot C_6H_4N\left\langle\begin{array}{l}N(CH_3)\cdot C\cdot CH_3\\ \qquad\qquad\quad\|\\ CO\text{———}CH\end{array}\right.$$

m.p. 137°, Riedel.

Tolysal. Tolypyrine salicylate, m.p. 102°, Riedel.

Trigemin. Dimethylamino antipyrine butyl chloral hydrate, m.p. 85° (D. R. P. 150799), Hoechst.

Tussol. Antipyrine mandelate $C_{11}H_{12}N_2O\cdot C_6H_5\cdot CH\cdot OH\cdot COOH$ m.p. 53° (U. S. Pat. 569415), Hoechst.

VII. **Hydrazine derivatives.** The nucleus of this class, hydrazine or diamide (H_2N-NH_2) is far more toxic than ammonia. Salts of hydrazine produce a condition of excitation followed by depression and coma with irregular pulse. Introduction of acyl groups decreases toxic action. Phenylhydrazine is a strong poison for connective tissue and hæmaglobin. Still more toxic, yet accompanied by a marked antipyretic effect, is the mono-acetyl compound (hydracetin) and laevulic acid phenylhydrazone (antithermin). Therapeutically better adapted with but minor secondary effects are the aromatic semi-carbazides, namely *m*-tolylhydrazide carbonate or *m*-tolyl semi-carbazide (maretin) and *m*-benzamido semi-carbazide (cryogenin).

Antithermin. Laevulic acid phenylhydrazone
$C_6H_5{\cdot}HN{\cdot}N:C(CH_3)CH_2{\cdot}CH_2{\cdot}COOH$
m.p. 108°.

Hydracetin (pyrodin) acetyl-phenylhydrazine
$C_6H_5{\cdot}NH{\cdot}NH{\cdot}COCH_3$
m.p. 128°, Merck.

Agathin. Salicylaldehyde methylphenylhydrazone $C_6H_5(CH_3)N{\cdot}N:CH{\cdot}C_6H_4{\cdot}OH$
m.p. 74°, Hoechst.

Maretin. *m*-Tolyl-hydrazid-carbamate
$CH_3{\cdot}C_6H_4NH{\cdot}NH{\cdot}CONH_2$
m.p. 184°, Bayer.

VIII. **Urethane derivatives.** It has been noted that the toxic action of aniline or the amino phenols is eliminated by the introduction of carboxyl and alkyl groups in different positions. It has been found that the hypnotic urethanes fulfil these conditions when coupled with a phenyl group, losing, however, their hypnotic characters through change in their structure. These compounds are more especially analgesics (*see Carbonic acid derivatives*).

Euphorine. Ethyl phenylcarbamate
$CO(HN{\cdot}C_6H_5)(OC_2H_5)$
m.p. 50°, Heyden.

Neurodine. *p*-Acetoxyphenyl urethane
$C_6H_4(OCOCH_3)NH{\cdot}COOC_2H_5$
m.p. 87°, Merck.

Thermodine. Phenacetin urethane
$C_6H_4(OC_2H_5){\cdot}N(CO{\cdot}OC_2H_5)(CH_3CO)$
m.p. 86°–88°, Merck.

Kyrogenin. *m*-Benzamino semi-carbazide
$C_6H_4(C{\cdot}CO{\cdot}NH_2)(C{\cdot}NH{\cdot}NH{\cdot}CO{\cdot}NH_2)$

HYPNOTICS.

Owing to our lack of knowledge concerning the physiology of sleep and possible chemical processes that take place, we are equally ignorant of the exact manner in which sleep is produced by hypnotics. In effect, we must distinguish between narcotics (represented by opium), which produce unconsciousness by intoxication, and the true hypnotics (represented by chloral), in which the sleep is apparently normal. In view of the fact that the sleep produced by the opium class is often attended with undesirable by-effects, and that during their prolonged administration the element of habituation must always be considered, they have been reserved for cases of insomnia due to severe pain, and have been largely replaced in other forms of sleeplessness by the synthetic hypnotics. While this latter class approach the normal conditions, yet the ideal hypnotic remains to be discovered. This must act upon the nerve centres followed later by the most automatic and stable centres, avoiding any profound influence on the respiratory or circulatory centres. Elimination must be rapid and complete leaving no trace of cumulative or secondary action such as digestive disturbances, headache, &c. Well known is the hypnotic effect of the aliphatic hydrocarbons, developed through the introduction of hydroxyl groups (alcohols). That the hydroxyl group serves no further purpose than an anchoring medium is proved by the inert properties of the polyhydric alcohols. That the ethyl group produces a profound hypnotic effect, as in alcohol, is further demonstrated by the decomposition of chloral in the blood to trichlorethyl alcohol, and the necessary presence of alkyl groups in the most important classes of hypnotics. The introduction of the ethoxyl group into caffeine imparts a narcotic effect. It can be said in general that the alkyl groups, more especially the ethyl, possess a distinctive sedative action upon the nervous system. The methyl group generally eliminates or diminishes hypnotic action when associated with an ethyl or propyl group; the propyl radicle with other higher radicles increases the intensity and also toxicity, while their corresponding *iso* groups generally diminish this. Sulphur replacing oxygen contributes to toxicity. The alkyl radicles do not carry hypnotic or sedative action under all conditions; it is only the association of certain groups or nuclei or their structural environment that determines this action. The presence of a sulphonic or carboxyl group inhibits physiological action, and diminishes toxicity. Another factor is insolubility, that is, failure to break down in the system: thus tetronal, which, theoretically, should possess a more profound hypnotic action than trional, is practically inert. A further insight is gained on studying the groups.

Alcohols. The primary alcohols are less narcotic than the secondary and these less so than the tertiary. The longer the carbon chain the more potent the alcohol; if more than one hydroxyl is present, narcotic effect disappears in proportion. In tertiary alcohols, the physiological action depends upon the alkyl groups linked to the tertiary carbon, if the methyl radicle be present, as in trimethyl carbinol (tertiary butyl alcohol), the action is relatively feeble: with ethyl groups, it increases in proportion to the number of such groups united to the tertiary carbon (*see Hydroxyl groups.*)

Amylene hydrate $C_2H_5{\cdot}C(CH_3)_2OH$-dimethyl ethyl carbinol, b.p. 99°–100°. The introduction of halogens into the hydrocarbons increases hypnotic action, as is shown in methyl chloride and chloroform. A similar effect is attained in:

Isopral, $CCl_3{\cdot}CH(CH_3){\cdot}OH$, trichlor-*iso*propyl alcohol (D. R. P. 151545), m.p. 49°, Bayer.

Brometone, tertiary-tribrom-butyl alcohol. Parke Davis $CBr_3{\cdot}C(OH)(CH_3)_2$, m.p. 167°.

Ethers. Methylal (formal) Methylen-dimethyl ether, $CH_2(OCH_3)_2$, b.p. 42°.

Aldehydes. Acetaldehyde is slightly hypnotic; much more so is its polymeride, paraldehyde. The aldols and acetals (ethylidene diethyl ether) possess a mild effect. The further introduction of alcohol groups as in sugar give inert compounds. As cited under the alcohols, the introduction of chlorine or bromine produces a marked increase in hypnotic effect exemplified in chloral, the first synthetic drug. This breaks down in the blood into urochloralic acid, a compound of trichlorethyl alcohol and glycuronic acid. To eliminate the secondary irritant action due to the aldehyde group, various combinations have been introduced. The corresponding bromine derivatives possess a toxic secondary action, whilst those containing iodine are inert. The following chloral combinations exhibit the same effects as chloral on the heart and respiration without an irritant effect on the stomach since they split up in the intestinal tract.

Chloralamide, $CCl_3{\cdot}CH(OH){\cdot}NH{\cdot}CHO$, chloral formamide, m.p. 115° (D. R. P. 50536), Schering.

Chloralimide, $CCl_3CH{:}NH$, m.p. 155°.

Dormiol, $CCl_3{\cdot}CH(OH){\cdot}O{\cdot}C(CH_3)_2C_2H_5$, dimethyl-ethyl carbinol-chloral (D. R. P. 99469), Kalle.

Hypnal, Chloral-hydrate-antipyrine, m.p. 67°, Hoechst.

Butyl-hypnal, Butylchloral-antipyrine, m.p. 70°.

Aromatic aldehydes are usually of low toxicity since they oxidise to inert acids.

Ketones. The action of these, like the alcohols, is governed by their alkyl groups. Dimethyl ketone produces intoxication, stimulation of heart's action, followed by paralysis of the central nervous system, whilst the diethyl and dipropyl ketones are mild hypnotics, free from action on the heart. In general, the aromatic ketones are only slightly hypnotic, while the mixed aromatic and aliphatic ketones are markedly so.

Hypnone $C_6H_5CO{\cdot}CH_3$, phenyl methyl ketone, b.p. 198°–200°.

Sulphonal group. This group was first studied, medicinally, by Baumann and Kast in 1886–1889. They are obtained by oxidising the condensation products of ketones and mercaptans and contain the basic group $>C<\begin{smallmatrix}SO_2-\\SO_2-\end{smallmatrix}$, which carries the hypnotic radicles in the form of methyl and ethyl groups. Only those disulphones which contain ethyl groups are active, and the intensity of effect depends upon the number of such groups contained in the molecule. This reaches its limit, however, in 'tetronal,' which contains four ethyl groups and because of its insolubility fails to break down in the system, and hence is almost inert.

Sulphonal $(CH_3)_2C(SO_2C_2H_5)_2$, diethylsulphone-dimethyl-methane, m.p. 125·6°, Bayer.

Trional $CH_3(C_2H_5){\cdot}C(SO_2C_2H_5)_2$, diethylsulphone-methyl-ethyl-methane, m.p. 76°, Bayer.

Carbonic acid derivatives. The hypnotics under this heading may be classed as derivatives of carbonic acid, carbamic acid and urea. From carbonic acid, no narcotic action can be expected, since the free carboxyl group is toxic. On the other hand, the esters of carbamic acid (urethanes), have the advantage that so long as the doses are not excessive, important life functions are not disturbed. Any toxic action, as collapse or feeble heart action, may be corrected through the introduction of an acetyl group. Hypnotic action is intensified through increase in size of the alkyl group. Urea is inert when an amino hydrogen is replaced by an alkyl group, the product exhibits the action of the latter. Derivatives with primary alkyls are inert; tertiary butyl urea is feebly hypnotic; tertiary amyl urea is stronger, whilst the tertiary heptyl urea is still more active. If both amino groups are replaced symmetrically by such radicles, medicinal action ceases, owing probably to excessive stability.

Adalin. Monobromodiethyl acetyl urea $(C_2H_5)_2CBr{\cdot}CO{\cdot}NH{\cdot}CONH_2$ m.p. 116° (U. S. Pat. 983425), Bayer.

Bromural, monobrom-*iso*valeryl-urea $(CH_3)_2CH{\cdot}CHBr{\cdot}NH{\cdot}CO{\cdot}NH_2$ m.p. 145° (U. S. Pat. 914518), Knoll.

Urethane group. The urethanes (carbamic acid esters), once quite popular, have given way to the sulphonal and barbituric acid derivatives. The latter were introduced by Schmiedeberg in 1885.

Urethane $CO(NH_2)OC_2H_5$, carbamic acid ethyl ester, m.p. 48°–50°.

Hedonal $CO(NH_2)O{\cdot}CH(CH_3)C_3H_7$, methyl-propyl-carbinol-urethane, m.p. 76°, b.p. 215° (U. S. Pat. 659202), Bayer.

Alendrin. The carbamic acid ester of *aa*-dichloro*iso*propyl alcohol $(CH_2Cl)_2CH{\cdot}O{\cdot}CONH_2$ m.p. 82°.

Aponol, $NH_2{\cdot}CO{\cdot}O{\cdot}C(CH_3)_2(C_2H_5)$. Amyl carbamate. Zimmer.

Although hypnotic action is obtained by associating ethyl groups directly with carbon, diethyl acetic and malonic acids are found to be inert, likewise their corresponding amides. This is due to the failure to replace all replaceable hydrogens of the carbon (in tertiary form). This is demonstrated by introducing a (sedative) bromine into diethyl acetamide, thus:

Neuronal $(C_2H_5)_2C(Br)CONH_2$, diethylbromacetamide, m.p. 66°, Kalle.

Malonyl urea derivatives, $CH_2<\begin{smallmatrix}CO{\cdot}NH\\CO{\cdot}NH\end{smallmatrix}>CO$

Neither malonic acid nor its amide possess hypnotic action. The introduction of two methyl groups into the latter is without effect, and one methyl and one ethyl imparts a mild hypnotic action; marked, however, is that produced through the presence of two ethyls, as in:

Veronal $(C_2H_5)_2C<\begin{smallmatrix}CO{\cdot}NH\\CO{\cdot}NH\end{smallmatrix}>CO$, diethyl malonyl urea, m.p. 188° (U. S. Pat. 782739), Merck and Bayer. This very popular hypnotic is furnished in the form of its soluble sodium salt (medinal). The introduction of the propyl radicle increases the duration of the hypnotic effect, whilst *iso*butyl and *iso*amyl radicles, diminish this. A substitution of the imide hydrogens of veronal by alkyls as well as that of oxygen by sulphur yield toxic bodies.

A mixture of 2 parts of codeine diethylmalonylurea with one part of the sodium salt is used as sedative and hypnotic—*Codeonal* (D. R. P. 239323). Knoll.

Chineonal. A compound of veronal and quinine which fuses at 132°. Used in infectious fevers, also as an analgesic. Merck.

Proponal $(C_3H_7)_2C<\begin{smallmatrix}CO{\cdot}NH\\CO{\cdot}NH\end{smallmatrix}>CO$, dipropyl malonyl urea, m.p. 145°, Merck and Bayer. The hypnotic nucleus of these substances is evidently the urea radicle —HN·CO·NH— when present in the cyclic form as a ureide; any change in the barbituric acid ring destroys the hypnotic action.

Luminal $C_6H_5{\cdot}C{\cdot}C_2H_5[CO{\cdot}NH]_2CO$, phenyl-ethyl-malonylurea. Veronal in which an ethyl is replaced by a phenyl group. Stronger hypnotic (U. S. Pat. 1051, 586). Bayer, Merck.

SEDATIVES.

This group serves to reduce nervous hypersensibility as an aid in the general systematic treatment of diseases of the nervous system. According to the specific purpose for which these drugs are used, they may be divided into three classes, namely bromine combinations, valeric acid esters, and derivatives of morphine.

Bromine combinations. When it is necessary to subject the system for a considerable period to the action of bromine and to avoid the undesirable secondary effects such as usually accompany the prolonged use of the alkali bromides, recourse may be had to the brominated fatty and albuminoid bodies. The decomposition of these derivatives usually takes place in the intestinal tract.

Bromipin. Bromine addition-product of sesame oil containing 10 and 33⅓ p.c. of bromine (D. R. P. 96495), Merck.

Bromlecithin. Brominated lecithin containing about 30 p.c. of bromine (D. R. P. 156110), A. G. f. A.

Bromalbacid. Brominated albumin, 6 p.c. bromine, Gans.

Bromochinol. Quinine dibromosalicylate, m.p. 197°, Zimmer.

Bromglidine. Brominated vegetable glidin, Klopfer.

Bromocoll. A brom-tannin-gelatin, 20 p.c. bromine, A. G. f. A.

Bromolein. Brominated unsat. fatty acids of almond oil, 20 p.c. bromine.

Lipobromol. Brominated poppyseed oil, 33 p.c. bromien.

Sabromin. Calcium dibrombehenate, 29 p.c. bromine, Bayer.

Valeric acid derivatives. The replacement of a carboxyl hydrogen by alkyl radicles produces a distinctive narcotic effect, as instanced by ethyl acetate. Here it is evident that the acid radicle remains indifferent, while, on the other hand, the natural and synthetic esters of valeric acid exhibit the sedative effects of both groups. The well-known sedative action of valerian is due chiefly to the presence of the borneol ester of *iso*-valeric acid now sold as:

Bornyval. Bornyl *iso*valerate, b.p. 255°–260°, Riedel.

Bornyval, New. Bornyl *iso*valerylglycollate

$(CH_3)_2CH{\cdot}CH_2{\cdot}COO{\cdot}CH_2{\cdot}COO{\cdot}C_{10}H_{17}$

b.p. 181°/12 mm. Reidel.

Brophenin. Brom-*iso*valerylphenocoll. A brominated phenetidine derivative.

Brovalol. Bornylbromovalerate

$CH_3{\cdot}CH(CH_3)CHBr{\cdot}COO(C_{10}H_{17})$

b.p. 163° (10 mm.) (U. S. Pat. 930504), Schering.

Eubornyl. *a*-Brom-*iso*valeric-borneol ester, Luedy.

Gynoval. *Iso*borneol ester of *iso*valeric acid, b.p. 132°–138°/12 mm., Bayer.

Iodival. ono-iodo-*iso*valeryl urea, m.p. 180° (D. R. P. 197648), Knoll.

Quietol. Hydrobromide of dimethylamino-dimethyl *iso*valeryl propyl ester, m.p. 105°–110°, when pure, 118°, Poulenc.

Validol. Menthol valerate; 30 p.c. free menthol, Zimmer.

Valisan. Borneol-bromo-*iso*valerate, Schering.

Valyl. Valeric diethylamide

$C_4H_9{\cdot}CO{\cdot}N(C_2H_5)_2$

b.p. 210° (U. S. Pat. 897730), Hoechst.

Synthetic morphine derivatives. The hydroxyl groups are intimately associated with the toxic action of morphine, which, through its narcotic characters, differs from all other opium alkaloids, its action being chiefly upon the nerve centres of the brain. Upon closing these OH groups by substituting one or both of the hydrogens by alkyl or acyl radicles, the narcotic characters disappear, while, on the other hand, a spinal excitant (tetanic action) is developed, increasing with the number of alkyls introduced. Thus, codeine produces, like morphine (but in lesser degree), narcosis, followed by an elevated reflex, which, if the dose be sufficiently large, develops tetanic convulsions. Other morphine esters, as codethyline $C_{17}H_{17}ON(OH)OC_2H_5$), and thebaine $C_{17}H_{15}(OCH_3)_2NO$, the latter of which is the most toxic alkaloid of opium, are characterised by their action on the spinal cord, the tetanic effects being identical with those produced by strychnine. This action increases with the number and molecular weight of the alkyl groups introduced; hence codethyline with its ethyl group is more intense in action than codeine, which contains but one methyl group. The same may be said of the acyl compounds, those containing two such radicles are distinctly tetanic in action.

Among all possible derivatives, it is immaterial as to whether an acyl or alkyl radicle, aliphatic or aromatic, is introduced, there is practically no qualitative difference in action so long as the same hydrogen is replaced. The more readily the acid or alkyl group splits off from the nucleus, the closer the properties of the derivative resemble those of morphine. On the other hand, too great a stability produces relatively inert bodies, morphine hydroxy-acetic, propionic or butyric acids are pharmacologically inactive, whereas, on the other hand, the methyl and ethyl esters of these acid derivatives produce intense picrotoxin-like convulsions, the seat of action being the *crura cerebri*.

Winternitz[1] has shown that codeine and dionine produce no effect upon respiration, whilst the introduction of acid radicles increase the respiratory influence of morphine.

In all instances, the narcotic action of morphine is very much diminished, while the tetanic and also the action on the motor nerves is increased. The morphine derivatives of the codeine type, while less active in relieving pain, exert a sedative effect on the unstriped muscles of the bronchi and reduce the disposition to cough; hence are of value in phthisis, bronchitis, asthma, &c.

Dionine. Morphine ethyl ether hydrochloride

$C_{17}H_{17}NO(OH)OC_2H_5.HCl+H_2O$

m.p. 123°–125° (D. R. P. 108075), Merck.

Heroin. Diacetyl morphine hydrochloride

$C_{17}H_{17}NO(O{\cdot}COCH_3)_2{\cdot}HCl$

m.p. 230°–231°, Bayer.

Peronin. Morphine benzyl ether hydrochloride

$C_{17}H_{17}NO(OH)O{\cdot}CH_2{\cdot}C_6H_5{\cdot}HCl$ Merck.

Morphosan. Morphine methylbromide, m.p. 265°,

$C_{17}H_{19}O_3N(CH_3)Br+H_2O$

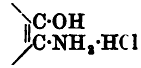
(D. R. P. 165898, 191088), Riedel Co.

Knorr's[2] investigations have demonstrated the presence of a phenanthrene and a morpholine (oxazine) nuclei to be the basic ring structure of morphine. Assuming that either one or the other of these rings might be the carrier of its physiological action, Knorr prepared a naphthalan-morpholine and methylated the imid hydrogen (methyl morphimetin); the product was

---

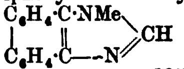
[1] Therap. Monatsh, 1899. [2] Knorr, Ber. 27, 1144.

found to be inert. Vahlen[1] assuming the phenanthrene nucleus to be active centre, prepared morphigenine (hydrochloride of 9-amino-10-hydroxy-phenanthrene)



and found that it had marked narcotic properties. The amidazole derivative of this, resembling morphine and codeine in its effects, was called :—

Epiosin, 4 : 5-diphenylene-1-methylimazole



m.p. 195°, Heinemann.

ANTISEPTICS AND DISINFECTANTS.[2]

Antiseptics are certain chemicals which have the power, in small quantities, to prevent infection or to arrest the multiplication of bacteria, and should be free from harmful action upon the human organism. Disinfectants destroy bacterial life and the noxious properties of putrefactive or fermentative products. Usually, small quantities of these chemicals are antiseptic, and large amounts disinfectant, in their effects.

The great variety of bacterial life, the kind, state, extent, composition, quantity, and condition of the associated matter, together with the difficulty of fixing, inhibiting and sterilising doses of disinfectants, makes the subject of standardisation of disinfectants perplexing and difficult. An ideal disinfectant must be able to destroy bacteria, be harmless to the human organism, penetrative, free from local irritation, toxic action and disagreeable odour. Very few, if any, of the disinfectants are adapted for universal use because of the great variety of conditions presented, hence each product is adapted for some special field of work.

Internal antisepsis is not attainable, because if the antiseptic were sufficiently powerful to destroy bacteria it must necessarily exhibit a toxic action on the human system. However, in certain lines, this class of antiseptics serve admirably in inhibiting the development of milder types of bacteria and neutralising the action of toxins in infections of the respiratory and urinary tracts. Combinations of bismuth and various antiseptics have become popular in treatment of intestinal disturbances due to fermentative changes or infection.

Inorganic antiseptics. More important and recent are fluorol (sodium fluoride), calcinol (calcium iodate), dymal (didymium salicylate), aluminium fluoride, iodine trichloride and tribromide, magnesium permanganate, vanadic acid, sodium perborate.

Peroxides. The peroxides of the alkaline earths possess antifermentative as well as antiseptic action owing to their generation of hydrogen peroxide and liberation of oxygen when in contact with water. Commercially known are the peroxides of magnesium (D. R. P. 171372), calcium, strontium and zinc (D. R. P. 171372); also sold under copyrighted titles as Gorit (CaO_2), Biogen (MgO_2), Dermogen and Ektogen (ZnO_2).

Colloidal silver is sold as Collargol (Heyden) and Lysargin (Kalle).

Aluminium, organic salts. These combine the astringent properties of aluminium salts with the disinfectant action of the respective organic acids.

Aluminium aceto-tartrate 'Alsol.'	Aethenstaedt.
„ salicylate 'Salumin.'	Riedel.
„ zinc acetate 'Zinol.'	Lewinsohn.
„ boro-formiate.	
„ „ tartrate 'Boral.'	
„ caseinate.	
„ formiate 'Alformin'	Elb.
„ gallate, basic, 'Gallal'	Riedel.
„ β-naphthol disulphonate 'Alumnol'	Hoechst.
„ *p*-phenol sulphonate 'Sozal.'	
„ potassium salicylate 'Alkasal'	Aethenstaedt.
„ sodium acetate 'Acetonal'	Aethenstaedt.
„ sozoiodolate	Trommsdorf.
„ boro-tannate 'Lutol.'	

Bismuth organic salts are of use in gastric or intestinal disturbances, the compounds splitting up into their constituents. Only those sold under registered names are given.

Bismuth albuminate 'Bismutose'	Kalle.
„ bilacto-monotannate 'Lactanin.'	
„ bitannate 'Tannismut'	Heyden.
„ borophenate 'Marcasol.'	
„ chrysophanate 'Dermol.'	
„ cinnamate 'Hetoform'	Kalle.
„ colloidal 'Bismon'	Kalle.
„ dithiosalicylate 'Thioform'	Speyer.
„ gallate 'Dermatol.'	
„ iodo-resorcin-sulphonate 'Anusol'	Schering.
„ „ gallate 'Airol'	La Roche.
„ „ salicylate 'Iodylin.'	
„ „ tannate 'Ibit'	G. C. I. Basel.
„ methylene digallate 'Bismal'	Merck.
„ β-naphthalate 'Orphol.'	Heyden.
„ nosophenate 'Eudoxin'	Rhenania.
„ para-nucleinate 'Parabismut.'	
„ pyrogallate 'Helcosol'	Merck.
„ quinolin-sulphocyanate 'Crurin'	Kalle.
„ tetrabrompyrocatechin 'Noviform'	Heyden.
„ tribromphenate 'Xeroform'	Heyden.

Mercurial antiseptics and mercurials. The value of mercury in treatment of syphilis and also in antiseptics, has brought out a great variety of combinations, some of which, because of their ready solubility, freedom from irritation, and slow elimination from the system, are especially adapted for subcutaneous and intramuscular injection. Others represent antiseptics equal in value to corrosive sublimate yet free from its objectionable action on instruments. With a few exceptions, only such as are marketed under registered names are enumerated. Others are given in Merck's List.

Apallagin. Mercury nosophen (tetra-iodo-phenolphtalein), Hoechst.

Asiphyl. Mercury atoxyl (paranilide arsenate).

---

[1] Arch. exp. Pharmakol, 47, 50, Zeitsch. physiol. Chem. 39.

[2] Standardizing of Disinfectants, J. Royal Institute of Public Health, London, 1908; Experimentelle Pharmakologie. H. Meyer and R. Gottlieb, Berlin, 1910; Jour. Hygiene, London, vol. viii., No. 5, Chick and Martin; Jour. Amer. Medical Assoc., vol. lv. p 1635, Post and Nicoll.

Antiperiostin. Mercury iodocantharidate (D. R. P. 163219), A. Klein, Berlin.
Asterol. Mercury *p*-sulphophenate with ammonium tartrate (D. R. P. 104904), La Roche.
Calomelol. Colloidal calomel (U. S. Pat. 740855) Heyden.
Enesol. Mercury salicylo-arsenate, Clin & Co., Paris.
Hermophenyl. Mercury sodium disulphonate, Merck.
Hydrargol. Mercury succinimid, Gehe Co.
Hydrargotin. Mercury tannate, Hell Co.
Hydrargyroseptol. Quinoline mercury-sodium chloride, Fritzsche.
Hyrgol. Colloidal mercury, Heyden.
Lévurargyre. Mercury nucleoproteid, Adrian, Paris.

Mercury phenates. The monophenol derivative, which is quite unstable in the body, is a valuable mercurial, whilst the diphenyl mercury is very poisonous because of its cumulative action. Dimethyl and diethyl mercury are similar. Such organic salts as the benzoate, tribrom-phenol acetate, &c., when used subcutaneously, accumulate locally and frequently produce mercurial poisoning.

Mercury ethyl chloride, albuminate, cacodylate and mercuric chloride-urea are used subcutaneously.

Anogon. Mercury-salt of diiodo-*p*-phenolsulphonic acid (30 p.c. iodine and 50 p.c. mercury), Trommsdorff.
Mercurol. Mercury nucleinate (U. S. Pat. 637355), Parke, Davis.
Mercuriol. Mercury amalgam with aluminium.
Mercochinol. Mercury hydroxyquinoline sulphonate, Fritzsche.
Mergal. Mercury choleate with albumin tannate, Riedel.
Meriodin. Mercury soziodolate (di-iodo-*p*-phenolsulphonate).
Phenegol. Mercury potassium *p*-nitrophenol sulphonate.
Sublamine. Mercuric sulphate ethylenediamine (U. S. Pat. 726125), Schering.

Copper compounds.

Cupratin. Copper albuminate.
Cupriaseptol. Copper *m*-phenolsulphonate, Gawalowski, Berlin.
Cuprol. Copper nucleinate, Parke Davis.

Organic silver antiseptics. Although it is one of the standard remedies for the treatment of infected and inflammatory conditions of mucous surfaces, silver nitrate possesses an irritating and caustic action which greatly restricts its usefulness. Apart from this, it has only a limited penetrating power, due to the fact that it is precipitated by albumin and sodium chloride, ordinary constituents of tissues and their secretions. This is a serious disadvantage, since many of the conditions in which it is employed are due to micro-organisms, which are found not only in the superficial, but also in the deeper portions of the mucous surfaces, and hence cannot be reached by solutions of this chemical, owing to the formation of an insoluble silver albuminate in the upper layers. The recognition of these drawbacks has led to the many new organic compounds of silver now on the market. The older organic salts have been practically superseded by the protein compounds. They are non-irritating when properly employed and are, with few exceptions, unaffected by either albumin or chlorides. They should never be boiled nor mixed with drug extracts.

Albargin. Gelatose silver (15 p.c. silver) (D. R. P. 146792) Hoechst.
Argentamine. Ethylene diamine silver nitrate (10 p.c. silver nitrate) (D. R. P. 74634), Schering.
Argentol. Silver quinaseptolate (31·7 p.c. silver) Fritzsche.
Argonin. Casein silver (4·3 p.c. silver) (U. S. Pat. 575277), Hoechst.
Argyrol. Silver vitellin (20–25 p.c. silver), Barnes.
Hegonon. Ammonio-silver nitrate albumose (7 p.c. Ag) (U. S. Pat. 567412), Schering.
Ichthargan. Silver sulphoichthyolate (30 p.c. silver), Merck.
Nargol. Silver nucleinate (10 p.c. silver), Parke Davis.
Novargan. Silver proteinate (10 p.c. silver) (U. S. Pat. 19989), Heyden.
Omorol. Protein silver (10 p.c. silver), Heyden.
Protargol. Protein silver (8·3 p.c. silver) (U. S. Pat. 615970), Bayer.
Sophol. Methylene nucleinic acid silver compounds (20 p.c. silver) (D. R. P. 852545), Bayer.
Silver salts. Citrate (Itrol, Heyden); electrolytic colloidal silver (Electrargol, Heyden); eosolate (acetyl guaiacol-tri-sulphonate); fluoride (Iachiol); lactate (Actol, Heyden); picronitrate (Picratol, Wyeth); sulphophenate (Silberol). Colloidal silvers are Collargol (Heyden), argoferment (Fritz), and Syrgol (Siegfried).

Inorganic salts of nucleinic acids. Nucleinic acid, a substance common to the blood corpuscles, organs, and vital tissues of the animal organism, has suggested itself as a means for the more ready and effectual administration of metals. The hypothesis that inorganic salts of the heavy metals pass into the blood only so far as they combine with the nucleinic acid, would seem to offer sufficient ground for the artificial preparation of derivatives which would be more readily absorbed and utilised in the human organism. Apart from this, certain of these combinations are especially adapted for external use as antiseptics because of their penetrability, freedom from irritation and decomposition by contact with albuminoids. These combinations comport themselves quite differently from the other more common organic salts, in that the usual inorganic reagents fail to produce any of the characteristic qualitative reactions. For example, copper nucleinate fails to turn blue upon the addition of ammonia water, nor does it react with hydrogen sulphide. The addition of chlorides fails to precipitate silver from these organic combinations.

Nucleinic acid may be obtained from the blood, salmon sperm, and yeast; from the latter source the acid is prepared by extracting with an alkali, when, after acidifying with acetic acid, the albuminoids are coagulated by heating to 75°; from the filtrate the crude nuclein is precipitated by means of acidified alcohol. Purification is effected by careful oxidation with permanganate. The slightly alkaline nuclein solution is then brought into reaction with the salts of silver, mercury, iron, &c., and then precipitated by the addition of alcohol and a neutral salt. In such combinations as the nucleinate or other albumin derivatives of the metals, the latter are retained in the albumin molecule in a masked (larvated) state beyond the reach of the usual inorganic reagents. In the case of the iron preparations we have a ready means of distinguishing this masked metal from that present in the form of the ordinary organic salts, as the peptonate, lactate, &c., in the well-known Macallum's test. This consists in adding a few drops of a 1 p.c. solution of hæmatoxylon to the solution of the preparation, whereby a blue to blue-black coloration ensues if it belongs to the latter class.

Cuprol. Copper nucleinate (6 p.c.), Parke Davis.
Argyrol. Silver vitellin (30 p.c.), Barnes Co.
Ferratogen. Iron nucleinate, Basel, C. F.
Mercurol. Mercury nucleinate (10 p.c.) (U. S. Pat. 637355), Parke Davis.
Nargol. Silver nucleinate (10 p.c.), Parke Davis.

Organic iodine derivatives.—*External iodoform type.* The organic iodine combinations are our standard antiseptics, especially intended for dry local application. Their bactericidal effect depends upon the action of the alkaline wound secretions in splitting up the compounds into their component parts. Iodoform is antiseptic only under conditions in which iodine is slowly eliminated. The newer combinations have aimed at overcoming the objectionable odour and occasional tendency to iodine poisoning peculiar to iodoform, also to combine a lower percentage of iodine with an antiseptic nucleus, securing thereby a milder iodine effect in conjunction with that of the nucleus. Many of this class are of considerable value.

Aristol. Diiodothymol $[C_6H_2(OI)(CH_3)\cdot C_3H_7]_2$ Bayer.
Chrysoform. Dibrom-diiodo-hexamethylenetetramine Merck.
Diiodoform. Ethylene periodide, C_2I_4, Schering.
Europhen. Di*iso*butyl cresol iodide $C_6H_2(C_4H_9)(CH_3)(OI)\cdot C_6H_2(CH_3)(:O)(C_4H_9)$ m.p. 110° (U. S. Pat. 495204), Bayer.
Formidin. Methylene disalicylic iodide $C_{15}H_{10}O_2I_6$ Parke Davis.
Griserin. Isomeride of loretin (D. R. P. 187943) Griserin Werke, Berlin.
Iodanisol. *o*-Iodo-anisol $C_6H_4I\cdot OCH_3$, m.p. 47° Merck.
Iodocrol. Carvacrol iodide $C_{13}H_{13}OI$, Merck.
Iodoformal. Iodoformin ethyl iodide, m.p. 128° (D. R. P. 87812), Marquart.
Iodoformin. Hexamethylenetetramine iodoform $CHI_3(CH_2)_6N_4$ m.p. 178°, Marquart.
Iodoformogen. Iodoform albumin (D. R. P. 95580), Knoll.
Iodogallicin. Bismuth hydroxyiodidemethyl gallol $C_6H_2(OH)_2(COOCH_3)(OBi\cdot I\cdot OH)$ Sandoz.
Iodol. Tetraiodopyrrol C_6I_4NH (D. R. P. 35120), Kalle.
Iodolen. Iodised albumin. Kalle.
Iodolin. Quinoline chloromethyl-iodo-chloride.
Iodophenin. Iodophenacetin, m.p. 130° (D. R. P. 58404), Riedel.
Iodothymoloform. Iodised thymoloform m.p. 150°, Henning.
Iodozol. Sozoiodolic acid (diiodo *p*-phenolsulphonic acid) $C_6H_2I_2(OH)SO_3H+3H_2O$ Trommsdorf.
Iothion. αγ-diiodopropane-β-ol $CH_2I\cdot CH(OH)CH_2I$ Bayer.
Isoform. *p*-Iodoxy anisole $C_6H_4(OCH_3)IO_2$ (D. R. P. 161725), Hoechst.
Loretin. 3-Iodo-4-hydroxyquinoline-1-sulphonic acid (D. R. P. 72924), Schuchardt.
Losophan. Tri-iodo-metacresol $CH_3\cdot C_6HI_3\cdot OH$ m.p. 121°, Bayer
Nosophen. Tetra-iodo-phenolphthalein (D. R. PP. 86069, 143596), Rhenania.
Sanoform. Di-iodo-salicylic methyl ester $C_6H_2(COOCH_3)(OH)I_2$ m.p. 110·5°, Hoechst.
Traumatol. Mono-iodo-cresol, Chevrier and Kraus, Paris.
Vioform. Iodo-chlor-hydroxyquinoline $C_9NH_6(OH)ICl$ (D. R. P. 117767), Basel.

For internal use. These are intended to replace the alkali iodides, claimed to be free from disagreeable taste, digestive disturbances, and tendency to produce iodism.

Iodalbacid. Iodised albumin (10 p.c. iodine), Gans.
Iodalbin. Iodised albumin (21·5 p.c. iodine), Parke Davis.
Iodeigons. An α-iodised albumin (20 p.c. iodine), sodium salt (15 p.c. iodine), Helfenberg.
β-Eigon, an iodised peptone.
Iodglidin. Iodised gluten (10 p.c. iodine), Klopfer.
Iodin. Iodised arachis oil.
Iodipin. Iodised sesamé oil (10 and 25 p.c. iodine) (D. R. P. 96495), Merck.
Iodival. Iodo-mono*iso*-valeryl urea $(CH_3)_2CH\cdot CHI\cdot CO\cdot NH\cdot CO\cdot NH_2$ m.p. 180° (D. R. P. 197648), Knoll.
Iodlecithin, 7 to 8 p.c. iodine (D. R. P. 155629), Riedel.
Iodomenim. Iodised casein containing bismuth (10 p.c. iodine) (D. R. P. 177109), Wuelfing.
Iodothyrin. Lactated active principle of thyroid gland (U. S. Pat. 686648), Bayer.
Iodyloform. Iodised gelatin (10 p.c. iodine), Kohlmeyer.
Sajodin. Mono-iodo-behenate of calcium (5 p.c. iodine) (U. S. Pat. 848230). Iron sajodin contains in addition 5·7 p.c. Fe. Bayer.

Formaldehyde derivatives. Formaldehyde is still sold under registered names such as Formal, Formysol, Holzin, Camolin, Methylal, Steresol. It has virtually supplanted all other embalming fluids. On account of the readiness with which it forms non-irritating condensation-products, the formaldehyde derivatives have been favourably received. These combinations usually form inodorous powders which, when in contact with the alkaline wound secretions, break up with liberation of formaldehyde.

Amyloform. Formaldehyde-starch (D. R. P. 92259), Gans.
Chinoform. Cinchotannicacid-formaldehyde, also quinine formiate.
Chrysoform. Dibrom-monoiodo-hexamethylene tetramine.
Empyroform. Formaldehyde tar condensation product, Schering (U. S. Pat. 761260).
Euguform. Acetylated-methylene guaiacol, Guestrow.
Formaldehyde casein, Merck.
Formicin. Formaldehyde acetamide compound, Kalle.

Forman. Chloromethyl-menthyl ether $C_{10}H_{19}O{\cdot}CH_2Cl$ b.p. 160° (16 mm.) (D. R. P. 119008), Lingner.

Fortoin. Methylene dicotoin (D. R. P. 104362). $CH_2(C_{14}H_{11}O_4)_2$ m.p. 211°–213°, Zimmer.

Glutol. Formaldehyde gelatin (D. R. P. 104365), Schering.

Phenyform. Condensation product of formaldehyde and phenol $[C_6H_4(OH)CH_2OH]_x CH_2O$ Phenyform Co., Berlin.

Tannoform. Methylene ditannin $CH_2(C_{14}H_9O_9)_2$ (D. R. P. 88841), Merck.

Thymoloform. Condensation product of formaldehyde and thymol $(C_6H_3(CH_3)(C_3H_7)O)_2CH_2$ Henning.

Sulphurated products. Salts of sulphonated tars obtained by the destructive distillation of fossilised fish or from petroleum are used as antiseptics. The first of this class to be introduced was:

Ichthyol, the ammonium salt of so-called ichthyol-sulphonic acid obtained by sulphonating the fossilised fish-tar. Other combinations are ichthalbin (ichthyol albumin), ichthargan (ichthyol-silver), ichthermol (ichthyol mercury), ichthoform (ichthyol formaldehyde), ichthyolidin (piperazin ichthyolate), etc. Cordes and Merck.

Products of similar nature are isarol, petrosulfol, sulfogenol, ichthosulfol, ichthynat.

Nafalan, similar to naftalan, Nafalan Co., Magdeburg.

Naftalan. Distillations-residue, free from resin and asphalt, obtained from Caucasian petroleum mixed with sodium stearate, Naftalan Co., Dresden.

Thiol. Sulphurated paraffin oil (D. R. P. 38416), Riedel.

Thiogenol. Sulphonated sulpho-oil, La Roche.

Sulfidol. Colloidal sulphur (D. R. P. 164664), Heyden.

Thilaven. A solution of linalylacet-thiozonide in an alkali thiozonate, 5 p.c. total sulphur, Helfenberg.

ANTISEPTICS CONTAINING PHENOL NUCLEI

During the last few years very few new derivatives of this class have appeared, although much work has been accomplished in tracing the groups to which their destructive action on pathogenic bacteria is due. The caustic action of phenol on the skin and mucus surfaces resides, without doubt, in the hydroxyl group which is also common to its homologues. The local antiseptic properties decrease with an increase in the number of hydroxyl groups as is the case with resorcinol and pyrogallol. Their toxicity increases with the number of hydroxyls. The relative positions occupied by these groups determines likewise relative toxicity, thus the *o*-dihydroxybenzene (pyrocatechol) is the most toxic, while the meta (resorcinol) is the least. The toxicity of phenols diminish, while antiseptic properties increase, by the introduction of alkyl radicles in the nucleus (cresol).

If the hydroxyl groups be closed by etherification, the phenols lose their peculiar caustic and antiseptic action as with veratrole, anisole, and phenetole. That this is not the case with the safroles is due to an active double-linked side chain. In the same way the relative toxicity of the polyhydric phenols is diminished by introduction of acid radicles in place of the hydroxyl hydrogens. Thus, such esters of pyrogallol as eugallol (mono-acetate), lenigallol (tri-acetate) and saligallol (di-salicylate) are comparatively non-toxic owing to their insolubility and the slowness with which they break up when applied to a mucus surface.

If a carboxyl group is introduced into the benzene ring, an acid (benzoic) of low antiseptic power and but slight medicinal activity results, which, however, increases with the molecular weight of the entering acid, as, for example, phenylacetic acid, phenyl propionic acid, and phenyl-butyric acid. On the other hand, the antiseptic powers of the aliphatic acids increase with decreasing molecular weight. Whilst the entrance of chlorine in aliphatic bodies lends hypnotic and narcotic properties, the replacement of hydrogen in the benzene nucleus by a halogen raises the antiseptic properties of the substance. No hypnotic action is discernible, since the human organism is incapable of splitting the halogen off from the nucleus. A comparative study of the relationship between chemical constitution and disinfectant action of antiseptics by Bechhold and Ehrlich (Zeitsch. Physiol. Chem. 1906, 47, 173), has cleared up this subject in a remarkable manner. The experiments were carried out on diphtheria bacilli and other pathogenic bacteria as *B. coli*, pyocyaneus, typhi, &c.

1. The introduction of halogens in phenol raises the disinfectant action corresponding to the number of halogen atoms (1 mol. of penta bromphenol is the equivalent of 500 mol. of phenol).

2. The introduction of alkyl groups in phenol and halogen phenols increases disinfectant action (tribrom-*o*-cresol is 20 times as active as tri-brom-phenol; tetra-brom-*o*-cresol is in effect 250 times as active as phenol and half as toxic).

3. The direct linkage of two phenols or halogen phenols through agency of a CH_2 or $CHOH$ or $CHOCH_3$ or $CHOC_2H_5$ group increases antiseptic action.

4. The union of two phenol groups through CO or SO_2 lessens disinfectant action.

5. The introduction of $COOH$ group into the nucleus lessens disinfectant action.

Among the newer disinfectants of high antiseptic powers against pathogenic bacteria are:

Tetrabrom-*o*-cresol (almost non-toxic) arrests diphtheria bacilli in a dilution of 1 to 200,000 (phenol 1 to 800). In dilution of 1 to 320,000 destroys bacteria in 24 hours.

Tetrabrom-*o*-diphenol (slightly toxic), a dilution of 1 to 640,000 corresponding to 1 to 800 of phenol.

Hexabromodihydroxydiphenylcarbinol (non-toxic) dilutions of 1 to 200,000 corresponding to 1 to 800 of phenol.

The introduction of halogens in phenol depresses at first the toxicity, increasing and reaching a maximum in the penta-halogenphenol. The tri-halogen derivative is equally toxic with phenol.

The introduction of the CH_3 group compensates the toxic action of halogens.

Acetozone. Acetyl benzoyl peroxide $C_6H_5CO{\cdot}O{\cdot}O{\cdot}COCH_3$ m.p. 36·6° (U. S. Pat. 710005), Parke Davis.

Antinosin. Nosophen sodium. *See Nosophen.*

Antisepsin (asepsin) *p*-brom-acetanilide, m.p. 165°, Benzonaphthol. Benzo-β-naphthol $C_6H_5{\cdot}COOC_{10}H_7$ m.p. 110°, Hoechst.

Bromol. Tribromophenol, m.p. 95°, Heyden.

Bromotan. Bromtannin methylene urea, Voswinkel.

Chinosol. Normal hydroxyquinoline sulphate
$(C_9NH_7O)_2H_2SO_4$
m.p. 175°–177·5° (U. S. Pat. 906918), Fritzsche.

Chrysoidin. Diaminoazobenzene hydrochloride
$C_6H_5N:N{\cdot}C_6H_3(NH_2)_2{\cdot}HCl$

Cresol preparations. Because of the insolubility of this antiseptic, different methods of suspending it in water have been resorted to. One class employs fats or resin mixed with pure or crude cresols which are then saponified. Among this class are creolin (Pearson), creosapol (de Haen), creosolin, cyllin (Jeyes Co., London), lysol (Schuelke and Mayer), &c. Another class sulphonate or acetylate cresols as solveol (Heyden), sanatol (Leonhardt), kresulfol (Riedel), kresin (Schering).

Diaphtherin. Hydroxyquinaseptol
$(C_9H_6N{\cdot}OH)_2C_6H_4(OH)SO_3H$
m.p. 85°, Hoechst.

Epicarine. *ω*-Naphthoxy-*o*-hydroxytoluic acid
$CO_2H{\cdot}C_6H_3(OH)CH_2{\cdot}O{\cdot}C_{10}H_7$
(U. S. Pat. 671622) m.p. 190°–195°, Bayer.

Euguform. Acetylated methylene diguaiacol, Hillringhaus.

Europhen. Isobutyl-*o*-cresol iodide
$C_6H_2(C_4H_9)(CH_3)(OI){\cdot}C_6H_2(CH_3)(:O)({\cdot}C_4H_9)$
m.p. 110° (D. R. P. 56830), Bayer.

Euphorin. Phenyl urethane
$CO(NH{\cdot}C_6H_5)(OC_2H_5)$ m.p. 50°, Heyden.

Hetocresol. *m*-Cresol cinnamate
m.p. 65° (D. R. P. 99567), Kalle.

Lygosins. Sodium and quinine salts of dioxydibenzalacetone
$CO:(CH:CH{\cdot}C_6H_4{\cdot}ONa)_2+7H_2O$
(D. R. P. 110521), Zimmer.

Nizin. Zinc sulphanilate, Burroughs.

Nosophen. Tetra-iodo-phenolphthalein
(D. R. P. 143596), Rhenania.

Paralysol. Solid cresol combination
$C_6H_4(CH_3)OK{\cdot}3C_6H_4(CH_3){\cdot}OH$ m.p. 146°.

Of value in granulative processes is amino-azo-toluene rendered not toxic by acetylation of its amino group, and called *azovernin*, m.p. 185° (A. G. f. A.). *Pellidol*, colourless diacetyl amino-azo-toluene (A. G. f. A.) is an improvement on Scarlet R (amino-azo-toluene coupled with *β*-naphthol).

Antiseptics, internal. This class is chiefly employed in diseases of the air passages. Apart from their antiseptic properties, the phenols possess more or less of an analgesic and local anæsthetic effect which, however, cannot be utilised unless substitution be resorted to in order to eliminate the caustic effect of the hydroxyl already referred to. Guaiacol
$(C_6H_4(OH)OCH_3(1:2)$
possesses in general an action similar to phenol and pyrocatechol, but is less toxic and caustic and has greater antipyretic effect. Because of its disagreeable taste and more irritant action upon the stomach compared with guaiacol, creosote has been largely replaced by the former. Guaiacol and its preparations excite the nervous centres, stimulating thereby the assimilative processes, also the activity of the leucocytes, elimination of the bronchial secretions and kidneys. The undesirable caustic and secondary effects of guaiacol and creosote formerly militated against their more general use until the influence of substituting groups was better understood. As has been pointed out, the toxicity of the dihydroxybenzenes depend on the presence of the free OH groups, reaching a maximum convulsive effect in pyrocatechol. If both hydroxyls are methylated, the product (veratrole) becomes three times less toxic than guaiacol, with, however, a disappearance of medicinal action. One hydroxyl must remain free or loosely covered if we desire to retain the specific properties of guaiacol. One method of accomplishing this is shown in the carbonic acid esters as duotal or creosotal, which are tasteless and non-irritant. The easily hydrolisable organic acid esters as benzosol, styracol, &c., are perhaps more readily absorbed in the intestinal canal. Another class of derivatives with a free hydroxyl group in which the nucleus is substituted are the ortho-guaiacol sulphonic acid (thiocol), the para derivative (monotal) possesses an undesirable action on the stomach. Condensation-products with formaldehyde in which two guaiacol radicles are linked by means of a methylene group (pneumin, euguform, pulmoform) liberate formaldehyde in minute traces. These products are quite insoluble, breaking up very slowly. Substitution in the nucleus, while yielding more soluble compounds, diminishes medicinal activity.

Aethacol (thanatol). Pyrocatechin monomethyl ether b.p. 210°, Kalle.

Benzosol. Guaiacol benzoate
$C_6H_5{\cdot}COO{\cdot}C_6H_4{\cdot}OCH_3$
m.p. 60° (U. S. Pat. 453035), Hoechst.

Cacodyliacol. Guaiacol cacodylate
$C_6H_4(OCH_3){\cdot}As(CH_3)_2O_2$ Merck.

Creosotal. Creosote carbonate (U. S. Pat. Exp. 501235), Bayer, Heyden.

Eucol. Guaiacol acetate
$C_6H_4(OCH_3)O{\cdot}COCH_3$
b.p. 235°–240°, C. Erba, Milan.

Euguform. Acetylated condensation product of guaiacol and formaldehyde, Hillringhaus.

Eosote. Creosote valerate, b.p. 81°–85° (3 mm.), Lehmann.

Duotal. Guaiacol carbonate (U. S. Pat. 466913), Bayer.

Geosote. Guaiacol valerate
$C_6H_4(OCH_3)O{\cdot}CO{\cdot}C_4H_9$ b.p. 260°, Lehmann.

Guaiacetin. Pyrocatechin sodium acetate
$C_6H_4(OH)OCH_2{\cdot}COONa$
m.p. 130°, Van Gember.

Guacamphol. Guaiacol camphoric ester
$C_8H_{14}(COO{\cdot}C_6H_4{\cdot}OCH_3)_2$
m.p. 126°, Henning.

Guaiachinol. Quinine dibromoguaiacolate
$C_6H_2Br_2(OCH_3)OH{\cdot}Q$

Guaiaperol. Guaiacol-piperidine
$C_5H_{11}NH{\cdot}C_6H_4(OH)OCH_3$ m.p. 80°.

Guaiacyl. Calcium orthoguaiacol sulphonate (local anæsthetic)
$(C_6H_3(OH)(OCH_3)SO_3)_2Ca$

Guaiaform, Geoform. Condensation product of guaiacol and formaldehyde, Henning.

Guaiamar. Glycerol guaiacolate
$C_6H_4(OCH_3){\cdot}O(CH_2OH{\cdot}CHOH{\cdot}CH_2)1:2$
m.p. 75° (U. S. Pat. 599125), Mkd't.

Guaiasanol. Diethyl glycocoll guaiacol HCl.
$C_6H_4(OCH_3){\cdot}O{\cdot}CO{\cdot}CH_2{\cdot}N(C_2H_5)_2{\cdot}HCl$
m.p. 183° (U. S. Pat. 624772), Hoechst.

Guatannin. Guaiacol-tanno-cinnamate (D. R. P. 133299), Berlin Lab.

Kreosal. Creosote tannate.

Monotal. Guaiacol methyl glycolate $CH_2(O{\cdot}CH_3)COO(C_6H_4{\cdot}OCH_3)$ b.p. 156° (15 mm.) (U. S. Pat. 822339), Bayer.

Pneumin. Methylene creosote (cond.-prod. formaldehyde and creosote), Speier.

Phosote. Creosote phosphate, b.p. 190°–203°.

Pulmoform. Methylene guaiacol. *See Pneumin.* Speier.

Salocreol. Creosote salicylate, Heyden.

Styracol. Guaiacol cinnamate, m.p. 130° (D. R. P. 62176), Knoll.

Tanno-cresoform and guaiaform. Comp. of creosote or guaiacol with tannin by aid of formaldehyde.

Taphosote. Tannophosphate of creosote, Lambiotte Fr., Paris.

Thiocol. Guaiacol sulphonate of potassium $C_6H_3(OH)(OCH_3)(SO_3K)$, 1 : 2 : 6 (U. S. Pat. 650218), La Roche.

Intestinal antiseptics. These compounds are intended to break up only under the influence of the alkaline intestinal secretions. Intestinal asepsis is unattainable, nevertheless numerous combinations serve valuable purposes in securing partial disinfection, inhibiting the development of milder types of bacteria, neutralising the action of toxins and arresting disturbing fermentative action in the canal. The many organic bismuth compounds serve in this capacity (as marcasol, thioform, iodylin, &c.), also various phenol esters of salicylic acid as salol, also guaiacol esters, naphthyl esters (alphol and betol).

Alphol. α-Naphthyl salicylate, m.p. 83°.

Benzonaphthol. β-naphthyl benzoate, m.p. 110°, Hoechst.

Betol. β-Naphthyl salicylate, m.p. 95°.

Chinaphthol. β-Naphthyl monosulphonate of quinine, m.p. 185°, Merck.

Enterol. Tricresol (pure cresol), Schering.

Eugenoform. Eugenolcarbinolsodium, m.p. 160°.

Isoform. *p*-Iodoxyanisole $C_6H_4{\cdot}OCH_3{\cdot}IO_2$ (D. R. P. 161725), Hoechst.

Kresalol. *m*-Cresol salicylate $CH_3{\cdot}C_6H_4{\cdot}O{\cdot}OC{\cdot}C_6H_4{\cdot}OH$ m.p. 74°.

Salacetol. Acetol-salicylic acid $C_6H_4(OH)COO{\cdot}CH_2{\cdot}CO{\cdot}CH_3$ m.p. 71°, Schoetensack.

Salithymol. Salicylic thymyl ester $CH_3{\cdot}C_6H_3(C_3H_7)O{\cdot}COC_6H_4(OH)$

Lactol. β-Naphthyl lactate $CH_3{\cdot}CH(OH)COO{\cdot}C_{10}H_7$

Intestinal astringents. These consist chiefly of condensation-products or similar compounds of tannin with formaldehyde or hexamethylene tetramine. In order to secure their astringent and other medicinal effects upon the intestinal mucus surface for relieving inflammatory conditions and retarding bacterial action, such combinations are intended to pass through the stomach unchanged and break up into their constituent parts under the influence of the alkaline secretions. They are chiefly employed in catarrhal and inflammatory conditions as dysentery, tubercular diarrhœa, cholera, &c.

Gallogen. Egallic acid (D. R. P. 137033–4), Heinemann.

Honthin. Keratinised tannin albuminate, Hell Co.

Rexotan. Methylene tannin urea, Voswinkel.

Tanargan. Tannin silver albuminate, Weil.

Tannalbin. Tannin albuminate (U. S. Pat. 563479), Knoll.

Tannigen. Diacetyl tannin (U. S. Pat. 533718), Bayer.

Tannisol. Methylene ditannin, Wôlfrum.

Tannocasum. Casein tannate.

Tannoform. Methylene ditannin, m.p. 230° $CH_2(C_{14}H_9O_9)_2$ (D. R. P. 88841), Merck.

Tannopin (tannon). Hexamethylenetetramine tannin $(CH_2)_6N_4(C_{14}H_{10}O_9)_3$ (U. S. Pat. 607172), Bayer.

Tannothymal. Condensation product of formaldehyde, thymol and tannin (D. R. P. 188318), Schimmel Co.

Tannyl. Tannin oxychlor casein, Gehe Co.

Tanocol. Tannin gelatin comp., A. G. f. A.

URINARY DISINFECTANTS.

The representative of this class, urotropin (hexamethylenetetramine), of which there are a number of combinations, breaks up in the system with liberation of nascent formaldehyde, which serves to prevent the development of the more sensitive micro-organisms as staphylococci, coli and typhus bacilli, &c. This class is usually employed in infections of the urinary passages; they also serve as prophylactics against infection in operations involving the bladder.

Amphotropin. Hexamethylenetetramine camphorate $C_8H_{14}{\cdot}(COOH)_2[(CH_2)_6N_4]_2$ Hoechst.

Atophan. Phenyl-quinoline-carbonic acid $C_9H_5N(C_6H_5)COOH$ (2 : 4) m.p. 208°–209°, Schering.

Borovertin. Hexamethylene tetramine triborate $(CH_2)_6N_4{\cdot}3HBO_2$ (D. R. P. 188815), A. G. f. A.

Cystopurin. Double salt of one mol. urotropin and two of sodium acetate, Wuelfing.

Diaphthol (chinaseptol). *o*-Hydroxyquinoline-*m*-sulphonic acid $C_9H_5N(OH)SO_3H$ m.p. 295°.

Galloformin. Comp. of urotropin and gallic acid $C_6H_2(OH)_3{\cdot}COOH[(CH_2)_6N_4]$ Henning.

Helmitol (urapurgol). Anhydro-methylene citrate of urotropin $C_7H_8O_7[(CH_2)_6N_4]$ (U. S. Pat. 722275) m.p. 165°–175°, Bayer.

Hetralin. Resorcinol urotropin $C_6H_6O_2[(CH_2)_6N_4]$

Hexal. Hexamethylenetetramine salicylsulphonic acid $[(CH_2)_6N_4]C_6H_3(OH)(COOH)HSO_3$ Riedel.

Saliformin. Urotropin salicylate Merck.

Urotropin. Hexamethylenetetramine $(CH_2)_2N_4$ m.p. 165°–175°, Schering.

This compound is supplied by other firms under such titles as formin, aminoform, cystamin, cystogen, uritone, &c.

DIATHETICS.

These remedies are employed more especially in uric acid diathesis and also exert an action similar to the previous class. The chief objects sought are either to diminish the production of uric acid or through profuse diuresis, secure thorough flushing, and the elimination of the urates; or by the aid of organic bases bring about solution of the acid urates. The theory of the solubility of the urates in alkaline solutions is based on the experience gained through the use of the salts of the vegetable acids, more especially citric acid, which also possesses a diuretic action. These acids diminish, in addition, the quantity of uric acid secreted. Experimentally, it has been shown that while the acid sodium urate is soluble 1 in 1150 of water, the piperazine salt is soluble 1 in 50 and the lysidin salt 1 in 6. While doubts have been expressed as to the accuracy of some of these theories, the clinical experiments have been generally successful.

Acitrin. 2-Phenylquinoline-4-carboxylic ethyl ester $C_9NH_5(C_6H_5)COOC_2H_5$ m.p. 61°, Bayer.

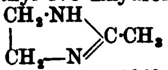
Chinotropin. Urotropin quinate, Schering.

Citarin. Sodium anhydro-methylene citrate $(CH_2COONa)_2:C:(O{\cdot}CH_2{\cdot}O{\cdot}CO)$ (D. R. PP. 129255, 150949), Bayer.

Formurol. Hexamethylenetetramine sodium citrate $C_6H_7O_7Na,C_7H_{12}N_4$, Falkenberg.

Lycetol. Dimethyl piperazine tartrate, m.p. 250° (U. S. Pat. 523018), Bayer.

Lysidin. 2-methyl-4:5-dihydroiminazole



m.p. 106°–105°, Hoechst.

New Sidonal. A mixture of quinic anhydride and quinic acid. Charlottenburg.

New Urotropin. *See Hedonal.* Schering.

Piperazine. Diethylene diamine $NH[CH_2{-}CH_2]_2NH+6H_2O$ m.p. 104° (U. S. Pat. 543214), Bayer, Schering.

Sidonal. Piperazine quinate, m.p. 168°–171° (Eng. Pat. 11420), Charlottenburg.

Solurol. Nucleotin phosphoric acid, Elb.

Urol. Urea quinate, m.p. 106° (D. R. P. 124426), Schulz.

Ursal. Urea salicylate. Erdmann.

The purine derivatives (diuretics). Qualitatively, the diuretic action of the methylated purine derivatives correspond to their influence upon the muscular system, while the reverse is noted in their exciting action on the central nervous system. That is, the stronger the effect of a purine derivative upon the muscular system, the more marked is its diuretic action and the less its influence upon the nervous system. The effect of theobromine on the nervous system is far weaker than that of caffeine, while its diuretic action is equally strong. The relative diuretic action of this class of derivatives depends upon the positions methylated, thus the positions 1 : 3 (theophyllin) and 1 : 7 (paraxanthine) are of greater pharmacological importance than 3 : 7 (theobromine). Trimethylxanthine (caffeine), while possessing a slight diuretic action, exerts a too powerful influence upon the brain for diuretic purposes (Archiv. Exp. Path. u. Phamakologie, 1900, 319.)

The introduction of ethyl groups in place of methyl, produces no material change in action. The objectionable slow action of the methylated xanthines, due to their insolubility, is relieved by combination with organic salts of the alkalis (sodium salicylate, benzoate, acetate) in the form of double salts.

Caffeine derivatives. *Symphorol.* Various alkali salts of caffeine sulphonic acid. With the introduction of sulphonic acid, caffeine loses its effect on the vasomotoric centre, while its diuretic action is retained.

Hetol: Caffeine sodium cinnamate (Kalle).

Dimethyl Xanthines. Theobromine (santheose), 3 : 7 dimethylxanthine.

Agurin.	Theobromine	sodium-sodium acetate. Bayer.
Barutin	,,	barium-sodium salicylate, A. G. f. A.
Diuretin	,,	sodium salicylate, Knoll.
Theobromose	,,	lithium.
Theophorin	,,	sodium-sodium formate, La Roche.
Theolactin	,,	,, ,, lactate, Zimmer.
Urocitral	,,	,, ,, citrate, Rump.
Uropherin	,,	lithium benzoate salicylate, Merck.

Theophyllin (theocin) synethetic 1 : 3-dimethylxanthine, m.p. 268° (D. R. P. 138444), Bayer, Boehringer.

Theocin sodium acetate $C_7H_7N_4O_2Na{\cdot}CH_3COONa+H_2O$ Bayer.

Euphyllin. Theocin ethylene diamine, Byk.

YEAST PREPARATIONS.

These were first introduced into medicine by T. Landau (Deuts. med. Wochschr. 1899, No. 11), and were recommended in treatment of chronic leucorrhœa and especially gonorrhœal affections. Internally, yeast is employed in eczema, anthrax, carbuncles, skin diseases of gastric origin, diabetes and infectious diseases (scarlet fever, erysipelas, measles, &c.). The yeast cells retain their activities in the digestive tract and serve to retard or destroy the toxicity of various pathogenic bacteria.

Cerolin. A solid extract of yeast, containing fat, Boehringer.

Furonculine.	A dry extract of yeast,	La Zyma.
Levuretin.	Dried yeast cells,	Feigel.
Levurinose	,,	Blaes.
Trygase	,,	Riedel.
Zymin	,,	Schroder.
Cerevisine	,,	Grimault, Paris.

ANÆSTHETICS.

We distinguish between products that produce (1) total anæsthesia and (2) local anæsthesia.

Total anæsthetics (by inhalation). This class belongs exclusively to the aliphatic series and depends largely, for its action, upon the presence of chlorine, intensity in action increasing with the number of chlorine atoms introduced; thus CH_3Cl is feebly narcotic, while CCl_4 paralyses the heart. The corresponding bromine derivatives also possess a narcotic effect, but because of their intense action only the ethyl bromide and bromoform are employed, and these internally. Such members of the alkyl halides as have a very low boiling-point, are employed as local anæsthetics by freezing. No improvement over chloroform or ether has appeared, although some of this group serve in certain specific cases (*see* introduction *Hydrocarbons*). More prominent are:

Ethyl chloride C_2H_5Cl, b.p. −29°. Used as inhalant and also as a local anæsthetic.

Ethyl iodide C_2H_5I, b.p. 70°–75°. Inhaled for asthma.

Ethyl bromide C_2H_5Br, b.p. 38°–40°. Total anæsthetic, rapid and short duration.

Ethylene chloride $C_2H_4Cl_2$, b.p. 83°. Inhalant and local anæsthetic.

Ethylene bromide $C_2H_4Br_2$, b.p. 130°. Internally in epilepsy.

Ethylidene chloride $CH_3{\cdot}CHCl_2$, b.p. 58°–60°. Anæsthetic.

Methyl chloride CH_3Cl, b.p. −22°. Local anæsthetic.

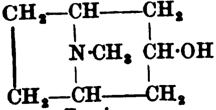
Methylene chloride CH_2Cl_2, b.p. 42°. Inhalant and local anæsthetic.

Somnoform. A mixture of ethyl chloride 60 parts, methyl chloride 35 parts, and ethyl bromide 5 parts. Anæsthetic.

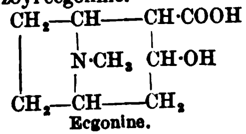
Pental, tri-methyl-ethylene $(CH_3)_2C{\cdot}CH{\cdot}CH_3$, b.p. 38°. Dental anæsthetic.

Local anæsthetics. Cocaine, introduced as local anæsthetic in 1885 by Koller, still retains its popularity because of its intensity and depth of action. Objectionable features are its irritant effects and dilation of the pupil in eye practice, hydrolysis through sterilisation, and excitation and paralysis of the central nervous system. Attempts have been made to find a substance possessing the virtues of cocaine but free as possible from untoward secondary effects. Partial success has been attained, all the compounds are designated stable to sterilisation, and in general, each is specially adopted for certain lines of local anæsthesia.

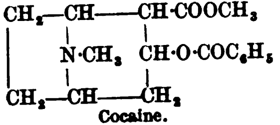
Modern developments in local anæsthetics are due to studies on the constitution [1] of cocaine, which may be concisely stated as follows: Cocaine is a heterocyclic body with a reduced pyridine ring; this nucleus is called ecgonine, and is the carboxyl derivative of tropine (the base of atropine). Important for the development of local anæsthetic action are the carboxyl group, present as methyl ester and a hydroxyl group, the hydrogen of which is replaced by a benzoyl group. Cocaine is then the methyl ester of benzoyl ecgonine.



Tropine.



Ecgonine.



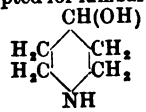
Cocaine.

The nuclei tropine and ecgonine are practically devoid of anæsthetic effect. This action also disappears with the removal of either the benzoyl or methyl group from cocaine. The replacement of methyl by other alkyls yields homologues which differ but slightly quantitatively. If other aromatic acid radicles replace the benzoyl group, anæsthetic action is materially lessened or disappears.

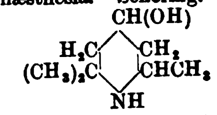
The general conclusions drawn from this are:—that the action of cocaine is dependent upon the presence of a nitrogenated nucleus, an esterified alkyl (COOR), and a benzoyl group; [2] consequently attempts to locate an 'anæsthiophore' nucleus have been without success. [3]

On these assumptions the search for ideal local anæsthetics has progressed in two directions; namely derivatives containing a cyclic nitrogen and the amino and oxyamino benzoic alkyl esters. Closely related to the ecgonine nucleus and containing the piperidine ring of cocaine are the acetonamine derivatives, most important among which is:

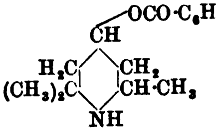
Beta eucaine, used chiefly in the form of lactate (m.p. 152°) or hydrochloride (m.p. 268°) in 2 to 3 p.c. solutions (D. R. P. 97672). Not adapted for lumbar anæsthesia. Schering.



γ-Hydroxypiperidine.

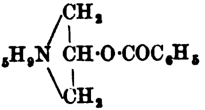


Vinyl diacetone alkamine.



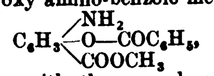
Eucaine B, benzoyl-vinyl-diacetone-alkamine.

Tropa cocaine. The hydrochloride of benzoyl derivative of pseudo-tropine, a *cis*-isomeride of tropine, found in the Japanese coca leaf also prepared synthetically. [1] Used like cocaine and is only ½ to ¼ as toxic; m.p. 271° (U. S. Pat. 628293), E. Merck.



Attempts involving the utilisation of the pyrrol ring of the ecgonine molecule were next made, but these were soon confined to benzene derivatives, since a number of well-known bodies, as creosote, eugenol, &c., belonging to this nucleus, possessed local anæsthetic properties.

Selecting a compound of a constitution analogous to that of cocaine, containing nitrogen, a benzoyl and an esterified alkyl group, namely benzoyl-hydroxy amino-benzoic methyl ester



$$C_6H_3\begin{cases}NH_2\\ O{-}COC_6H_5,\\ COOCH_3\end{cases}$$

in accordance with theory, a local anæsthetic was produced. Subsequent experiments demonstrated that the benzoyl group was superfluous, since a benzene ring was already present, also the benzoyl free compound possessed a more marked anæsthetic action. The phenol hydroxyl was found not to be absolutely essential, although its presence bestowed antiseptic properties.

These experiments, made in 1897 by Einhorn and Heinz, [2] demonstrated that the *esters of aromatic, amino and hydroxyamino acids* possessed, in general, local anæsthetic properties.

The first of this group to be introduced was:

Orthoform, methyl *p*-amino-*m*-hydroxybenzoate, m.p. 120°–121°. A cheaper isomeride followed in—

Orthoform, new methyl *m*-amino-*p*-hydroxybenzoate, $C_6H_3(COOCH_3)(NH_2)(OH)1:2:4$,

[2] Virchow's Archiv. 1896, 145, 78; 1897, 149, 217 1898, 154, 547

m.p. 142°. Because of their insolubility, these are used dry. The acid soluble salts are irritating and frequently produce necrosis. (U. S. Pats. 610348, 625158.) Hoechst.

Simple alterations in the above formulæ produced—

Anæsthesin, *p*-amino-benzoic-ethyl ester

$C_6H_4(NH_2)(COOC_2H_5)1:4$,

m.p. 90°–91° (D. R. P. 19416 K.). Used locally, especially internally in hyperæsthesia of stomach, gastralgia, excessive vomiting, &c. No secondary effects as yet observed. The hydrochloride of anæsthesin is used hypodermically in 1 to 4 p.c. solutions. Hoechst.

Cycloform, *p*-amino-benzoic-*iso*-butyl ester

$C_6H_4(NH_2)COOC_4H_7$

m.p. 65°. (U. S. Pat. 958110.) Bayer.

Propæsin, *p*-amino-benzoic propyl ester

$C_6H_4(NH_2)(COOC_3H_7)1:4$,

m.p. 73°. Like anæsthesin, it is non-irritant and non-toxic for internal and local uses. (U. S. Pat. 950926.) Fritzsche.

Subcutin (soluble anæsthesin) anæsthesin phenolsulphonate

$C_6H_4(COOC_2H_5)(NH_2{\cdot}SO_3H{\cdot}C_6H_4OH)1:4$

m.p. 195·6°. Ritsert.

In the endeavour to produce a substance related to orthoform, soluble in water with neutral reaction and adapted for subcutaneous use, the following resulted:—

Nirvanin, diethyl-glycocoll-*p*-amino-salicylic methyl ester

$C_6H_3(NHCOCH_2{\cdot}N(C_2H_5)_2)(OH)(COOCH_3)$

m.p. 185°. Used chiefly in dental and eye practice; less toxic but less penetrating than cocaine. Hoechst.

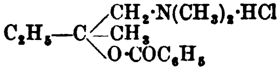
Novocaine, *α*-*p*-aminobenzoyl-*β*-diethylamino-ethane (U. S. Pat. 812554)

$C_6H_4(NH_2)COO{\cdot}CH_2{\cdot}CH_2N(C_2H_5)_2{\cdot}HCl$,

m.p. 156°. This is a diethylamino derivative of anæsthesin, m.p. 155°. Used in conjunction with adrenaline, toxic effects only noticed in lumbar anæsthesia. Claimed to be ⅙ as toxic as cocaine. Hoechst.

In some of the more recent introductions, the amino group has been transferred to the side chain, yielding compounds which represent substituted tertiary alcohols. The dimethylamino groups have a very important bearing on the physiological action of these compounds.

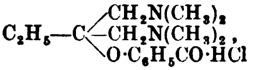
Stovaine, *β*-benzoxy-*β*-methyl-*α*-dimethylaminobutane hydrochloride



$$C_2H_5{-}C\left\langle\begin{array}{l}CH_2{\cdot}N(CH_3)_2{\cdot}HCl\\CH_3\\O{\cdot}COC_6H_5\end{array}\right.$$

m.p. 175°: should not be sterilised above 115°. About ⅓ as toxic as cocaine, used in ½ to 1 p.c. solutions as general all-round local anæsthetic, but especially in spinal anæsthesia. (U. S. Pat. 829374.) Poulenc Frères & Co..

Alypin, hydrochloride of benzoyl *αβ*-tetramethyldiamino-*β*-ethyl-*iso*propyl alcohol



$$C_2H_5{-}C\left\langle\begin{array}{l}CH_2N(CH_3)_2\\CH_2N(CH_3)_2,\\O{\cdot}C_6H_5CO{\cdot}HCl\end{array}\right.$$

m.p. 169°; sterilisable. Used in spinal anæsthesia, also as a non-toxic general local anæsthetic like cocaine. Does not produce mydriasis. (U. S. Pat. 808748.) Bayer.

A slight local anæsthesia was noticed while experimenting with the aniline antipyretics, formanilide being stronger than acetanilide. By the addition of a second basic group to phenetidin derivatives, marked anæsthetic action is developed. To this class belong:

Holocaine, *p*-diethoxy-diphenyl-ethenyl-amidine

$CH_3{\cdot}C:(N{\cdot}C_6H_4OC_2H_5)(NH{\cdot}C_6H_4OC_2H_5){\cdot}HCl$,

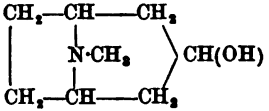
m.p. 189°. Used only in eye practice. Too toxic for subcutaneous use (D. R. P. 80568). Hoechst.

Acoin, di-para-anisyl-monophenetyl-guanidine $C:(N{\cdot}C_6H_4{\cdot}OC_2H_5)(NH{\cdot}C_6H_4{\cdot}OCH_3)_2HCl$, m.p. 176°. Used in eye practice and dentistry. Strong solutions cause irritation. No toxic effects from weaker solutions: less toxic than cocaine. V. Heyden.

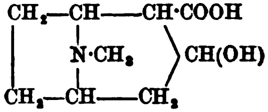
Chloretone, acetone chloroform, trichlorbutyl alcohol $CCl_3(CH_3)_2C{\cdot}OH+\frac{1}{2}H_2O$, m.p. 96°–97°. The 1 p.c. aqueous solution sold under name of anesin (aneson). Employed as local anæsthetic in conjunction with cocaine and adrenaline. Parke Davis.

Adrenaline, anterenol and homorenon, *see* under *Organo-therapeutic agents*.

Mydriatics. Closely related chemically and in some respects pharmacologically are atropine and cocaine. They are derived from a condensation-product of a pyrrolidine and piperidine rings in which the nitrogen and its two neighbouring carbons are common to both. Atropine is a derivative of tropine, an alcohol of such a bi-cyclic nucleus with a methylated nitrogen (I.). Cocaine, a derivative of ecgonine, is an ortho carboxylate of tropine (II.).



I.

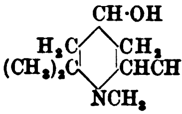


II.

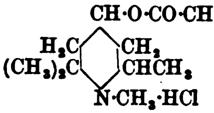
In both, the hydroxyl group is esterified by an aromatic acid, tropic acid

$(C_6H_5{\cdot}CH(CH_2OH)COOH)$

serving in atropine and benzoic acid in cocaine, in addition to the methyl group attached to the carboxyl. Both atropine and cocaine influence alike the central nervous system, first as excitants, then paralysing; they also exert a paralysing influence on the peripheral terminals of certain nerves, whilst cocaine exerts this effect particularly on the sensory nerve terminals, the action of atropine is manifold in other directions. Mydriatically, both alkaloids are alike; cocaine, while producing a less marked dilation of the pupil, has a more prolonged effect. The basic nuclei of these alkaloids occasion a paralysing effect upon peripheral nerve terminals, reaching full development only through substitution. Tropine is not mydriatic, while its action on the heart is influenced by esterification by means of aromatic acids; this latter effect diminishes and that on the nerve terminals is developed, according to the nature of the acid radicle introduced. The tropines of benzoic, cinnamic and salicylic acids possess varying anæsthetic action with but little or no mydriasis. If the esterifying aromatic acid contains an hydroxyl in the side chain, the characteristic mydriatic effect is developed as seen in mandelate of tropine (homatropine). The introduction of other negative radicles in the alcoholic hydroxyl group of the tropic acid radicle does not seem to produce any effect on its activity. By addition of halogenated alkyls, atropine becomes a salt of the quarternary bases, namely alkyl atropinimines, which possess a more evanescent mydriatic and lesser toxic action, such as eumydrin. Of interest in this same series is the use of the unsymmetrical cyclic bases of the acetone alkamine series, for example, in the labile forms of the unsymmetrical (*n*) alkylated bases of the tri-acetone-alkamines, the hydrogen of the hydroxyl, when replaced by the benzoic, mandelic, tropic or phenyl acetic acid radicles, yields mydriatic bodies. If a mandelic acid radicle is introduced in methyl-vinyl-diacetone-alkamine (I.), the mydriatic euphthalmine (II.) results. It is a hydrochloride of (*n*)methyl vinyl-diacetone-alkamine-phenyl-glycol or the hydrochloride of the mandelic acid derivative of eucaine 'B.'



I.



II.

Of simpler constitution and belonging to the pyrrolidine derivatives is the mydriatic mydrol.

Eumydrin. Methylatropine nitrate
$C_6H_5(HO{\cdot}CH_2)CH{\cdot}CO_2{\cdot}C_7H_{11}N(CH_3)_2NO_3$
m.p. 163° (D. R. P. 137662, 138443), Bayer.

Euphthalmine. 1 : 2 : 6 : 6-tetramethyl-4-mandeloxy-piperidine-hydrochloride
(U. S. Pat. 663754), Schering.

Mydrol. Iodomethyl phenyl pyrazolone, m.p. 178°, Merck.

ORGANIC ARSENICALS AND CHEMOTHERAPEUTICS (PARASITOTROPICS).[1]

Whilst many microbial infectious diseases are amenable to serum treatment, there are a number, especially those of protozoal origin, which can only be treated by means of chemical specifics. These react with such micro-organisms in a manner somewhat analogous to that of sera. Study in this direction has been greatly stimulated by the discovery of the protozoal parasites (trypanosoma) of the African sleeping sickness. Through the investigations of Ehrlich and others, considerable attention has been directed to the chemo-therapeutics of spirochetal diseases (syphilitic, intermittent), and those of a malignant parasitic origin, namely the protozoal parasites of the trypanosoma, of which there are several varieties. Parasito-chemicals tend to destroy parasites in the living organism without injury to the tissues or organs, contrary to the organotropic. Ehrlich states that all parasitotropic bodies are also poisonous to the living organism (organotropic), hence such as are curative must contain organo and parasitotropic properties in proper proportions. Such coal-tar colours as are of value in trypanosomiasis may be divided into (*a*) certain azo-dyes, (*b*) certain basic triphenyl methane dyes as *p*-fuchsine, methyl violet, pyronine, &c. To these may be added the organic arsenicals. Ehrlich found that methylene blue was more strongly 'organotropic' than 'parasitotropic,' a dilution of 1 in six million caused cessation of movement *in vitro* when tested on the spirilla of relapsing fever, but with animal experiments it required 500 times as much of the dye. He then tried trypan red (diamino-naphthalene disulphonic acid 2,7,3,6), which was found to possess curative effects in trypanosoma of a certain type (*mal de caderas*); frequently, however, the disease reappeared after intervals. This same effect was peculiar to the azo- colours of the benzidine type. After testing a large number of colours, Ehrlich established the fact that effective bodies must be the tetrazo colours derived from naphthalene disulphonic acids with the sulphonic groups in positions 3 and 6. They must be naphthalene derivatives containing at least one amino and two sulphonic groups. Among the diamines, the di-chlor products were the best, especially those in which the benzene groups are connected by a divalent group (=NH, =CO). The symmetrical colours were found to be less injurious to animals. Malachite and brilliant greens with their di- and tri-hydroxy-derivatives as well as *o*-hydroxyhexamethyl rosaniline exerted curative effects. According to Ehrlich, the toxicity of malachite green is due to its four methyl groups and that of brilliant green to its four ethyl, which is overcome through the introduction of a faintly acid hydroxyl group. He therefore prepared di- and tri-hydroxy- malachite greens which, when combined with trypan red, showed excellent curative effects in nagana infection. Of all the rosaniline derivatives, pararosaniline gave the best results. Most effective was the simultaneous treatment with atoxyl and trypan red or blue or fuchsine.

In conjunction with his study of the colours in treating trypanosoma infection, Ehrlich took up the organic arsenicals in combating spirochetal diseases, more especially syphilis. After the elucidation of the constitution of atoxyl, a great variety of other arsenical organic derivatives were synthesised and studied pharmacologically, finally resulting in the discovery of the Ehrlich-Hata '606.' The arsenical preparations have always been employed in diseases arising from disturbances of the nutrition or of malarial origin, and through recent researches in syphilis, diseases of syphilitic and protozoal origin. Some years ago it was discovered that cacodylic acid and its salts, because of their stability, suffered but little change in the organism, 1 grm. of the sodium salt (containing ½ as much As_2O_3 as arsenic acid) could be taken without harm. Inorganic arsenic compounds are very slowly eliminated, remaining stored in the system producing at times cumulative effects. Since the organic arsenicals are more readily eliminated, their structure should be such as to render them slowly soluble, securing thereby a slow protracted action. The aim in

---

[1] Chemotherapie der Spirillosen-Ehrlich. Ber. 42, 17.

the study of the organic derivatives of arsenic acid has been to find products free from cumulative and secondary effects and adapted for hypodermic and intravenous use, avoiding thereby any derangement of the digestive tract. The newer and more successful products of this class are substituted arsenic acid derivatives of para-aminophenol, securing thereby a stable ring system from which the arsenic is liberated very slowly, producing a more continuous, less toxic and irritating action. Atoxyl, one of the first of this class to be introduced, was found to be more satisfactory than inorganic arsenic. While a greater percentage passed unchanged through the body, yet sufficient underwent some alteration in the system with the production of new synthetic types which were active in the destruction of these parasites. Ehrlich considers that in therapeutic action, benzene derivatives contain two different pharmaco-dynamic radicles, of which one acts as salt forming (—OH,—NH_2) and an increased action must result when a third group is introduced in the ortho- position to the salt forming radicle. Pentavalent arsenic compounds are secondary in spirilloidal power, and large doses are necessary with but little danger of optical atrophy. Many organic compounds of arsenic have been synthesised and tried clinically[1]: more successful commercially are arsacetin, arsylin, atoxyl, and arrhénal. Atoxyl gained a considerable reputation as a remedy in syphilis and sleeping-sickness (trypanosomiasis), but its use was attended frequently by degeneration of the optic nerve, leading to blindness, hence the attempt at acetylation (arsacetin), such as was done with aniline in converting into acetanilide.

As already stated, Ehrlich's experiments with atoxyl in treating trypanosoma infection culminated in his discovery of salvarsan which is likewise of value in malaria, leprosy, framboesia, as well as being a specific in syphilitic affections. The alkalinity of salvarsan corresponds to that of the blood, and its relative low toxicity in comparison with other arsenicals is due to its insolubility in the blood. Owing to the frequent occurrence of thrombosis arising from faulty neutralisation of salvarsan a soluble derivative has been prepared by precipitating a salt of 3:3′-diamino-4:4′-dihydroxyarsenobenzene with sodium methanal-sulphoxylate and dissolving the precipitate in alkali. This is called *neosalvarsan*. (Sodium 3:3′-diamino-4:4′-dihydroxyarsenobenzene-methanal-sulphoxylate

$NH_2\cdot C_6H_3(OH)As_2\cdot C_6H_3(OH)NH(CH_2O)SONa)$

D. R. P. 245756. Hoechst.

The relationship of the simpler derivatives of arsenic acid will be noted from the formulæ:

$AsO(OH)_3$	$AsO(OH)_2CH_3$	$AsO(OH)(CH_3)_2$
Arsenic acid	Methyl arsenic acid	Dimethyl arsenic . acid

$AsO(CH_3)_3$
Trimethyl arsenic acid

$AsO(OH)_2C_6H_4NH_2$	$C_6H_4NH_2\cdot AsO(OH)ONa$
Aniline arsinate	Aminophenyl arsinate of sodium (atoxyl)

Arrhénal. Methyl disodium arsenate
$AsO(CH_3)(ONa)_2,6H_2O$, m.p. 130°–140°, Merck.

Arsacetin. *p*-Acetylamino-phenyl-sodium arsenate $CH_3CO\cdot NH\cdot C_6H_4(AsO)OH\cdot ONa$
Hoechst.

Atoxyl. *p*-Aminophenyl arsenate of sodium
$NH_2\cdot C_6H_4\cdot AsO(OH)ONa\cdot 3H_2O$
Charlottenburg.

Asyphil, the mercury salt of atoxyl
Charlottenburg.

Cacodylic acid. Dimethyl arsenic acid, its salts with metals, guaiacol and alkaloids.

Soamin. Sodium arsanilate
$C_6H_4(NH_2)AsO(OH)ONa+5H_2O$ Burroughs.

Salvarsan[1] ('606'). *p.p*-Dihydroxy-*m.m*-diaminoarsenobenzene
$HO(NH_2\cdot HCl)C_6H_3\cdot As:As\cdot C_6H_3(NH_2\cdot HCl)OH,2H_2O$

Owing to its insolubility, it is necessary to add a calculated quantity of caustic soda for the preparation of salvarsan.

(U. S. Pat. 986148; Eng. Pat. 13485), Hoechst.

SYNTHETIC CATHARTICS.

The close relationship existing between the phenols and the quinones (oxidation-products of phenols) is marked in their physiological properties, more especially in their stimulating to irritant action in the intestinal canal. This is also true of the naphthaquinones and anthraquinones. The hydroxyanthraquinones stimulate intestinal peristaltic action increasing in intensity with the number of hydroxyls present; thus trihydroxyanthraquinone (anthrapurpurin)

$(C_6H_4[CO]_2C_6H(OH)_3)$ [1:2:7]

produces severe colic through its action on the smooth muscular fibres. Best known in this respect are a number of *a*-hydroxy derivatives of methyl anthraquinone, present in the glucosidal form in such cathartic drugs as aloes, rhubarb, senna, cascara sagrada, frangula, &c. The synthetic polyhydroxyanthraquinones are more drastic cathartic than the natural emodin of rhubarb. This suggested closing of part of the hydroxyl hydrogens by acyl or alkyl radicles, which would serve to secure a slower decomposition in the intestinal canal. Too rapid absorption increases undesirable action on the kidneys. The closing of all hydroxyls in this manner gave inert products.

The first experiments in this direction were purgatol, a diacetylanthrapurpurin, and exodin, a mixture of the feebly active diacetyl tetramethyl ether of rufigallic acid (hexa hydroxyanthraquinone) with their acetyl pentamethyl ether. The cathartic action of phenol groups containing carbonyls, as noted among the anthraquinones, explains this action attributed to phenolphthalein, which, however, was discovered through accident. It may be added that phenolphthalein is to-day the most successful synthetic cathartic, because it is practically entirely eliminated unchanged from the system.

Exodin.[2] A mixture of 30 p.c. rufigallic hexamethyl ether, 23 p.c. diacetyl rufigallic tetramethyl ether, and 47 p.c. of acetyl rufigallic pentamethyl ether, m.p. 180°–190° (D. R. P. 151724), Schering.

Phenolphthalein. Sold under such titles as purgen, purgolade, purglets, laxan, laxol, &c.

ORGANO-THERAPEUTIC AGENTS.

Opo-therapeutics or animal remedials. One of the first to call attention to this class of remedial agents was Brown-Séquard, who advanced the hypothesis that 'all glands of the body, whether they have excretory canals or not, give to the blood useful principles, the absence of which is felt when these glands are extirpated or destroyed by disease.' This hypothesis was extended to include various other organs; and it was found that when one of these was in a diseased condition an extract prepared from the same organ of a healthy animal, serves as a remedial agent. For example, myxœdema, cretinism and Basedow's disease are traceable to a diseased condition of the thyroid gland which fails to perform its normal functions, hence the administration of extracts of this gland in treatment of these diseases. A tubercular affection of the supra-renal gland causes a malignant form of Addison's disease, now treated by suprarenal extracts. This same theory has been extended to include the thymus gland, the testicles, spleen, ovaries, spinal cord, brain, &c.

With few exceptions, the chemical nature of the organic principles which are present in these secretions is but little known, owing to minute quantities present and difficulties encountered in isolation. These remedials are sold in either powder or extract form. Owing to dangers arising from putrefactive changes, the organs are removed from freshly slaughtered animals (principally sheep, cattle and swine), thoroughly cleansed, and handled under aseptic conditions. They are either expressed, the juice being collected, mixed with lactose and dried at lowest possible temperature, or the entire organ is sliced and dried, or liquid extracts are prepared by digesting the sliced organ in a sterilised mixture of glycerol and water or salt solution or fatty oil. Since these secretions are of a basic character they readily form double or soluble compounds with sodium chloride. One part of Poehl's opotherapeutics represents 5 parts of the fresh organ. The other dry preparations are standardised in a like manner.

Suprarenal preparations.[1] Extracts or preparations from the suprarenal glands cause a contraction of the arteries with a corresponding increase of blood pressure. Locally, they produce ischæmia, through powerful contraction of the smaller blood vessels, and are chiefly employed in conjunction with local anæsthetics. The vaso constrictor action of these preparations is used to intensify and prolong the anæsthetic effect of local anæsthetics by retarding the circulation in affected parts and preventing the dilution of the local anæsthetic by too rapid absorption into the blood.

Adnephrin solution. A sterile 1 to 1000 solution of the suprarenal active principle in physiological salt solution containing 0·5 p.c. of chloretone. Stearns.

Adrenal-Poehl. A crystalline base from the suprarenal gland which is sold in 2 p.c. and 1 to 1000 solutions. Poehl.

Adrenaline (Takamine). Orthodihydroxyphenyl-ethanol methylamine hydrochloride: a lævorotary white crystalline base (m.p. 205°) obtained from the suprarenal glands.[1] Parke Davis.

Adrin (epinephrin hydrate). Solutions of active principle prepared according to method of V. Fuerth (Zeitsch. physiol. Chem. 26, 18). Mulford.

Arterenol $(OH)_2C_6H_3{\cdot}CH(OH)CH_2{\cdot}NH_2{\cdot}HCl$. The hydrochloride of *o*-dihydroxyphenyl-ethanolamine. A white crystalline powder, m.p. 141°; prepared synthetically. Hoechst.

Epinephrine $(OH)_2C_6H_3{\cdot}CH(OH)CH_2{\cdot}NH{\cdot}CH_3$ orthodihydroxy-4-methylaminoethanol benzene. Active crystalline principle first isolated by Abel from suprarenal glands.

Epirenan. Identical with adrenaline. Byk.

Hemisine. Identical with adrenaline. Burroughs.

Homorenon $(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2NH(C_2H_5){\cdot}HCl$. The hydrochloride of ethyl-amino-aceto-pyrocatechol. Colourless acicular crystal, m.p. 260°. Prepared synthetically: a 5 p.c. homorenon solution is equivalent to a 1 to 1000 adrenalin or suprarenin. Hoechst.

Suprarenalin. Identical with epinephrine. Armour, Chicago.

Suprarenin (synthetic[2]) $(OH)_2C_6H_3{\cdot}CH(OH)CH_2{\cdot}NH(CH_3)HCl$ ortho dihydroxyphenyl-ethanol-methylamino-hydrochloride. A white crystalline powder, m.p. 210°–212° (HCl salt, m.p. 161°). Lævorotary, synthetic, identical with adrenalin. Hoechst.

Suprarenin. A sterile solution of the active principle of the suprarenal gland. Hoechst.

Preparations of the suprarenal glands are:

Ext. glandulæ suprarenalis, an aqueous extract.

Glandulæ suprarenales sic, dried gland 1 : 5.

Paranephrin (Merck), a sterile purified extract.

Rachitol (Merck), dried glands.

Renoform. A solution of active principles. Freund.

Supradin. Iodised dried gland. La Roche.

Suprarenaden. An extract of gland. Knoll.

Opo-suprarenalin. A liquid extract. Poehl.

Chemically related to the suprarenal preparations, but reducing blood pressure less than adrenaline is *Tyramine*, *p*-hydroxy-phenyl-ethylamine hydrochloride $OH{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2,HCl$, m.p. 268°-270° (Eng. Pat. 1560), a synthetic base discovered by Barger (Apoth. Zeit. 1909, 886) in ergot. Its action is similar, though feebler and more prolonged than that of adrenaline; produces uterine contractions and is not hæmostatic. Burroughs.

Thyroid preparations. Employed in psoriasis, lupus, exophthalmic goitre, myxoedema, obesity, &c. The glands from freshly slaughtered sheep are used. Most important are:

---

[1] Review of literature, see Adrenalin and Adrenalin-like Bodies, Hygienic Laboratory, Bulletin No. 55, Washington, D. C.

[2] D. R. P. 152814–157300.

Iodothyrine, thyroiodine (thyrein). A milk sugar trituration of the active principle of the thyroid gland containing 0·0003 grm. of iodine to 1 grm., representing 1 grm. of the fresh gland (U. S. Pat. 626648). Bayer.

Thyreoidin. The dried gland, 0·6 grm. of which represents a fresh gland. Prepared by Merck, Poehl, Notkin, Burroughs.

Other similar preparations are *thyraden* (Knoll), *gland thyreoidæ sic, thyradol, thyrcoprotid* and *thyron.*

Serums from animals immunised against the thyroid toxine or those from which the gland has been removed.

Antithyreoidin (thyreoid serum), moebine. Merck.

Rodagen. Prepared from milk of thyroid extirpated goats. Charlottenburg.

Thyreoidectin. Red-brown powder. Parke Davis.

Hormone Therapy. A term used by Starling (Zentr. Physiol. Pathol. des Stoffwechels, 1907, 5, 6) to designate a group of physiological chemical substances (chemic reflexes), produced by certain cell groups, which, conducted by the blood to various parts of the body, stimulate certain cell complexes to specific functions. It has been shown that the spleen of animals elaborates in sufficient quantity for isolation a hormone which specifically stimulates intestinal peristaltis when employed intravenously. This is sold as

Hormonal. Liquid extract obtained from the spleen of an animal killed during digestion (U. S. Pat. 1034528). Schering.

MISCELLANEOUS ORGANO-THERAPEUTIC AGENTS.

Bone marrow preparations. Used in anæmia and chlorosis. *Medulla ossium rubra sic,* (Merck), *Medulladen* (Knoll), *Opomedullin* and *Opoossinum* (Poehl).

Brain preparations. For neurasthenia, hysteria, psychosis, diseases of nervous system. Prepared from gray matter of calves' brains. *Cerebrum siccatum* (Merck), *Opocerebrinum* (Poehl) and *Cerebrin.*

Liver preparations. For atrophic cirrhosis of liver, diabetes, hemeralopia, cholelithiases, &c. Heparaden (Knoll), Hepar sicc. (Merck), Opohepatoidin (Poehl), Heparon.

Ovaries preparations. For amenorrhæa, consequences following removal of ovaries. Oophorin (Dr. Freund, Berlin), Ovaria sicc. (Merck), Ovarinum (Poehl), Ovaraden (Knoll), Ovadin (La Roche), Ovariinum sicc. and lutein.

Mammary gland preparations. For menorrhagia, metrorrhagia, uterine fibroma, &c. Mammæ sicc. (Merck), Mammin and Opomammin (Poehl).

Pituitary body preparations. Used as cardiac tonic. Hypophysis cerebin sicc. (Merck), Opohypophysin (Poehl). Pituitrin (P. D. & Co.). Pituglandol (La Roche).

Spleen preparations. For anæmia, myxoedema, leucocythæmia, rachitis, enlarged spleen, &c. Lien sicc. (Merck), Lienaden (Knoll), Linadin (La Roche), Opolieninum (Poehl), Stagnin (Freund), Splenin and Splenon.

Testicle extracts: Orchitic fluid. For neurasthenic conditions and disturbances due to auto-intoxication. A tonic stimulant for entire nervous system. Didymin (Burroughs, Wellcome), Orchidin, Orchipin, Opoorchidin (Poehl), Spermin (Merck), Spermin-marpmann, Testes sicc. (Merck), Testaden.

Thymus gland preparations. For scrofula, Basedow's disease and pseudo-hypertrophy of the muscles. Glandulæ thymus sicc. (Merck), Opothymiium (Poehl).

Kidney preparations. Employed chiefly in nephritis. Renes sicc. (Merck), Renaden (Knoll), Renoform (Freund and Redlich, Berlin), Oporenin (Poehl). V. C.

SYRINGIN *v.* GLUCOSIDES.

SZMIKITE. Native monohydrated manganous sulphate $MnSO_4,H_2O$ (Schröckinger, J. M. 1877, 729).

T

TACAMAHAC *Tacamahacin v.* OLEO-RESINS.

TACHHYDRITE $CaCl_2 \cdot 2MgCl_2, 12H_2O$. A mineral occurring in the salt deposits of Stassfurt in roundish, yellow, deliquescent masses.

TACHIOL *v.* SYNTHETIC DRUGS.

TAGUA NUT. The stony seeds of several species of the South American genus of palms, *Phytelaphas,* are known as tagua-nuts and are worked as 'vegetable ivory.' The two species mainly affording the commercial product are *P. macrocarpa* (Ruiz et Pav.) and *P. microcarpa* (Ruiz. et Pav.).

TA-HONG. A lead glass containing ferric oxide, used by the Chinese as a red enamel on porcelain.

TAIGU WOOD. A wood from Paraguay, resembling guaiacum wood in appearance. Has a greenish-brown colour when fresh; becomes covered on exposure to the air with a greenish-yellow crystalline powder; and exhibits under the microscope yellow oblique prisms, together with shining, colourless, thin six-sided tables. The latter are not altered by alkalis; the former, which consist of *taiguic acid,* are reddened thereby. Strong boiling alcohol extracts from it 13·7 p.c. of a mixture of taiguic acid with resinous and waxy substances. Taiguic acid $(C_4H_4O)_n$ crystallises in oblique prisms of a bright-yellow colour; is tasteless and odourless; m.p. 135°, and sublimes at 180°. Very slightly soluble in water, except under pressure; readily soluble in acetone, ether, benzene, or strong alcohol. Forms crystallisable salts with bases; those with the alkalis are deep red and easily soluble in water, the lead salt is yellow, and the silver salt cinnabar-coloured (Arnaudon, J. 1858, 264).

TALC (Ger. *Talk*). A mineral species consisting of hydrogen magnesium silicate

$$H_2Mg_3Si_4O_{12}$$

occurring as foliated or compact masses. The name, said to be from the Arabic 'talq,' has no doubt long been applied to a variety of foliated minerals, such as mica and gypsum; and even at the present time it is sometimes used as a popular name for mica. The term *steatite* (Ger. *Speckstein*) is restricted to the compact, massive varieties of talc. *Soapstone* and *potstone* are impure forms of steatite; but, like the name agalmatolite (*q.v.*), they are more general in their application, and no doubt include minerals of other kinds.

Talc never occurs as distinct crystals, but only as folia or scales, which possess a perfect micaceous cleavage and a pearly to silvery lustre on their surface. The folia are flexible but not elastic, thus differing from mica. Talc is extremely soft and can be readily scratched with the finger nail; it is chosen as No. 1 in Mohs's scale of hardness. The massive varieties are often rather harder, and may range up to 2½–4 on the scale; but they are usually sufficiently soft to be readily cut with a knife and carved. A very characteristic feature of the mineral is its greasy or soapy feel. The colour of foliated talc is silvery-white or often a delicate shade of green; steatite is creamy-white, greyish, or greenish; and potstone and soapstone are of darker shades of colour. Sp.gr. 2·6–2·8. The mineral is very resistant to heat (no water being lost below a red-heat), to acids and to solutions of alkalis.

Analyses: I. Green, foliated talc from Tyrol (Scheerer, 1851). II. Fibrous talc ('agalite') from Edwards, St. Lawrence Co., New York (E. S. Sperry in Dana's System of Mineralogy, 1892). III. Pseudomorphous steatite from Göpfersgrün, Wunsiedel, Bavaria (Scherrer, 1851). IV. Steatite from Hewitt mine, Swain Co., North Carolina (J. H. Pratt, Economic paper No. 3, North Carolina Geol. Survey, 1900). V. Soapstone from Grafton, Vermont (G. P. Merrill, The Non-Metallic Minerals, 2nd ed., New York, 1910). VI. Soapstone from Francestown, New Hampshire (G. P. Merrill, *l.c.*).

Talc is of wide distribution, occurring more especially in schistose rocks and those of metamorphic origin (*e.g.* talc-schist). It is a common alteration-product of many minerals, and in the impure, massive form is intermingled with other secondary and residual products (chlorite, mica, &c.). Distinctly shaped pseudomorphs after various crystallised minerals are not uncommon.

Workable deposits, forming veins, beds, and lenticular masses, are found at many localities. Veins of steatite in the serpentine of the Lizard district in Cornwall were formerly worked for supplying material used in the manufacture of old Worcester porcelain. At Göpfersgrün near Wunsiedel in the Fichtelgebirge, Bavaria, important deposits of steatite occur at the junction of granite and limestone; the latter and its contained minerals having been largely altered by magnesium-bearing solutions emanating from the granite. Deposits are also worked in the Pyrenees and in the Italian and Austrian Alps. The best qualities for toilet and medicinal purposes have long been obtained near Pinerolo in the Chisone valley, Piedmont. At several places in India large quantities of steatite and potstone are quarried for carving into bowls, plates, cups, and other domestic utensils and ornamental objects. The largest amounts (about 120,000 tons per annum) are obtained in the United States. The fibrous talc ('agalite,' *q.v.*), which occurs as an alteration-product of tremolite and enstatite in crystalline limestones, in the Gouverneur district, St. Lawrence Co., New York, is employed in large quantities in the manufacture of writing and printing papers. Steatite and soapstone are obtained from Virginia, North Carolina, Vermont, &c.

The uses of talc are many. Powdered talc enters largely into the composition of toilet-powders; it is used as a dry lubricant; for dressing leather, cloth, rubber, &c.; for foundry facings; for adulterating soap and other goods; in the manufacture of paper and paints (enamel paints, and especially those for preserving the iron work of bridges and ships); as a non-conducting material for covering steam-pipes; as a preservative coating on stone work. Steatite (the well-known 'French chalk') is used for marking on cloth, metal, glass, slate, and blackened paper. It forms the tips of gas-burners, backs of stoves, furnace linings, &c. Being soft and readily worked, it is a favourite material for elaborate carvings, especially in the East. It has also been used as a source of magnesium salts, particularly the sulphate. Sawn slabs of soapstone are extensively used in America for benches (in chemical laboratories, hospitals, &c.), acid tanks, sinks, laundry tubs, hearth-stones, foot-warmers, and even for building purposes. Being a good insulator, it is used for electrical switchboards, and the floors of generating stations.

Another mineral also applied to many of these purposes is pyrophyllite ($H_2Al_2Si_4O_{12}$) (*q.v.*; *v.* also AGALMATOLITE).

TALIPOT. A variety of starch obtained from a palm, *Corypha umbraculifera* (Linn.). Known in Ceylon as 'raw palmira root flour.'

TALLOW. In commerce a distinction is made between *beef* tallow and *mutton* tallow. The former is obtained from oxen, cows, and calves; the latter from sheep and goats. The distinction is, broadly speaking, supported by chemical differences in the composition of the respective triglycerides, mutton tallow being as a rule richer in stearin than beef tallow.

The quality—especially the hardness—of tallow depends on the breed and the age of the animal, and to some extent on the food. The fat from the male beast is generally harder than that obtained from the female. Animals fed on grass yield a harder fat than those fed with

---

[1] Also NiO, 0·24.

[2] Also Na_2O, 0·62.

[3] Also Na_2O, 0·16; K_2O, 0·32.

oilcakes; brewery refuse produces especially soft tallow. Hence we have all gradations from the hard South American beef tallow to home-melt tallow of somewhat softish consistence.

The 'rough fat' is delivered with the adhering tissue, &c., to the tallow-melters, and is rendered at a temperature of about 100° (*see Rendering* under Oils, Fixed, and Fats).

The fats from different parts of the carcase, although of unequal value, are not kept separate, unless the fat be intended for the manufacture of oleomargarine or of tallow of best commercial quality.

At present the tendency prevails to collect the rough fat, as far as possible, in large rendering establishments fitted up with modern appliances. Hence the slaughter-houses in large towns—especially on the Continent of Europe—have at present as an adjunct a tallow-rendering establishment. These are found on the most gigantic scale in the large packing-houses of the United States of America as also of South America.

For the production of tallow for the manufacture of margarine the more valuable kidney fat ('suet,' 'edible fat') and bowel fat ('midgerum fat') is dealt with separately and not mixed with the caul- (or kell-, *i.e. omentum*) fat and the fat from other parts of the carcase.

By melting this selected fat at low temperatures—not exceeding 50°—the 'premier jus' is obtained (*see* Margarine).

The following commercial brands of tallow are differentiated :—

(1) Rendered tallow, which contains all the fat from the carcase.

(2) 'Premier jus.'

(3) Pressed tallow (tallow stearine, beef stearine, mutton stearine, oleostearine).

(4) Oleomargarine, oleo oil.

The first named quality of tallow, viz. 'rendered tallow,' is frequently expressed in hydraulic presses for the preparation of 'tallow stearine' and 'tallow oil.'

It is almost impossible to estimate the quantity of home-melt tallow produced in European countries, as the production is scattered over the smallest establishments, embracing even those of butchers in villages.

None of the European countries is at present exporting tallow, the quantities exported from the United Kingdom being in fact re-exports. Russia, which up to about two decades ago was a tallow-exporting country, has been forced to draw upon the world's supply for her own demands. Even the United States of North America, which for many years have been large suppliers of tallow, have practically ceased to export tallow, they themselves importing tallow from South America.

The chief sources of tallow—in addition to the 'home-melt' productions—are at present Australasia, South America, and to a smaller extent New Zealand. Large quantities of tallow are expected in the near future from Rhodesia.

The imported tallows are chiefly of the quality enumerated above under No. 1, viz. rendered tallow containing all the fat from the carcase. These tallows are sold according to their titer (titre), solidifying point of fatty acids and colour (*see* Oils, Fixed, and Fats).

As regards colour the commercial brands are differentiated as 'good colour,' 'off colour,' 'no colour,' &c., and are merely judged by the standards agreed upon between sellers and buyers on the London market. There is a further distinction made between 'beef,' 'mutton,' and 'mixed' tallows.

During recent years, in consequence of the great demand for edible fats, the production of 'premier jus' for export to Europe has been established on a large scale in oversea countries. Such tallow is not only carefully prepared from selected rough fat, but it is also filtered over fuller's earth, so that it arrives in a perfectly sound state in Europe When carefully packed, it will keep for months in good condition. Thus the production of oleomargarine and oleostearine for export to Europe has assumed considerable dimensions during the last few years.

On pressing tallow for the production of 'stearine,' *tallow oil* is obtained as a by-product: this is liquid or semi-solid according to the temperature at which it has been expressed. Tallow oil is chiefly used in admixture with mineral oils as a lubricating oil. Its solidifying and melting-points, as also its iodine values, naturally vary according to the conditions under which the tallow has been expressed.

Beef tallow. (For characteristics *see* Oils, Fixed, and Fats.) Beef tallow when freshly rendered is nearly white, free from disagreeable odour, and almost tasteless. Such quality is represented by 'home-melt beef tallow.' Imported tallow passes through all gradations, from 'bleached' white to slightly yellowish tallow (Australian), through darker yellow (North American, South American) to, finally, the 'off-coloured' lowest grades (North American, Australian 'no colour').

Tallow was until recently considered to consist exclusively of the glycerides of palmitic, stearic, and oleic acids. The amount of olein used to be calculated from the iodine value. It is not unlikely that owing to the influence of vegetable oils given with the food (oilcakes, &c.) less saturated acids than oleic acid may be found.

Boemer has shown that by frequently repeated crystallisation of tallow from ether, approximately 1½ p.c. of pure tristearin can be isolated.

On the assumption that the fatty acids of tallow consist of palmitic, stearic, and oleic acids only, the composition of a sample may be arrived at by determining the proportion of stearic acid (*see* Oils, Fixed, and Fats). The proportion of oleic acid can be calculated from the iodine value; the difference gives then the amount of palmitic acid.

Beef stearine is the hard portion of tallow left in hydraulic presses after removal of the tallow oil (*see* above). Boemer has shown that by frequently repeated crystallisation of beef stearine from ether, approximately 4·5 p.c. of pure tristearin can be isolated. Beef stearine obtained from 'premier jus' is used for edible purposes in the manufacture of margarine, as also in the manufacture of compound lards and in the preparation of 'suet substitutes.'

The amount of free fatty acids in tallow varies considerably with the state of purity. In freshly rendered tallows, the proportion of free fatty acids is negligible and rarely exceeds 0·5 p.c.; in commercial samples, the percentage of free fatty acids may rise to 25 p.c. and even more.

For the complete commercial examination of tallow, *see* Lewkowitsch, Chem. Tech. ii. 640.

Mutton tallow. (For characteristics, *see* OILS, FIXED, AND FATS.) Mutton tallow closely resembles beef tallow; it is frequently mixed with the latter and is then sold as 'mixed tallow.' Mutton tallow is, as a rule, harder than beef tallow, and consequently its solidifying and melting points, as also those of its fatty acids, are higher. It is more liable to turn rancid than beef tallow. For this reason it cannot be used in the manufacture of first-class butter-substitutes or high-class toilet soap.

Boemer has shown that by frequently repeated crystallisation of mutton tallow from ether approximately 3 p.c. of pure tristearin and 4–5 p.c. each of stearodipalmitin and palmitodistearin can be isolated. J. L.

TALMI GOLD. An alloy of 86·4 p.c. copper, 12·2 p.c. zinc, 1·1 p.c. tin, and 0·3 p.c. iron, used in the manufacture of trinkets.

TA-LOU. A Chinese term for a glass flux used for enamelling on porcelain. Consists mainly of a lead silicate containing a small quantity of copper (Ebelmen and Salvétat, Ann. Chim. Phys. [iii.] 35, 344).

TAMBAC or **TOMBAC.** *White copper.* An alloy of 85 p.c. copper and 15 p.c. zinc.

TANACETONE *v.* KETONES.

TANGHIN or **TANGUIN.** The celebrated judicial poison used by the inhabitants of Madagascar has been examined by Arnaud. It was known that the toxic principle was contained in the almonds of the *Cerbera Tanghin* (Hook.) belonging to the family of the *Apocynaceæ*. The almonds contain about 75 p.c. of fatty matter which could not be got rid of by simple pressing. By treating with carbon disulphide, however, which does not take up the tanghinin, the fat was extracted. Subsequent boiling with strong alcohol, and evaporation, yield a crystalline substance of powerful toxic properties. It has a strong action upon the heart, resembling strophanthin and ouabaïne (J. Soc. Chem. Ind. 1889, 211; 1888, 765), having, however, a more general convulsive action than these bodies.

Tanghinin forms colourless, rhombic, anhydrous crystals which melt at 182°, and are very sparingly soluble in water, but easily in strong alcohol. It is lævorotatory, and has the following composition: Carbon, 65·74; hydrogen, 8·19; oxygen, 26·07 (Arnaud, Compt. rend. 1889, 108, 1255; *ibid.* 109, 701).

The poisonous properties of a tanghin or ksopo extracted from the plant *Menabea venenata* (Baill.) of the family *Asclepiadeen* and used by the Sakalaves, are described by Camus (Compt. rend. 1903, 136, 176).

TANNASE. A diastase found in nut-galls, sumac leaves, &c., capable of hydrolysing tannin (Fernbach, Compt. rend. 131, 1214; Poltevin, *ibid.* 131, 1215).

TANNASPIDIC ACID *v.* FILIX MAS.

TANNING *v.* LEATHER.

TANNINS (*Acides tanniques*, Fr.; *Gerbstoffe*, Ger.). This term has been applied to a large class of substances which have been found in many plants and are distinguished by the following characters: they have an astringent taste; give a blue-black or green coloration with ferric salts; are precipitated by a solution of gelatin, by albumen and by alkaloids; unite with hide to form leather.

It was formerly believed that only one tannin existed, and it was assumed that the difference in properties of tannin from different sources was due to the presence of foreign matter. It is, however, now well known that tannin from different sources frequently differs both in composition and in properties, and although it is probable, owing to the difficulty of obtaining these compounds in an even approximately pure condition, that the number of distinct individuals may not be so great as is usually supposed, there can be no doubt that at least three important classes of tannins exist in nature. The earliest suggestion was to divide the tannins into two classes—the iron-blueing tannins, and the iron-greening tannins—according to their behaviour towards salts of iron, and it was considered that whereas the former were pyrogallol compounds, that the latter were derived from catechol. This differentiation appears in the main to be correct, and the employment of ferric chloride for this purpose, or better iron alum as a preliminary step, is of general application; but on the other hand, it is to be borne in mind that the presence of acid, alkali, or organic impurity has considerable effect upon the colour production. Thus, although the method is no doubt of service in many cases even with the plant infusion, its exact significance can only be ascertained from the coloration given by the purified tannin itself.

Stenhouse (Proc. Roy. Soc. 11, 405) believed that those tannins which give blue-black precipitates with ferric salts are mostly glucosides. Wagner (Zeitsch. anal. Chem.) made a distinction between *pathological* and *physiological* tannins and considered that the former class represented by gallotannic acid only existed in pathological formations of certain species of oak and sumac [*Rhus javanica* (Linn.) and *R. semilata* (Murr.)], whilst the latter class include all tannins which are produced under normal conditions of plant life. As, however, gallotannic acid has been found to exist in some plants as a physiological tannin, Wagner's classification is untenable.

Böttinger (Ber. 1884, 17, 1123) has examined the action of bromine on aqueous tannin extracts, and determined the percentage of bromine contained in the precipitated bromo products. As a result, it was shown that certain tannins may be grouped together according to the amount of bromine which they take up.

Hemlock bark tannin . .	43·6
Quebracho tannin . . .	44·5
Mangrove tannin . . .	42·15
Mimosa tannin . . .	49·36
Chestnut oak tannin . .	50·48
Terrajaponica tannin . .	53·2
Spruce bark tannin . .	52·8

A very large amount of attention has been given to the classification or identification of aqueous extracts of tanning materials, by the coloured and other effects given by certain reagents. It remains to be decided whether in all cases these reactions in reality arise from the tannin itself.

The more important methods which may be used to classify the tannins into groups, according to our present knowledge of these substances are as follows:—

Coloration with ferric chloride or iron alum (see above).

Digestion with boiling dilute sulphuric acid. In this method of procedure, three definite reactions are observed: (*a*) the hydrolysis of the tannin with formation of gallic acid (gallotannic acid); (*b*) the precipitation of ellagic acid (ellagitannic acid); (*c*) the gradual production of an amorphous red-coloured precipitate known as a 'phlobaphene' (catechol or phlobatannin).

Precipitation with bromine water indicates the presence of a so-called catechol or phlobatannin (Procter, Leather Industries Handbook, 1898).

Pine wood and hydrochloric acid test. If a deal shaving be moistened with a solution of phloroglucinol and then with strong hydrochloric acid, a deep red-violet colour due to the formation of phloroglucinol vannillein is produced. Resorcinol reacts similarly giving a blue-violet (Procter). These colorations are an indication of the presence of a phloroglucinol or resorcinol nucleus in the tannins. Gallotannin and ellagitannin solutions do not react in this manner.

Diazobenzene chloride. Solutions of certain tannins in the presence of alkali or alkaline acetates give a red coloured precipitate of the azobenzene tannin with this reagent, a fact which indicates with some certainty the presence of a phloroglucinol or resorcinol grouping. Gallotannin and ellagitannin do not react in this manner.

Fusion with alkali. Procter (Leather Industries Handbook, 1898) recommends adding 20 grms. of tannin to 150 c.c. of a solution of potassium hydroxide of sp.gr. 1·20 and concentrating the liquid during 3 hours until it becomes pasty. Or 5 to 10 parts of caustic potash and a few drops of water are heated with one part of the tannin to 210°–240° for 20 minutes. Gallotannin, by this method, gives gallic acid, and possibly traces of pyrogallol, whereas the so-called catechol tannins yield protocatechuic acid or other allied acid, alone, or together with phloroglucinol or resorcinol, &c.

Heating with glycerol. The tannin (1 grm.) is heated with 5 c.c. of glycerol slowly raising the temperature from 160°, and keeping it for half an hour between 200°–210°. The product diluted with 20 c.c. of water is extracted with ether, the extract evaporated and the residue tested for pyrogallol or catechol. According to Trimble (The Tannins), paraffin wax may be employed in place of glycerol.

Formaldehyde test. When an aqueous solution of a so-called catechol tannin is treated with formaldehyde and a little hydrochloric acid and gently warmed the tannin is completely precipitated. Pyrogallol tannins do not yield an entirely insoluble compound in this manner. This reaction, discovered by Stiansy (Der Gerber, 1905, 185), has by numerous writers been assigned to Jean and Frabot (Ann. Chim. anal. 1907, 12, 49).

Lead acetate test (Stiasny and Wilkinson, Collegium, 1911, 475 (2 ix.) 318). All natural tannins are completely precipitated by lead acetate solution in so far as the filtrate from the precipitate does not give the iron test. In the case of catechol or phlobatannins this precipitate is dissolved by dilute acetic acid, whereas with the gallotannins the lead com-ound is insoluble or but partially soluble. The is preferably made by adding 10 c.c. of acetic acid (10 p.c.) to 5 c.c. of the tannin solution, and then adding 5 c.c. of lead acetate (10 p.c.). No precipitate is thus produced in the case of the catechol or phlobatannins.

By these methods it is easy to divide the tannins into three classes, usually distinguished as (1) gallotannins, (2) ellagitannins, and (3) catecholtannins. Since the discovery of synthetical tannins by Fischer and Freudenberg (Annalen, 1911, 384, 225), it is evident that this nomenclature, as applied to the first group, is imperfect. Thus, whereas the term 'gallotannin' is in reality only applicable to compounds containing pyrogallol nuclei and in fact merely relates to digallic acid and its derivatives, it is now known that diprotocatechuic acid, diresorcylic acid, and digentisic acid, members of the same group, possess tanning property. On this account it is considered more reasonable to distinguish such tannins by the term 'depside,' a nomenclature which is due to Fischer and Freudenberg, although it is not suggested that such a group is absent in the other tannins.

Again, as regards the so-called 'ellagitannin' group (2), new tannins belonging to this class may also be either synthesised or isolated in the future. The term 'ellagitannin' is therefore here replaced by 'diphenylmethylolid,' the name by which the group mother substance is known.

Exception is again to be taken to the designation 'catechol' tannin (3) for reasons similar to those given above and which are discussed later in this article, and this name is also replaced by 'phlobatannin,' in that these compounds, apparently without exception, possess the property of yielding phlobaphenes. In respect of this latter group, it is to be noted in connection with the qualitative tests above enumerated that the formation of phlobaphene and of precipitates with bromine water and with formaldehyde sufficiently indicate the presence of this variety of tannin, because these compounds may not all react with pine wood and hydrochloric acid, or diazobenzene chloride, or give protocatechuic acid as one of their decomposition products.

There appears to be ample evidence also of the existence of special varieties of glucoside belonging to this third class, distinguished by their extremely hygroscopic nature and the fact that they are insoluble or nearly so in acetic ether. They give, however, the well-marked reactions of the phlobatannins. None of these compounds has yet been obtained in a pure condition, but when they are digested with boiling dilute mineral acids a sugar and phlobaphene appear to be mainly produced.

Methods of isolation.

All the well-known tannins are dissolved by hot water, and yield precipitates with lead acetate solution, and thus by decomposing the well washed lead precipitate from a plant infusion in the moist condition with sulphuretted hydrogen a crude solution of the tannin is obtained. This can be concentrated *in vacuô* over caustic potash or sulphuric acid. In the place of lead acetate, stannous chloride was employed by Proust in 1798 (Ann. Chim. Phys. 25, 225), who is credited with being the first to prepare tannic acid in a nearly pure condition. As, however, the tannin usually exists in the plant side by side with yellow colouring matter, either in the free state or as glucoside, and other secondary substances soluble in water, a fractional precipitation with lead acetate is preferably adopted, in which case the middle portion usually yields the purest tannin (Grabowski, Sitz. Ber. 1867, 55, ii. 567; Trimble, The Tannins, 1892, i. 85). A preliminary treatment with lead acetate in the presence of a little acetic acid is serviceable in some cases for the precipitation of coloured impurities. Probably the solvent most extensively employed since 1880 in the investigation of tannins has been ethyl acetate, in which case it has been usual to agitate a solution of the substance or extract of the plant with this solvent. A preliminary addition of salt or sodium sulphate to the liquid is beneficial.

Certain tannin glucosides, owing to their sparing solubility in ethyl acetate, cannot be satisfactorily isolated in this manner, and the method is not applicable to the case of mineral salts of the tannin, in which the preliminary production and subsequent decomposition of the lead salt is to be recommended. Numerous methods have been adopted for the purification of the tannin thus prepared, and are given under the head of the special substance with which they have been employed.

In many cases it has been found preferable to extract the tannin matter with an organic solvent rather than with water. This is, as a rule, to be advised, as the crude substance is thus more readily isolated in a concentrated form. Indeed, one of the oldest methods of separating tannins from other substances is that of Pelouze (Ann. Chim. Phys. 1834, 55, 337), who exhausted powdered gallnuts with commercial ethers. Various mixtures of alcohol, ether and water have been recommended, and also dilute alcohol in the case of gallnuts for preparing gallotannic acid, although these methods must not be considered of special advantage for the isolation of tannins as a whole. Probably the most efficient solvent for general purposes of investigation is acetone which was employed by Trimble for the percolation of numerous tannin matters (The Tannins).

I. Depside Group.

Tannin, *Tannic acid*, *Gallotannin*, *Gallotannic acid* is found to the largest extent in galls which arise from the puncture of insects of the genus *Cynips* on the leaves and buds of various species of oak, more especially the *Quercus lusitanica* (Lam.), and on a species of sumach, *Rhus semilata* (Murr.). Aleppo galls, derived from the young shoot of the oak and which are the best variety of oak gall on the market, contain 50–60 p.c. of gallotannic acid, whereas Chinese galls from sumach yield as much as 70 p.c. In smaller amount it occurs also in numerous plants, and is probably the main tannin of various sumachs, of valonia, divi-divi, and algarobilla.

The methods employed for the isolation of gallotannic acid from galls are more or less modifications of that of Pelouze, which consists in extracting finely powdered galls with commercial ether. The extract separates into two layers, the upper consisting of an ethereal solution of gallic acid, wax, and resinous substances, whereas the lower represents a concentrated solution of gallotannic acid which, on evaporation, remains as a porous mass. In place of the ether, a mixture of 75 p.c. commercial ether and 25 p.c. alcohol, can be employed. The method of Leconnet (Annalen, 1836, 18, 179) consists in stirring powdered galls into ether until a thin cream results, pressing the mixture and repeating the operation until tannin is no longer removed. According to Domine (J. Pharm. Chim. 1844, [3] 5, 231), it is advantageous to allow the powdered galls before extraction to remain for some time in a moist atmosphere, and Pelouze's process with this modification was adopted by the British and United States pharmacopœias.

For the manufacture on the large scale, Chinese or Japanese galls are preferably employed owing to their richness in tannin. The finely powdered material is stirred with sufficient water at 50°–60° to form a concentrated aqueous extract, and after filtration the clear liquid is agitated with one-fourth of its volume of ether until an emulsion results. After standing for several days, the upper ethereal liquid which has separated is removed, and the lower layer, which contains all the tannin matter, is run into a still and the ether which is present recovered. After cooling the syrupy liquid is spread out on sheets of tin, and heated by means of a steam coil, when the gallotannic rapidly puffs up and dries.

Thus prepared the commercial tannin contains some quantity of gallic acid, plant wax, glucose and other impurities; to remove these the material may be washed with ether, or the aqueous solution shaken with ether, or the aqueous liquid fractionally precipitated with common salt, the precipitate dissolved in ethyl acetate, and the tannin recovered by evaporation under reduced pressure. Trimble (The Tannins, 85) treats a 5 p.c. solution of the tannin with 10 p.c. lead acetate, drop by drop, until the precipitate at first yellow coloured ceases to be granular and is colourless. This is collected, the filtrate agitated two or three times with ethyl acetate and the extract evaporated. The colourless product, which still contains gallic acid, is redissolved in water, and the solution, after agitation with ether, evaporated under reduced pressure. Finally, the residue dissolved in ether with a little water is again brought rapidly to dryness under reduced pressure, and thus obtained is colourless and gives no reactions for gallic acid or glucose. With the object of preparing a homogeneous product, Walden (Ber. 1898, 30, 3154) has employed dialysis, and also the precipitation of a solution of the purest commercial tannin in ethyl acetate with benzene. Rosenheim and Schidrowitz (Chem. Soc. Trans. 1898, 73, 882) point out the extreme difficulty of removing the last traces of gallic acid from the tannin and employ a mixture of ether and acetone for this purpose. Paniker and Stiasny (Chem. Soc. Trans. 1911, 9, 1821) state, however, that the process of Rosenheim and Schidrowitz only partially removes gallic acid The method suggested by Perkin, which consists in neutralising a solution of the tannin with sodium bicarbonate, extracting the mixture with ethyl acetate, and subsequently precipitating the substance from the extract with benzene, gives a product free from even traces of gallic acid (*see* also Iljin, Ber. 1909, 42, 1731). Fischer and Freudenberg (Ber. 1912, 45, 919) find the addition of dilute sodium hydroxide to the tannin solution until faintly alkaline before extraction with ethyl acetate is similarly beneficial.

Gallotannic acid as found in commerce consists of an amorphous powder possessing a faint yellow colour, although when exhaustively purified it is colourless. It is readily soluble in water and alcohol, more sparingly in ethyl acetate, insoluble in pure ether, chloroform or benzene. With solutions of ferric salts, gallotannic acid gives a bluish-black coloration or precipitate, according to the concentration, whereas ferrous salts give with strong solutions only, a white precipitate which gradually turns blue in the air. Many metallic salts give precipitates with the tannin, those of lead and tin being colourless whereas the copper and silver compounds possess a brown tint. Cold alkaline solutions absorb oxygen from the air and darken in colour with production of the so-called *metagallic acid.* When boiled hydrolysis occurs and gallic acid is formed. Gallotannic acid precipitates most alkaloids and gives precipitates with albumen and gelatin, the latter, according to Trunkel (Zeitsch. Biochem. 1910, 26, 458), in quantitative amount.

Analyses of gallotannin by Berzelius, Pelouze, Mulder, Bijlert, Strecker, Gautier, Trimble, Dekker and Walden have been in fairly close agreement, varying from about C=51·5 to C=52·3; H=3·7 to H=4·1 p.c. Iljin (Ber. 1909, 42, 1735) has suggested higher numbers (C=54·13; H=3·22), the correctness of which he has again emphasised (J. pr. Chem. 1910, [ii.] 82, 422; *cp.* Nierenstein *ibid.* 1909, 42, 3552). Mulder (J. pr. Chem. 1849, 48, 90) was the first to assign to gallotannin the formula $C_{14}H_{10}O_9$, and this was subsequently adopted by Schiff (Ber. 4, 231) and until recently generally accepted as correct. Very numerous salts of gallotannic acid have been described which are in fair agreement with this view, of which *ammonium tannate* $NH_4C_{14}H_9O_9$, *potassium tannate* $KC_{14}H_9O_9$, *sodium tannate* $NaC_{14}H_9O_9$, and *barium tannate* $Ba(C_{14}H_9O_9)_2$ (Buchner, Annalen, 53, 361) may be given as examples. For a complete list reference should be made to Beilsten (1896, ii. 1926).

Gallotannic acid isolated from plants is said to contain glucose which is difficult to eliminate. Strecker (Annalen, 90, 340) indicated the possible existence of a glucoside of the formula $C_{27}H_{22}O_{17}$, although Schiff (*ibid.* 170), while agreeing that unaltered tannin is probably a glucoside of digallic acid, preferred the formula

$$C_{34}H_{28}O_{22}(=C_6H_{12}O_6+2C_{14}H_{10}O_9-2H_2O).$$

This corresponds to a yield of 23 p.c. of glucose; in natural tannin about 22 p.c. has been detected.

When gallotannic acid is heated at from 160°–215°, water, carbon dioxide and *pyrogallol* are evolved, and a dark coloured non-volatile substance known as metagallic acid is produced. According to Trimble (*l.c.*) the best yields of pyrogallol are obtained by raising the temperature slowly to 215° and then keeping it between 190°–210° for half an hour. Digested with boiling dilute mineral acids, gallic acid is produced, and Wetherill, who employed for this purpose 50 grms. of tannic acid and 500 c.c. of sulphuric acid (1 vol. acid + 4 of water), obtained a yield of 87·4 p.c. of gallic acid. Knop (Annalen, 170, 44) obtained 95 p.c., and Stenhouse the theoretical amount, whereas Trimble (*l.c.*) states that when pure gallotannic acid is heated with a 2 p.c. solution of absolute hydrochloric acid, gallic acid only is produced. This reaction was formerly assumed to be expressed by the following equation

$$C_{14}H_{10}O_9+H_2O=2C_7H_6O_5.$$

Boiling alkaline solutions also produce gallic acid, but hot aqueous ammonia yields *ammonium gallate* and *gallamide* as follows:

$$C_{14}H_{10}O_9+2NH_3=C_7H_5O_5NH_4+C_7H_5O_4NH_2.$$

According to Voswinkel (D. R. P. 1905), on adding formaldehyde to an aqueous solution of tannin and carbamide in molecular proportion, a precipitate of *methylene tannin carbamide* is formed

$$C_{14}H_{10}O_9+CO(NH_2)_2+H{\cdot}CHO$$
$$=C_{14}H_9O_9{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}NH_2+H_2O.$$

It is a yellow powder decomposing about 220° and is insoluble in organic solvents with the exception of alcohol.

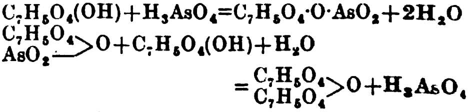
By heating barium gallate with silver nitrate, Löwe (J. pr. Chem. 1867, 102, 111) obtained a substance resembling gallotannic acid, and the same compound, together with ellagic acid, was also produced by the action of arsenic acid on gallic acid. Schiff (Ber. 1871, 4, 231) found that when gallic acid was heated with phosphorus oxychloride at 100°, and subsequently at 120°, digallic acid was produced and this had the same percentage composition, and properties as natural gallotannin. The reaction (Annalen, 1873, 170, 56) most probably occurred as follows:

$$2C_7H_5O_4(OH)+POCl_3=2HCl+\begin{matrix}C_7H_5O_4-O\\C_7H_5O_4-O\end{matrix}\!\!>POCl$$

$$C_{14}H_{10}O_{10}{\cdot}POCl+4C_7H_6O_5$$
$$=3C_{14}H_{10}O_9+H_3PO_4+HCl$$

and there was indeed evidence of the intermediate formation of a phosphorus compound. Further, it was noticed that pure tannin gives some ellagic acid when heated with phosphorus oxychloride at 130°–140°. Schiff (Ber. 1871, 4, 967) also corroborated Lowe's statement that digallic acid is produced from gallic acid by means of arsenic acid. The reaction could be expressed thus:

$$C_7H_5O_4(OH)+H_3AsO_4=C_7H_5O_4{\cdot}O{\cdot}AsO_2+2H_2O$$



$$\begin{matrix}C_7H_5O_4\\AsO_2\end{matrix}\!\!>O+C_7H_5O_4(OH)+H_2O$$
$$=\begin{matrix}C_7H_5O_4\\C_7H_5O_4\end{matrix}\!\!>O+H_3AsO_4$$

The following constitution was first assigned by Schiff to his digallic acid:

$$COOH(OH)_2C_6H_2{\cdot}O{\cdot}C_6H_2(OH)_2COOH$$

and indeed by means of acetic anhydride only a tetra-acetyl compound was apparently produced. Later (*l.c.* 1873), a study of acetyltannin which was obtained as warty nodules, m.p. 137° (Trimble, The Tannins, I. 87), gives m.p. 139°; Nierenstein (Collegium, 1905, 23), 129°–131°; Dekker (Ber. 1906, 39, 2497), 129°; and Nierenstein (*ibid.* 1907, 40, 917), 146° (*cf.* Böttinger, *ibid.* 1884, 17, 1478), indicated that this possessed the formula $C_{14}H_5O_9Ac_5$, and the constitution given below was therefore adopted—

$$COOH(OH)_2{\cdot}C_6H_2{\cdot}O{\cdot}CO{\cdot}C_6H_2(OH)_3.$$

A penta-acetyl derivative was also given by digallic acid prepared both by the phosphorus oxychloride and arsenic methods (Ber. 1873, 68, 72), and there appeared at the time to be no doubt that this artificial product was identical with the natural tannin. Phosphorus pentachloride and phosphorus trichloride again produced digallic acid from gallic acid. According to Geschwender (Inaugural Diss. Munich, 1906), penta-acetyldigallic acid can be obtained in a crystalline condition from dilute alcohol.

By heating protocatechuic acid with arsenic acid, Schiff (Ber. 1882, 15, 2589) obtained his *diprotocatechuic acid* in the form of a hygroscopic glassy mass. This possessed the characteristics of a tannin and with boiling dilute mineral acids was converted into protocatechuic acid.

Dipyrogallol carboxylic acid from pyrogallol carboxylic acid and phloroglucinol tannic acid from phloroglucinol carboxylic acid were also prepared (Annalen 295, 40). Freda (Ber. 11, 2033; 12, 1576) did not obtain digallic acid by the interaction of gallic and arsenic acids, but only an arsenic compound, which on treatment with sulphuretted hydrogen gave gallic acid.

Biginelli (Gazz. chim. ital. 1909, 39 ii. 68) obtained from arsenic and gallic acid *arsenic gallic acid* $AsO(OH)_2O{\cdot}C_6H_2(OH)_2COOH$, *arsenic digallic acid*

$$(OH)AsO[O{\cdot}C_6H_2(OH)_2COOH]_2$$

and *dihexahydroxybenzophenone arsenic acid*

$$(OH)AsO[O{\cdot}C_6H_2(OH)_2CO{\cdot}C_6H_2(OH)_3]_2.$$

The second of these compounds, Biginelli suggests, forms one of the constituents of Schiff's artificial tannin.

Similar compounds are produced by the action of phosphoryl chloride or antimonic acid on gallic acid (Biginelli, *ibid.* 283) to which the following formulæ have been assigned:

$$PO(O{\cdot}C_6H_2(OH)_2COOH)_3,$$
$$SbO(OH)_2O{\cdot}C_6H_2(OH)_2COOH,$$
and $$(OH)SbO(O{\cdot}C_6H_2(OH)_2COOH)_2.$$

All these substances react as tannins, and it seems possible that Schiff's digallic acid preparations are in reality similarly constituted. On the other hand, Walden (Ber. 1898, 81, 3168) prepared Schiff's digallic acid by the arsenic acid method, and although he noted the difficulty of completely removing arsenic, this appeared to be absent from the purified compound (*cf.* also Nierenstein, Chemie der Gerbstoffe, Stuttgardt, 1910, 44).

By heating gallotannin with benzoyl chloride, Böttinger (Ber. 1889, 22, 2707) prepared a *benzoyltannin* in the form of a sandy light yellow coloured powder. Sisley (*l.c.*) and Dekker (*l.c.*) describe similar products. Vournasos (Le tannin de la noix de galle, 27), on the other hand, describes *pentabenzoylgallotannin* as a well-defined crystalline compound.

By heating a mixture of ethyl gallate and pyruvic acid with sulphuric acid, Böttinger (Ber. 1884, 17, 1476), prepared a substance $C_{14}H_{10}O_9,2H_2O$, which he at first regarded as digallic acid. It consisted of a very hygroscopic mass which had the properties of a tannin, gave a penta-acetyl compound, and with lead acetate solution yielded a dull yellow precipitate. As, however, by digestion with boiling dilute hydrochloric acid no gallic acid was produced, it could only be an isomeride of natural gallotannin.

According to Hunt (Chem. News, 52, 49), a substance which behaves in many respects like tannin can be prepared by the interaction of monobromoprotocatechuic acid and potassium gallate

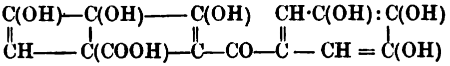
$$C_6H_2(OH)_3COOK + C_6H_2Br(OH)_2COOH$$
$$= C_6H_2(OH)_3CO{\cdot}O{\cdot}C_6H_2(OH)_2COOH + KBr.$$

but Schiff (Gazz. chim. ital. 1897, 21, i. 90) was unable to synthesise tannin by this method.

Herzig and Tscherne (Ber. 1905, 38, 989) obtained *methyltannin* by the action of diazomethane on gallotannin suspended in ether, and describe it as a colourless amorphous powder, m.p. 124°–126°. It had the composition $C_{24}H_8O_7(OCH_3)_8$ or $C_{24}H_{10}O_7(OCH_3)_5$, is dextrorotatory and when hydrolysed gives a mixture of *trimethylgallic acid* and 3 : 4-*dimethylgallic acid*. The percentage of methoxyl found, however, approximates to that required for a pentamethylgallotannin (Herzig, *ibid.* 1908, 41, 83). Later, Herzig and Renner (Monatsh. 1909, 30, 543) consider that their methyltannin may possibly be a mixture of substances which have approximately the same composition, and indeed contain pentamethoxy derivatives of the tannin constituents described by Nierenstein (see below). Rosenheim (Chem. Soc. Proc. 1905, 21, 157), by means of methyl sulphate, obtained a compound having the composition of a tannin pentamethyl ether.

Whereas, for a considerable time, Schiff's formula was generally recognised as the best known expression for the constitution of gallotannin, it had been pointed out by Scheibler in 1866 (Zeitsch. Zuckerind. 16, 33), by van Teigheim in 1867 (Ann. Sci. Nat. [v.] 8, 210) and by Gunther in 1872 (Ber. pharm. Ges. 5, 172) that natural gallotannin was optically active.

Owing no doubt to the idea that unless carefully purified, gallotannin obstinately retains traces of sugar, this fact did not attract special attention until Schiff (Gazz. chim. ital. 1895, 25, ii. 437) noted that the pure substance possesses a dextro-rotation ($[\alpha]_D = +14°$ to $+67°$). In order to provide for the assymetric carbon atom, a modification of his earlier formula was accordingly necessary, and he now suggested that gallotannin should be represented as a ketonic compound of the following constitution:



$$\begin{array}{llllll} C(OH)- & C(OH)- & C(OH) & & CH{\cdot}C(OH):C(OH) & \\ \| & | & \| & & \| \qquad\qquad | & \\ CH- & C(COOH)- & C- & CO- & C - CH = C(OH) & \end{array}$$

On the other hand, by the action of phenylhydrazine under varied conditions, no hydrazone could be prepared from gallotannin.

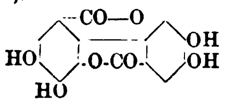
According to Walden (Ber. 1897, 30, 3151), who examined the purest samples of commercial tannin available, these products, as already indicated by Schiff, vary considerably in optical activity, having $[\alpha]_D$ from $+15°$ to $+67°$, and are evidently mixtures.

Whereas Paterno (Zeitsch. physikal. Chem. 1899, 4, 458) found the molecular weight of tannin in water to be 2643–3700, and that of Schiff's digallic acid 660, Sabanéeff (J. Russ. Phys. Chem. Soc. 1890, 22, 104) showed that in acetic acid gallotannin gave the figure 1322. Krafft, again (Ber. 1899, 32, 1613), found for gallotannin in water 1587–1626.

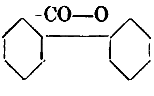
Walden (Ber. 1899, 31, 3167), on the other hand, showed that the molecular weight indicated by Schiff's digallic acid in boiling acetone is about 316, whilst samples of Merck's and Schuchardt's tannin in the same solvent respectively gave figures of 753–763, and 1350–1360. Again, the affinity coefficient of Schiff's digallic acid is K=0·0012, whereas that of tannin, which varies greatly with the concentration, is from K =0·0001 to K=0·00006. Spectrometric examination of solutions of gallotannin and digallic acid showed also that their absorption powers for all regions of the spectrum are entirely different, and from these facts there could be no doubt that gallotannin and Schiff's digallic acid are distinct compounds. Moreover, it was not possible to regard digallic acid as the inactive modification of gallotannin. Rosenheim and Schidrowitz (Chem. Soc. Trans. 1898, 73, 878), who examined samples of commercially 'pure' gallotannins, again pointed out the wide limits through which the rotation of these varied, the minimum being $[\alpha]_D+11°$ and the maximum $+74·2°$. The important point was also indicated that these commercial products could be separated into fractions the rotatory powers of which varied from $[\alpha]_D\pm0°$ to $[\alpha]_D+75·2°$, and it was further concluded that in each of the original samples a homogeneous gallotannin exists, possessing an optical activity of about $[\alpha]_D+75°$. As a confirmation of this point it was noted that the quinine salts and penta-acetyl compounds prepared from gallotannins of $[\alpha]_D+11°$, up to $[\alpha]_D+75°$ were identical in rotatory power *inter se* with those prepared from the purified gallotannin.

According to Nierenstein (Ber. 1905, 38, 3641) when gallotannin is distilled with zinc dust, diphenylmethane is produced, a result which is in harmony with Schiff's formula for digallic acid, in that it has been previously found that ellagic acid (1), and diphenylmethylolid (2) (Graebe, *ibid.* 1903, 36, 212) by a similar method give fluorene (3) (*cf.* also Perkin and Nierenstein, Chem. Soc. Trans. 1905, 87, 1412).

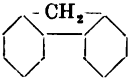
(1)



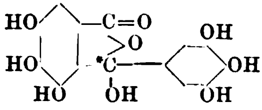
(2)



(3)



Dekker (Ber. 1906, 39, 2497; *ibid.* 3784) suggested that gallotannin should be represented as a derivative of phthalic anhydride.



and it was considered that this formula is in harmony with the optical activity, almost complete hydrolysis to gallic acid and the formation of diphenylmethane. According to numerous workers, however, gallotannin gives only a penta-acetyl derivative, whereas such a constitution indicates seven hydroxyl groups, and though Dekker describes a hexa-acetyl tannin $[\alpha]_D+64·4°$ the existence of this is doubtful.

Dekker (De Looistoffen, 1908, ii. 30, 1908) was unable to confirm the production of diphenylmethane from tannin as observed by Nierenstein (*l.c.*), and obtained in this manner diphenyl. Nierenstein (Chemie der Gerbstoffe, 1910, 47), however, maintains the correctness of his former work.

Lloyd (Chem. News, 1908, 97, 133) concludes that gallotannin contains three digallic groups united to each other to form a six-membered ring of the type $CXY{<}{O\cdot CXY \atop O\cdot CXY}{>}O$ in which

X=  and Y=  .

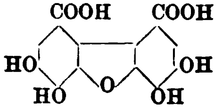
Nierenstein (Ber. 1907, 40, 916) separates acetyl gallotannin which, on analysis, behaves as a penta-acetyl compound, into two amorphous components (*a*), m.p. 203°–206°, present in small quantity, and (*b*) the main product, m.p. 166°. The former when hydrolysed gives gallic acid, and on oxidation by means of potassium persulphate and acetic acid, ellagic acid. By means of zinc dust, the penta-acetyl tannin, m.p. 203° (Ber. 1908, 41, 77), may be reduced to the acetyl derivative, m.p. 166°. Again the compound, m.p. 166°, which is termed *acetyl-leucotannin*, is not a fully acetylated compound, but on further treatment gives hexa-acetyl-leucotannin, m.p. 159°. Thus gallotannin is considered to be a mixture of digallic acid and leucotannin

$$C_6H_2(OH)_3CH(OH)O{\cdot}C_6H_2(OH)_2COOH$$

the latter being evidently the main component of the mixture.

Penta-acetyl-leucotannin (Ber. 1909, 42, 1122) is hydrolysed by boiling dilute sulphuric acid with formation of *gallic aldehyde* and *gallic acid* as its formula suggests, and when oxidised with persulphate and sulphuric acid in boiling acetic acid gives in addition to ellagic acid, a red amorphous product *purpuro-tannin* (C =69·14, H=2·84) which on distillation with zinc dust yields naphthalene.

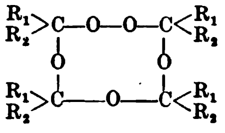
In a later paper (Nierenstein, Annalen, 1912, 386, 318) the formula $C_{14}H_8O_9$ (C=52·5; H=2·5 is assigned to this compound, and the *quinolin* salt $C_{14}H_8O_9{\cdot}2C_9H_7N$ *tetra-acetyl* compound, m.p. 324°–327°, *tetrabenzoyl* compound, m.p. 279°–281°, and *tetramethylether*, m.p. 242°–244°, are described. By distillation with zinc dust it gives *diphenylene* and not naphthalene, as was at first considered to be the case. With piperidine at 180° it gives 1:2:7:8 *tetrahydroxydiphenylene oxide* $C_{12}H_8O_5$, m.p. 334°–338°, with hydriodic acid and phosphorus *diphenylene oxide*, and from these results appears to possess the following constitution:



Iljin, who studied the action of zinc dust on a boiling 10 p.c. aqueous solution of tannin for 15 to 20 hours, obtained an amorphous substance which has $[\alpha]_D^{18·4}+24·1°$ in 95 p.c. alcohol, gives coloured precipitates with metallic salts, and gallic acid without gallic aldehyde when heated with 20 p.c. sulphuric acid in a current of hydrogen (J. pr. Chem. 1909, [ii.] 5, 80, 332).

According also to Herzig and Renner (Monatsh. 1909, 30, 543), tannin methyl ether (*l.c.*) is practically unaffected by boiling with acetic acid, zinc, sodium acetate and acetic anhydride, no leuco compound being thus produced.

Iljin (J. Russ. Phys. Chem. Soc. 1908, 39, 470; Chemie der Gerbstoffe, 1910, 49) obtained two phenylhydrazine derivatives $C_{74}H_{58}N_6O_{30}$ and $C_{98}H_{82}N_{14}O_{26}$ from gallotannin. He suggests for gallotannin the formula $C_{56}H_{40}O_{33}$, and proposes the following constitution, in which $R_1 = -CO{\cdot}C_6H_2(OH)_3$ and $R_2 = -C_6H_2(OH)_3$:



E. Fischer (Ber. 1908, 41, 2875), by coupling tricarbomethoxygallyl chloride with dicarbomethoxygallic acid, obtained a product which, on hydrolysis, gave a substance, m.p. 275°–280°, crystallising in prisms or needles. This was considered to be possibly a mixture of digallic acid with gallic acid, but was subsequently shown (1911, see below) to be a slightly impure *digallic acid*

$$(OH)_3C_6H_2{\cdot}CO{\cdot}O{\cdot}C_6H_2(OH)_2COOH.$$

According to Nierenstein (Ber. 1910, 43, 628), by converting gallotannin into the carboethoxy derivative, hydrolysing this with pyridine and repeating the operation three or four times, there is obtained a digallic acid $C_{14}H_{10}O_9,2H_2O$ crystallising in small needles from alcohol and water (1 : 3) which sinters at 214° and melts at 268°–270°. It (1) is optically inactive, when hydrolysed gives gallic acid, and on oxidation with hydrogen peroxide ellagic acid, but is not identical with Fischer's digallic acid (2) which does not yield ellagic acid. Nierenstein formulates these compounds as follows:

(1) 
(2) 
Penta-acetyldigallic acid needles, m.p. 211°–214°, *pentabenzoyldigallic acid* needles, m.p. 187°–189°, *pentacarbethoxydigallic acid*, small cubes, m.p. 194°–195°, and *sodium digallate* are described.

By digestion with boiling acetic anhydride and zinc dust, penta-acetyldigallic acid gives dl-*hexa-acetyl-leucotannin*, m.p. 154°–155°, cubes, and may be separated by means of the strychnine salt into l-*hexa-acetyl-leucotannin*, having m.p. 151° and $[\alpha]_D^{15} - 4{\cdot}6$, and *d-hexa-acetyl-leucotannin*, having m.p. 153°–154° and $[\alpha]_D^{20} + 121{\cdot}5°$.

Iljin (J. pr. Chem. 1910, [ii.] 82, 422) redetermined the molecular weight of specially purified gallotannin in acetone, and found values of 1247–1637, confirming the results of Sabanéeff and of Walden (*l.c.*). Accordingly he considers that gallotannin must consist largely of a complex derivative of gallic acid, distinct from the digallic acid and leucotannin of Nierenstein.

When gallotannin is boiled for 4 hours with zinc oxide the filtrate does not react with ferric chloride. The residue decomposed with sulphuric acid gives gallic acid and the compound previously obtained by the action of zinc dust on tannin (*l.c.*) in approximately equal amount (Iljin, *ibid.* 1910, [ii.] 81, 327). Manning (J. Amer. Chem. Soc. 1910, 32, 1312) prepares *ethyl gallotannate* $C_{51}H_{52}O_{28}, 5H_2O$ yellow crystals, m.p. 157°, by passing dry hydrogen chloride into an alcoholic solution of gallotannin; this on hydrolysis gives ethyl alcohol, dextrose and gallic acid. This compound may be synthesised by treating a mixture of ethyl gallate and dextrose with phosphoryl chloride.

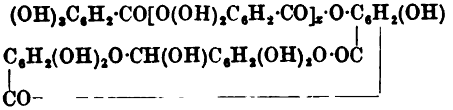
Fischer and Freudenberg (Annalen, 1911, 384, 225) coupled dicarbomethoxygallic acid and tricarbomethoxygallyl chloride in alkaline solution, and by hydrolysis of the resulting product, obtained a pure *digallic acid*. It crystallises in needles, is much less sparingly soluble in water than gallic acid (approximately 12 times), and melts at 275° (corr. 282°) with decomposition. With ferric chloride it gives a blue-black coloration and possesses the properties of a tannin. For a description of the diprotocatechuic acid, digentisic acid and di-β-resorcylic acid, of these authors, see below.

Paniker and Stiasny (Chem. Soc. Trans. 1911, 99, 1819), who consider that the chemical constitution of gallotannic acid is not definitely settled, investigated the acid character of this substance by the diazo-acetic ester method of Fraenkel (Zeitsch. physikal. Chem. 1907, 60, 202), because, according to the previously expressed view of Böttinger (Ber. 1884, 17, 1503), Dekker (*ibid.* 1906, 39, 2497), and Walden (*ibid.* 1898, 31, 3170), no free carboxyl group is present in this compound. It is shown that gallotannin is to be regarded as an acid, the affinity constant being of a distinctly higher order than that shown by phenols.

Gallotannin can be divided into two parts by saturating its solution with sodium bicarbonate, one part being soluble in ethyl acetate, whilst the other forms a sodium salt. Thus the former product is shown to be only half as acid as that which is set free on acidifying the sodium salt in solution. The experiments favoured the view of Kunz-Krause (Schweiz. Wochensch. Chem. Pharm. 1898, No. 38), Walden (*l.c.*), Aweng (Rev. Int. Falsif. 1898, 11, 29), and Nierenstein (*l.c.*), that gallotannin is a mixture of two or more chemical individuals.

With alcoholic potassium acetate, gallotannin gives a precipitate of the potassium salt which appears to have the unimolecular formula $C_{14}H_9O_9K$. This compound is devoid of optical activity.

According to Nierenstein (Annalen, 1912, 388, 223), when an aqueous solution of tannin is reduced with zinc dust by Iljin's method (*l.c.*), dl-*leucodigallic acid*, fine needles, m.p. 278°–280°, is produced, and the same compound can also be prepared by the reduction of digallic acid. By means of the carbethoxy derivative, this can be resolved into l-*leucodigallic acid*, m.p. 276°–277°, which has $[\alpha]_D^{15} -70\cdot26°$, and d-*leucodigallic acid*, m.p. 276°–277°, which has $[\alpha]_D^{19} +104\cdot2°$ in water. As leucodigallic acid does not possess tanning property, it cannot be present in gallotannin, and the author now therefore discards his theory that the latter is composed of a mixture of digallic and leucodigallic acids. Tannins are accordingly now considered to consist of *polydigallyl-leuco-digallic anhydrides*



$$\begin{array}{l} (OH)_3C_6H_2\cdot CO[O(OH)_2C_6H_2\cdot CO]_x\cdot O\cdot C_6H_2(OH) \\ C_6H_2(OH)_2O\cdot CH(OH)C_6H_2(OH)_2O\cdot OC \\ CO- \end{array}$$

Schering's tannin, employed by the author, gives digallic and leuco-digallic acids in the proportions 3 : 1 or 4 : 1 (compare Ber. 1907, 40, 916), and is consequently a digalloyl, tri- or tetraleucodigallic anhydride. For further details, the original paper must be consulted.

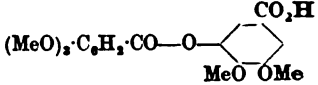
E. Fischer and Freudenberg (Ber. 1912, 45, 915) take an entirely different view of the constitution of gallotannin, and announce the important fact, not generally suspected, that this compound contains a glucose nucleus. Purified preparations of gallotannin have $[\alpha]_D^{20}$ approximately +70°, and these samples, when hydrolysed with acid, yield gallic acid and a small amount of dextrose. Gallotannin is most probably a compound of dextrose with five molecules of digallic acid, of the nature of penta-acetyldextrose, and such a constitution will agree with its high molecular weight, optical activity, faint acidity and ready solubility in water. Synthetical tannin compounds, derivatives of dextrose, are described, the properties of which favour this suggestion. Tricarbomethoxygalloyl chloride in chloroform solution reacts with dextrose in the presence of quinoline, to form penta-tricarbomethoxygallyl glucose, from which, by hydrolysis with alkali, *pentagalloyl glucose* is produced. It is a yellow powder of astringent taste, possesses the power of precipitating gelatin solutions, and has $[\alpha]_D +31°$ to +35° in water, or +44·4° in alcohol. Similar compounds of gallic acid with *a*-methylglucoside and glycerol, and of *p*-hydroxybenzoic acid with dextrose are also described.

Manning and Nierenstein (Ber. 1912, 45, 1546) consider that a sugar nucleus is not present in pure gallotannin, and point out that this is not produced when either Schering's tannin or Herzig and Renner's methyl tannin (*l.c.*) is hydrolysed with alkali. Again, ethyl gallate is the sole product of the esterification of this tannin.

Herzig (Ber. 1912, 45, 1985) considers that the argument of these authors is no proof of the absence of a sugar nucleus in methyl tannin or tannin itself, whereas Biddle and Kelley (J. Amer. Chem. Soc. 1912, 34, 918) show that the so-called ethyl tannate of Manning is in reality ethyl gallate. On the other hand, Feist reiterates the fact (Ber. 1912, 45, 1493) that in 1908 (Chem. Zentr. 1908, ii. 1352) he isolated glucogallic acid, a compound of gallic acid and glucose, from Turkish gall nuts.

Fischer and Freudenberg (Ber. 1912, 45, 2709) further support their view that gallotannin is a pentadigalloyl glucose, and in continuation of their syntheses of tannin compounds employ pentamethyl-*m*-digalloyl chloride with interesting results. Whereas the digallic acid previously synthesised by these authors is the *p* compound (Ber. 1910, 43, 628), gallotannin is derived from the *m*-acid, for Herzig has shown that methyl tannin, when hydrolysed, gives gallic acid trimethylether and 3 : 4 gallic acid dimethyl ether (*cf.* also Nierenstein).

When the trimethylether of galloyl chloride reacts with 3 : 4 gallic acid dimethyl ether, according to the method employed by these authors, *pentamethyl*-m-*digallic acid*



m.p. 192°–193°, is produced (*cf.* Mauthner, Ber. 1905, 38, 389; Monatsh. 1909, 30, 543), and from this the chloride, m.p. 109°–110°, is readily obtained. In the presence of quinoline, this is condensed with *a*- and *β*-glucose respectively, and such a procedure was adopted, because it was found that benzoyl and cinnamyl chlorides, in a similar manner, give with *a*- and *β*-glucose stereoisomeric compounds.

The *m*-digalloyl derivatives thus prepared are amorphous, possess the composition of penta-[pentamethyl-digallyl]-glucose, but appear in each case to be a mixture of stereo-isomerides Thus the *a*-glucose product in acetylene tetrachloride had $[\alpha]_D +28°$ (approx.), and after repeated solution in hot alcohol $[\alpha]_D +14°$ (approx.), whereas the *β*-glucose compound $[\alpha]_D +19\cdot5°$ behaved similarly.

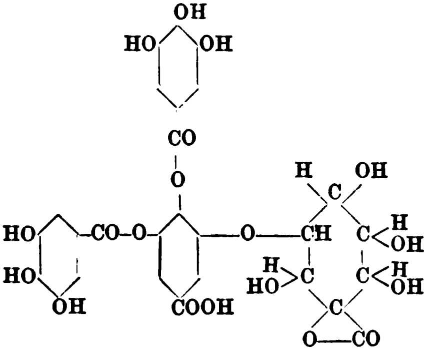
In case gallotannin is penta-*m*-digalloyl glucose it is evident that this product will represent its methyl ether, and indeed a very close resemblance appears to exist between this substance and the preparation of Herzig. The methyl ether prepared from natural tannin (Herzig, *l.c.*) is not a uniform substance, but probably also a mixture of stereo-isomerides, the sample employed having in acetylene tetrachloride $[\alpha]_D^{26} +14°$, and after repeated solution in acetone and methyl alcohol $[\alpha]_D^{21} +10\cdot6°$. Finally, the criticisms of Manning and Nierenstein (*l.c.*) as to the absence of glucose in pure tannin are shown to be valueless. It is likely that the work of Fischer and Freudenberg may soon culminate in the synthesis of penta-*m*-digalloyl glucose itself, in which case it is to be hoped that the mystery which has so long enshrouded the constitution of this important compound will be finally dispersed. On the other hand, the elaborate results of Nierenstein on such a basis are at present difficult to comprehend.

For further references to *Gallotannin* see Harnack (Arch. Pharm. 1896, 234, 537), colour reaction; Ljubavin (J. Russ. Phys. Chem. Soc. 1901, 33, 680), tannin and tartar emetic; Thibault (Bull. Soc. chim. 1903, (iii.) 29, 745), tannin and bismuth; Vigneron (J. Pharm. Chim. 1906, [vi.] 23, 469), iodotannin; Farbewerke vorm. Meister, Lucius and Brüning (D. R. P. 173729), mixed anhydrides of tannic and cinnamic acids; Biginelli (Gazz. chim. ital. 1907, 37, ii. 205; *ibid.* 1903, 38, i. 559), tannates of quinine; Hildebrandt (D. R. P. 188318), tannin and formaldehyde; Francis and Nierenstein (Collegium, 1911, 335), action of benzoyl chloride and potassium cyanide on benzoylhydroxybenzoic acids and on acylated hydroxybenzoylhydroxybenzoic acids; Nierenstein (Die Gerbstoffe).

Chestnut tannin. Chestnut tannin has been examined by Nass (Inaugural Diss. 1884, Dorpat, Russia) and by Trimble (The Tannins, ii. 119). According to the latter author it is probably identical with ordinary gallotannin (*see* CHESTNUT EXTRACT).

Chebulinic acid or Eutannin. This tannin was isolated by Fridolin from myrabolans, *Terminalia Chebula* (Retz.), which also contain an ellagitannin. It crystallises in rhombic prisms, is sparingly soluble in cold water, gives with ferric chloride a blue-black precipitate and by heating with water is converted into gallic acid and a new tannin.

Thoms (Chem. Zentr. 1906, i. 1829; Apotheker Zeit. 1906, 21, 354) has found that commercial *eutannin* is identical with chebulic acid $C_{28}H_{22}O_{19}$. It consists of small colourless needles, containing water of crystallisation, reacts acid to litmus paper, decomposes at 234°, and has $[\alpha]_D$ initially $+61·7°$, gradually rising to $+66·9°$. An *ennea-acetyl* and *methyl* derivative are described, the latter giving trimethylgallic acid by the action of sodium hydroxide solution. With water at 100°–150° the tannin yields gallic acid and *eutannin hydrate* $C_{28}H_{24}O_{20}$, a colourless powder decomposing at 200°–210°. When eutannin is dissolved in cold sodium hydroxide, the solution acidified with acetic acid, and then treated with lead acetate solution, the resulting precipitate, after decomposition with sulphuretted hydrogen, gives gallic acid, and a tannin $C_{14}H_{16}O_{12}$ or $C_{14}H_{14}O_{11}$, which consists of a yellow powder, having $[\alpha]_D +26°$ at 15°, and giving a blue coloration with ferric chloride. To chebulinic acid the following constitution is assigned:



According to Fischer and Freudenberg (Ber. 1912, 45, 915), when hydrolysed chebulinic acid gives dextrose.

Hamamelitannin. This compound, one of the few gallotannins to be isolated in a crystalline condition, occurs in the bark of the *Hamamelis virginiana* (Linn.), a tree, 10 to 12 ft. high, common in North America. The bark, previously extracted with light petroleum to remove plant wax, is exhausted with ether-alcohol (5 : 1), the solution evaporated, the residue dissolved in a little alcohol and treated with ether to precipitate certain impurities. Evaporation of the ethereal liquid gives a product, a hot aqueous solution of which, after treatment with alumina and animal charcoal, deposits, on cooling, the substance in the form of small colourless needles. From a dilute aqueous solution, hamamelitannin

$$C_{14}H_{14}O_9$$

crystallises with $5H_2O$, but deposited from strong solutions the crystals contain $2\frac{1}{2}H_2O$. The air-dried substance melts at 115°–117°, although when dried at 100° the melting-point is 203°. Hydrolysed with boiling dilute sulphuric acid, gallic acid only was produced, and the presence of a sugar could not be detected. Hamamelitannin is dextrorotatory $[\alpha]_D=+35·43°$. According to Fischer and Freudenberg (Ber. 1912, 46, 2712), however, this tannin can contain a sugar nucleus.

Benzoylhamamelitannin $C_{14}H_9O_9(C_7H_5O)_5$ is a yellow powder which melts at about 125°–132° (Grüthner, Arch. Pharm. 236, 303).

Oak wood tannin is probably a member of this group, but is described under the heading of *Phlobatannins*.

Sumach tannin (*see* SUMACH).

Diprotocatechuic acid is prepared by coupling monocarbomethoxyprotocatechuic acid with dicarbomethoxyprotocatechuyl chloride in alkaline solution and subsequently hydrolysing the product. It possesses the constitution

$$(OH)_2C_6H_3·CO·O·C_6H_3(OH)COOH,$$

and consists of fine needles which begin to sinter at 230° and melt with decomposition at 237°–239°. It is much more sparingly soluble in water than protocatechuic acid, gives with ferric chloride a bluish-green coloration and possesses tanning properties (Fischer and Freudenberg, Annalen, 1911, 384, 2, 238).

Di-β-resorcylic acid prepared from β-resorcylic acid by the same general method

$$(OH)_2C_6H_3·CO·O·C_6H_3(OH)COOH,$$

forms small microscopic needles, melting at 215° (corr.), sparingly soluble in water. It gives with ferric chloride a violet-red coloration and behaves as a tannin.

Digentisic acid

$$(OH)_2C_6H_3·CO·O·C_6H_3(OH)COOH$$

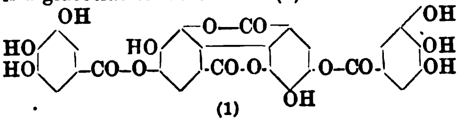
crystallises in fine needles, m.p. 208°–209° (corr.), sparingly soluble in water. The aqueous solution precipitates gelatin and gives a blue coloration with ferric chloride.

Fischer and Hoesch (*l.c.* 224) and Fischer and Lepsius (*l.c.* 224) have prepared numerous other acids of this type, but it is not stated as yet if these are to be regarded as tannins. Lecanoric acid, ramalic acid, evernic acid and no doubt other lichen acids which structurally belong to this group may be found also to possess tanning property.

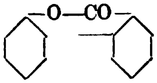
GROUP II.—DIPHENYLMETHYLOLID OR ELLAGITANNINS.

This tannin group, which has for its mother substance diphenylmethylolid (2), is at present only represented by one well authenticated member known as ellagitannin, unless indeed pomegranate tannin (*see* below) is a distinct compound. Whereas Perkin and Nierenstein

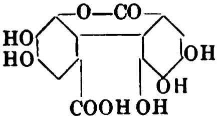
(Chem. Soc. Trans. 1905, 87, 1428) considered that ellagitannin was probably formed by the condensation of two molecules of digallic acid and possessed the formula (1) or was a glucoside of this substance, according to Nierenstein, ellagitannin (*q.v.*) (*cf.* also Ber. 1912, 45, 365) is a glucoside of luteoic acid (2).



(1)



(2)



(3)

Numerous natural tannin matters yield ellagic acid, but these have been little investigated, and it is likely that glucosides forming ellagic acid but differing from ellagitannin itself in the character of their sugar nuclei will be discovered.

Though various hydroxydiphenylmethylolid compounds have been synthetically prepared, *e.g.* metellagic acid $C_{15}H_5O_4(OH)$, catellagic acid $C_{14}H_4O_4(OH)_2$, flavellagic acid $C_{14}HO_4(OH)_5$ and cæruleoellagic (cyanellagic) acid $C_{14}O_4(OH)_6$, ellagic acid is the only member of this group which has been isolated from natural sources.

Pomegranate tannin $C_{20}H_{16}O_{13}$ is an amorphous greenish-yellow substance contained in the root bark of *Punica Granatum* (Linn.). Boiling dilute sulphuric acid hydrolyses it with formation of a sugar and ellagic acid (Rembold, Annalen, 143, 385).

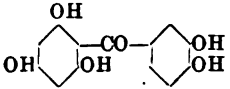
GROUP III.—CATECHOL OR PHLOBATANNINS.

The catechol tannins are characterised among other distinctive features by the important fact that when digested with boiling dilute mineral acids a red precipitate known as 'anhydride' or 'phlobaphane' is produced. The designation 'catechol,' arises from the fact that the majority of these substances give a green coloration with ferric chloride, and protocatechuic acid or catechol as one of their decomposition products. Such a classification is, however, misleading, in that by comparison with gallotannin, one is led to infer that these substances are similarly constituted and derived from diprotocatechuic acid only

$$(OH)_2C_6H_3\cdot CO\cdot O\cdot C_6H_3(OH)COOH.$$

When hydrolysed, however, diprotocatechuic acid gives two molecules of protocatechuic acid without production of phlobaphane (Emil Fischer, private communication). Moreover certain phlobaphane-yielding compounds are now known to exist in which a catechol nucleus is absent. Thus the cyanomaclurin of Jakwood (*q.v.*) is an instance in point, for although it contains only phloroglucinol and resorcinol nuclei, it readily yields a red anhydride of this character (*cf.* also Mimosa tannin, Pistachia tannin and Maletto · tannin). Evidently therefore the phlobaphane reaction is either due to the special structure of the tannin itself, or to the presence of a second phenolic grouping other than catechol in the molecule. This structure may perhaps vary in certain cases, but until this is clear it appears to be preferable to include all phlobatannins under one group rather than to complicate the subject by the introduction of subdivisions.

Böttinger and Etti (*l.c.*) have suggested a benzophenone structure for certain tannins, and this applied to the phlobatannins has, at first sight, the merit that *maclurin* (*see* OLD FUSTIC)



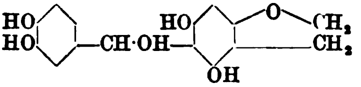
with dilute hydrochloric acid gives rufimoric acid (Wagner, Jahres. 1851, 420), a red amorphous phlobaphane-like mass. ***Kinoin*** (*see* Kino), usually regarded as the methyl ether of a pentahydroxy-benzophenone, is readily transformed into kino-red, whereas ***aromadendrin*** (*see* Kino), apparently also a benzophenone derivative, and probably a maclurin monomethyl ether, resembles, according to Maiden and Smith, ***catechin*** in many of its properties. It has not yet been ascertained if the carboxylic acids of certain hydroxybenzophenones are tannins, but on the other hand it is to be remembered that compounds possessing such a structure will be strong mordant dyestuffs, a property which is generally absent from tannins of the so-called catechol type. As already indicated, many phlobatannins are known which contain two distinct nuclei, more frequently phloroglucinol in addition to catechol, a fact which in these cases accounts for their reactivity with diazobenzene. More difficult to understand, however, is the precipitation of all phlobatannins in aqueous solution with bromine; this could be accounted for in those instances in which phloroglucinol or resorcinol nuclei are present in the compound, but curiously enough no difference in this respect appears to have been observed in cases where evidence as to the existence of these latter groupings has been of a negative character. Though by incautious alkali fusion, the existing phloroglucinol nucleus may escape detection and probably in many instances has done so, this evidence is such that it is hard to presume that in all cases bromine precipitation arises from the presence in these compounds of a specific phenolic grouping.

It is most probable that the phlobaphane reaction is, in many cases, to be assigned to the well-known reactivity of the phloroglucinol group present in these substances, and this has also been suggested by Emil Fischer. Thus coloured compounds can be obtained by the interaction of phloroglucinol with many aldehydes of which the red phloroglucinol vanillein is an example, and moreover the phloroglucides of Counder (Ber. 1895, 28, 26), prepared by passing hydrogen chloride into mixtures of phloroglucinol and various sugars in aqueous solution are coloured, the *d*-galactose phloroglucide possessing a red tint. Again, by boiling dextrose and phloroglucinol with dilute hydrochloric acid, a brownish-red precipitate of a phlobaphane-like character can be easily produced (private communication). Interesting in this respect also is the 'phlorotannin red' of Schiff (Annalen, 245, 40), which he obtained by heating his so-called diphloroglucinol carboxylic acid to 160°–175°.

That phlobatannins like gallotannin owe their tanning property, as a rule, to the depside grouping appears likely, and it has been observed by Trimble (The Tannins, II. 91) that tannins from various species of oak, on long digestion with boiling 2 p.c. hydrochloric acid, give not only phlobaphane but some quantity of protocatechuic acid.

In the light of the researches of E. Fischer and Freudenberg (*l.c.*), it is also to be anticipated that many of these compounds will be eventually found to possess a sugar nucleus.

Closely connected with the phlobatannin group are the well-defined crystalline substances catechin, aca-catechin and cyanomaclurin, to the first of which the constitution



has been assigned by v. Kostanecki and Lampe.

Catechin, although not a tannin, reacts with pine wood and hydrochloric acid, gives with bromine water the insoluble bromcatechuretin and readily yields substances of the phlobaphane character. Though the evidence is not precise it is stated by Loewe and also by Etti that catechin can be readily transformed into catechutannic acid, a substance existing side by side with it in the plant and possessing properties typical of the phlobatannin group. This change from catechin to catechutannic acid occurs, it is suggested, by mere abstraction of water, presumably between two molecules, and in any case it is difficult to understand how, by the simple processes employed, a depside grouping could be here produced. If, therefore, the statement of these authors is correct, some explanation other than those suggested above is required to express the tanning properties of this compound, and indeed there is no absolute reason to presume the depside grouping to be essential in this respect. It has indeed been surmised that the catechol tannins of numerous plants owe their origin to the prior existence of substances of the catechin type, and that in addition to the compounds previously enumerated, the so-called quebracho resin and guarana catechin are intermediate products of tannin formation. Again, according to Procter (private communication), a colourless catechin-like substance is to be found in mangrove cutch.

With the exception of coca-tannic acid, no crystalline catechol tannins have been described, but all are amorphous and very similar in appearance to natural gallotannin, although on keeping, especially in the moist condition, they are apt to develop a red tint. According to Perkin, most phlobatannins can be prepared in a nearly colourless condition by extracting a solution of the crude tannin to which sodium bicarbonate has been added with ethyl acetate (*cf. Gallotannin*).

Numerous phlobatannins have been isolated, and a description of them is given below, although it is extremely doubtful whether the majority of these are individuals. In many cases, indeed, the general reactions of these compounds are the same, and considering the extreme difficulty in the effective purification of amorphous preparations of this character, specific differences which have been observed will no doubt, on further investigation, largely disappear. Trimble (*l.c.* ii. 132), who submitted certain phlobatannins to careful purification, found that there was a fair approximation in their percentage compositions, and it is thus natural to presume that the known members of this group are not so numerous as was formerly considered to be the case.

Anachueta wood and bark contain a tannin which gives a green coloration with iron salts.

Aspertannic acid $C_{14}H_{16}O_8$ was obtained by Schwarz from Woodruff (*Asperula odorata* [Linn.]), and gives a green colour with ferric salts. It does not yield precipitates with albumen, gelatin, and tartar emetic solutions.

Atherospermatannin from the bark of *Atherosperma moschatum* (Labill.), gives a green colour with ferric salts. A lead salt $C_{10}H_{14}PbO_9$ has been described by Zeyer (Jahrb. Min. 1861, 769).

Barbitamao tannic acid from the bark of the *Stryphnodendron Barbatimum* (Mart.) (Wilbuszwitcz, Ber. Ref. 1886, 19, 349), is an amorphous red powder, which yields a phlobaphane and, on fusion with alkali, *protocatechuic acid* and *phloroglucinol*.

Beech tannin from the bark of the red beech contains a tannin of the composition $C_{20}H_{22}O_9$ (Etti, Monatsh. 10, 650).

Caffetannic acid $C_{15}H_{18}O_9$ occurs in coffee berries in the form of calcium and magnesium salts (Rochleder, Annalen, 59, 300); in cainia root *Chiococca brachiata* (Ruiz. et Pav.) (Rochleder and Hlasiwetz, *ibid.* 1848, 66, 35); *Nux vomica* (Sander, Arch. Pharm. 1897, 235, 133); St. Ignatius beans (*ibid.*) and Paraguay tea, *Ilex paraguensis* (A. St. Hill.) (Rochleder, Annalen, 1847, 66, 39) (*cp.* also Graham, Stenhouse and Campbell, J. pr. Chem. 1856, 69, 815; Arata, Ber. 1881, 14, 2251; Kunz-Krause, Arch. Pharm. 1893, 231, 613; Ber. 1897, 30, 1617).

It is an amorphous powder readily soluble in water, gives a dark green coloration with ferric chloride, and when boiled with potassium hydroxide solution gives *caffeic acid* and a sugar (Hlasiwetz, Annalen, 1866, 142, 220), which is glucose (Sander, *l.c.*). On dry distillation *catechol* is formed, and by fusion with alkali *protocatechuic acid* is obtained. The ammoniacal solution becomes green on exposure to air with formation of viridic acid, a substance which is also present in coffee berries in the form of its calcium salt (Rochleder, Annalen, 63, 197). According to Griebel (Inaugural Diss. Munich, 1903) caffetannic acid is $C_{13}H_{24}O_{10}$, and a penta-acetyl derivative corresponding to this formula is described.

Callutannic acid $C_{14}H_{14}O_9$ contained in heather, *Calluna vulgaris* (Salisb.), is an amber coloured substance. It gives a green coloration with ferric chloride and when heated with dilute mineral acids yields an amorphous anhydro derivative $C_{14}H_{10}O_7$ (Rochleder, Annalen, 84, 354; Sitz. Ber. 9, 286).

Canaigre tannin is present in the tuberous roots of the *Rumex hymenosepalus* (Torr.), an important American tanning material. It has been submitted to an elaborate examination by Trimble (The Tannins, 1894, ii. 115), who describes it as a yellowish-white powder readily soluble in water, which gives with lead acetate solution a yellow precipitate, and with ferric chloride a green precipitate. It reacts with bromine water to give a yellow deposit, and on heating to 160°–190° is decomposed with production of *catechol.* Boiling 2 p.c. hydrochloric acid yields an insoluble red phlobaphane together with some *protocatechuic acid.* Sugar is not formed in this decomposition. Analysis gave C=58·10 ; H=5·33, figures which approximate to, though they are somewhat lower than, those given by the best known phlobatannins.

Catechu-tannic acid (see CATECHU).

Cherry-bark tannin $C_{21}H_{20}O_{10}+\frac{1}{2}H_2O$ is present in the bark of the *Prunus Cerasus* (Linn.) (Rochleder, Sitz. Ber. 59, 819) and gives a green coloration with ferric chloride. It is not a glucoside but when digested with boiling dilute acids gives a red phlobaphane $C_{21}H_{18}O_8+\frac{3}{4}H_2O$.

Cocatannic acid $C_{17}H_{22}O_{10}+2H_2O$ (?) present in the leaves of the *Erythroxylon Coca* (Linn.) (Niemann, Jahrb. Min. 1860, 386), is sparingly soluble in cold water and gives a green coloration with ferric salts. According to Warden (Pharm. J. 18, 985) it can be obtained in microscopic crystals of a sulphur yellow colour.

Colatannin or **Kolatannin** $C_{16}H_{20}O_8$, a light red amorphous powder, exists in the Kola nut, *Cola acuminata* (Schott and Endl.), in combination probably with caffeine and theobromine (Knox and Prescott, J. Amer. Chem. Soc. 1897, 19, 63). With ferric acetate it gives a green coloration, and on fusion with alkali *protocatechuic acid* is obtained. *Penta-acetylkolatannin* $C_{16}H_{15}O_8(C_2H_3O)_5$ colourless powder, *tribromkolatannin* $C_{16}H_{17}O_8Br_3$ red-brown powder, *penta-acetyl-tribromkolatannin* $C_{16}H_{12}O_8Br_3(C_2H_3O)_5$, *pentabrom*, and *hexabromkolatannin* have been described. On heating, kolatannin yields various anhydrides $(C_{16}H_{19}O_7)_2O$ at 107°–110°, $(C_{16}H_{17}O_6)_2O$ at 135°–140° and $C_{16}H_{16}O_6$ at 155°–156°.

Cortepinitannic acid $C_{32}H_{34}O_{17}$ occurs together with pinicortannic acid in the bark of the Scotch fir, *Pinus sylvestris* (Linn.). It consists of a bright red powder, the aqueous solution of which gives an intense green coloration with ferric chloride (Kawalier, Sitz. Ber. 11, 363).

Euphrasia tannin is present according to Enz (Vierteljarsch. Pharm. J. 8, 175) in the green parts of *Euphrasia officinalis* (Linn.), and gives a green colour reaction with ferric salts. Its lead salt has the composition $C_{32}H_{20}Pb_3O_{20}$.

Fragarianin *v. Strawberry tannin.*

Filitannic acid $C_{41}H_{36}NO_{18}$ (?) exists in fern-root (*Aspidium filix mas* (Swartz.)) (Malin, Annalen, 143, 276), and forms a red-brown powder which, in aqueous solution, gives an olive green coloration with ferric chloride. By boiling with dilute sulphuric acid it gives *filix red* $C_{20}H_{18}O_{12}$, an amorphous compound, and this when fused with alkali gives *phloroglucinol* and *protocatechuic acid* (*cp.* also Reich, Arch. Pharm. 1900, 238, 648).

Fraxitannic acid $C_{26}H_{32}O_{14}$ (?) occurs in the leaves of the ash tree *Fraxinus excelsior* (Linn.). It consists of a brownish-yellow deliquescent powder, and when heated at 100° loses water and forms an almost insoluble anhydride $C_{26}H_{30}O_{15}$ (Gintl and Reinitzer, Monatsh. 3, 745). Aqueous ferric chloride produces a dark green coloration, and when oxidised with permanganate this tannin yields quinone. *Acetylfraxitannic acid* $C_{26}H_{28}O_{14}(C_2H_3O)_4$, *benzoylfraxitannic acid* $C_{26}H_{28}O_{14}(C_7H_5O)_4$, *tribromfraxitannic acid* $C_{26}H_{29}Br_3O_{14}$, and *tetra-acetyltribromfraxitannic acid*

$$C_{26}H_{25}Br_3O_{14}(C_2H_3O)_4$$

have been described.

Galitannic acid $C_{14}H_{16}O_{10},H_2O$ exists in the bark of the *Galium verum* (Linn.) (Schwarz, Annalen, 83, 57). It gives a yellow precipitate with basic lead acetate and a green colour reaction with ferric chloride.

Guarana tannin is present in the *Paullinia Cupana* (H. B. and K.), the seeds of which, known as 'guarana,' contain theine and are extensively used in South America for medicinal purposes. According to Nierenstein (Die Gerbstoffe, 20) the tannin consists of small colourless crystals, m.p. 199°–201°, and yields an acetyl derivative, m.p. 134°–136°. It is lævorotatory, having $[\alpha]_D^{20} = -72{\cdot}4°$ in water, and $[\alpha]_D^{20} = -39{\cdot}1°$ in alcohol.

Hemlock tannin $C_{20}H_{18}O_{10}$ (?) is present in Hemlock bark, *Tsuga* [*Abies*] *canadensis* (Carr), the extract of which is prepared on a very large scale in North America for tanning purposes. According to Böttinger (Ber. 1884, 17, 1125), it is probably related to the quercitannic acid of the oak and on heating with sulphuric or hydrochloric acid gives the anhydride *hemlock red* $C_{40}H_{30}O_{17}$. With hydrochloric acid at 180°, hemlock red evolves methyl chloride : when heated with acetic anhydride the acetyl compound $C_{40}H_{23}O_{17},(C_2H_3O)_7$ is produced, whereas bromine gives a mixture of the compounds $C_{40}H_{20}Br_{10}O_{17}$ and $C_{40}H_{16}Br_{14}O_{17}$. Bromine added to the diluted tannin extract precipitates *tetrabromhemlock tannin* $C_{20}H_{14}Br_4O_{10}$, a yellow powder which yields the *penta-acetyl* derivative $C_{20}H_9Br_4O_{10}(C_2H_3O)_5$, and by the further action of bromine the bromine compound $C_{20}H_{12}Br_6O_{10}$ (*cp.* Trimble, Amer. J. Pharm. 1897, 69, 354, 406 ; J. Soc. Chem. Ind. 1898, 17, 558) is produced.

Hop-tannin $C_{22}H_{26}O_9$ present in hops (*Humulus Lupulus* [Linn.]) (Etti, Annalen, 180, 223 ; Monatsh. 10, 651) has all the properties of a catechol tannin. It gives with ferric chloride a dark green coloration and with boiling dilute mineral acid the phlobaphane 'hop red' $C_{32}H_{26}O_{15}$. Hop red forms a cinnamon coloured powder and on fusion with potash yields *phloroglucinol* and *protocatechuic acid.*

Horse chestnut tannin $C_{26}H_{24}O_{12}$ is present in nearly all parts of the *Aesculus Hippocastanum* (Linn.) and in the root bark of the apple tree (Rochleder, Sitz. Ber. 53, [ii.] 478 ; 54, [ii.] 609). It consists of a nearly colourless powder, the solution of which gives a green coloration with ferric chloride, and when boiled with dilute mineral acid the phlobaphane $C_{26}H_{22}O_{11}$ or $C_{26}H_{20}O_{10}$. On fusion with alkali, *phloroglucinol* and *protocatechuic acid* are produced. *V.* also *phyllæscitannin* and article CHESTNUT EXTRACT.

Ipecacuanhic acid $C_{14}H_{18}O_7$ was obtained by Willigt (Annalen, 76, 345) from the roots of *Psychotria Ipecacuanha* (Stokes), and consists of a reddish-brown, bitter hygroscopic substance. Its solution gives a green coloration with ferric chloride.

Japonic acid (see CATECHU).

Kino v. Article.

Larch tannin. The bark of the larch *Larix europaea* (DC.) contains considerable quantities of a tannin which was examined by Stenhouse (Phil. Mag. 23, 336). It forms an olive green precipitate with ferric salts, and when boiled with dilute sulphuric acid a red phlobaphane is produced.

Maletto tannin occurs in the bark of *Eucalyptus occidentalis* (Endl.) and other species of eucalyptus. According to Strauss and Geschwender (Zeitsch. angew. Chem. 1906, 19, 1121) it possesses the formula $(C_{43}H_{50}O_{20})_2$ and appears to be identical with quebracho tannin. Dekker (Arch. Néerland, 1909, ii. 14, 50) prefers the formula $(C_{19}H_{20}O_9)_n$ and describes the acetyl derivative $C_{38}H_{23}O_{17}Ac_{10}$ and benzoyl derivative

$$C_{19}H_{25}O_{12}Bz_5.$$

Heated with zinc dust and sodium hydroxide solution the tannin gives small quantities of *gallic acid* and *phloroglucinol*, whereas dry distillation yields *pyrogallol* and traces of other phenols. Boiling dilute sulphuric acid forms 'malleto red' $C_{57}H_{50}O_{22}$ from which the *acetyl* derivative $C_{57}H_{35}O_{22}Ac_{15}$ can be obtained.

Mangrove tannin $C_{24}H_{26}O_{12}$. This important tannin is derived from the *Rhizophora Mangle* (Linn.), *R. mucronata* (Lam.), *Ceriops Candolleana* (Arn.), *C. Roxburghiana* (Arn.), and other allied species. It is described as an amorphous red powder, which on fusion with alkali gives *protocatechuic acid*, and with boiling dilute sulphuric acid the phlobaphane $C_{48}H_{46}O_{21}$. The *monacetyl* derivative $C_{24}H_{25}O_{12}(C_2H_3O)$ melts at 205° (Nierenstein. Die Gerbstoffe). This tannin closely resembles in its properties catechutannic acid (*see* CATECHU) and indeed mangrove cutch and catechu may be employed in many cases for the same purpose. Possibly these two substances are identical and Procter (private communication) has isolated from mangrove cutch a small quantity of a colourless crystalline substance resembling catechin. Perkin who examined an ethyl acetate extract of the fresh bark of the *C. Candolleana*, prepared in Borneo, was unable to detect the presence of a catechin, but obtained the tannin as a pale yellow powder, which gave a green coloration with ferric chloride solution, and resembled catechutannic acid in many respects.

Mimosa tannin is derived from various species of *Mimoseae*, such as the *Acacia arabica* (Willd.) of Egypt, the so-called 'Wattles' of Australia, and numerous others. The tannin present is interesting in that though it possesses the reactions of a phlobatannin, such as phlobophane production, precipitation by bromine water and solubility of its lead compound in acetic acid, &c., it gives a bluish-violet coloration with ferric chloride. Ammonium sulphide gives a precipitate with a mimosa solution when after removal of the excess by boiling, a few drops of sulphuric acid are added, followed by a small quantity of salt. All other phlobatannins, except Maletto and Pistaschia tannins, give no precipitate by this method (Stiansy, private communication).

Moritannic acid, see *Maclurin*, art. OLD FUSTIC (Old Fustic is apparently not a tannin matter).

Oxypinitannic acid v. *Pinitannic acid.*

Oak bark tannin or *Quercitannic acid* is found in the bark of the oak, and is not to be confused with the tannin of oak-wood from which it is distinct, and which is described below under the name of quercinic acid. In 1792, George Swayne communicated to the Society of Arts his results on the use of oak leaves in tanning (Trimble, The Tannins, ii. 51), and it was again discussed by Berzelius in his Lehrbuch, 1827, and by Liebig (Handbuch der Chemie, 1843). Assumed at that time to be identical with the tannin of nut-galls (gallotannin), it was first shown by Stenhouse (Phil. Mag. 22, 425) to differ from this substance. According to Grabowski (Sitz. Ber. 56, [ii.] 388), Oser (*ibid.* 72, [ii.] 178), Johanson (Arch. Pharm. [iii.] 9, 210), Böttinger (Ber. 14, 1598), quercitannic acid is in reality a glucoside, but Etti (Ber. 14, 1826; Monatsh. 4, 512) showed that the pure substance did not yield a trace of sugar. Various formulæ have been assigned to this substance, viz. Eckert (J. 1864, 608) $C_{28}H_{20}O_{20}$; Oser (J. 1875; 600) $C_{30}H_{20}O_{11}$; Löwe (Zeitsch. anal. Chem. 20, 210) $C_{25}H_{30}O_{15}$; Böttinger (Ber. 1883, 16, 2712) $C_{15}H_{12}O_9,2H_2O$, and Etti (Monatsh. 10, 650) $C_{17}H_{16}O_9$, $C_{18}H_{18}O_9$ and $C_{20}H_{20}O_9$.

Quercitannic acid is described by Etti as a reddish-white powder almost insoluble in water. One of its most characteristic properties is the readiness with which it forms reddish-brown anhydrides when heated by itself or with dilute acids. Thus at 130°–140° the *first anhydride* $C_{34}H_{30}O_{17}$ is produced, and this by heating with dilute sulphuric or hydrochloric acid gives the *second anhydride* $C_{34}H_{28}O_{16}$. Boiling dilute sulphuric acid again converts the original tannin into the *third anhydride*

$$2C_{17}H_{16}O_9-3H_2O=C_{34}H_{26}O_{15}.$$

These compounds are insoluble in water, but coloured a solution of ferric chloride blue. Löwe (*l.c.*) again examined an anhydride $C_{28}H_{24}O_{12}$ and an 'oak red' $C_{28}H_{22}O_{11}$. Böttinger, who prepared the oak red from the tannin by means of dilute sulphuric acid, adopted the formula $(C_{14}H_{10}O_6)_2,H_2O$. Etti (Ber. 1884, 17, 1823) isolated from the bark of the *Quercus pubescens* (Willd.) a tannin $C_{20}H_{20}O_9$, practically identical with the substance $C_{17}H_{16}O_9$ previously found in the *Q. robur* (Linn.), but giving a green solution with ferric chloride, and not a blue, as formerly stated.

When heated with dilute sulphuric acid at 130°–140°, quercitannic acid gives in addition to anhydride 1·5 p.c. of *gallic acid*, and with strong hydrochloric acid at 150°–180° the formation of oak red was accompanied by the evolution of methyl chloride (Etti, Monatsh. 1, 274). On dry distillation it yields *dimethylcatechol* and *catechol*, and on fusion with alkali *protocatechuic acid*, *catechol*, and *phloroglucinol*.

By the action of bromine on the aqueous bark extract, Böttinger (Ber. 1883, 16, 2710) obtained *dibromquercitannic acid* $C_{19}H_{14}Br_2O_{10}$ as a yellow precipitate, and from this *pentaacetyldibromquercitannic acid* was prepared. Heated with hydrochloric acid at 180°, *methyl chloride* was evolved, and by means of hydroxylamine hydrochloride the compound

$$C_{19}H_{15}Br_2NO_{10}$$

was produced. Reduced with sodium amalgam *hydroquercinic acid* $C_{15}H_{14}O_7$ or $C_{15}H_{16}O_6$ ar *hydroquergalic acid* $C_{14}H_{14}O_6$ are formed (Annalen, 263, 121). When suspended in chloroform and further brominated it yields tetrabromdehydroquercitannic acid. Quercitannic acid was thus $C_{19}H_{16}O_{10}$, contained five hydroxyls, and the group $COOCH_3$.

According to Etti (Monatsh. 10, 647), a further investigation of the tannins $C_{17}H_{16}O_9$ and $C_{20}H_{20}O_9$ has proved that they are not glucosides, but derivatives of a ketonic acid

$$C_6H_2(OH)_3CO{\cdot}C_6H(OH)_3COOH.$$

Trimble (The Tannins, 1894, ii. 77) carried out an elaborate investigation of the tannins present in the barks of the *Quercus alba* (Linn), *Q. coccinea* (Wargenh.), *Q. discolor* (Ait.), *Q. falcata* (Michx.), *Q. palustris* (Du Roi), *Q. Prinus* (Linn.), *Q. bicolor* (Willd.), *Q. obtusiloba* (Michx.), *Q. phellos* (Linn.), *Q. rubra* (Linn.), *Q. robur* (Linn.), *Q. semicarpifolia* (Sm.), employing acetone for the purpose of extraction. The tannins in most cases had a pale yellow colour, gave with ferric chloride a *green* coloration, and practically identical results with all the usual tannin reagents.

Heated with glycerol at 160°, the tannins of *Q. tinctoria*, *Q. palustris*, *Q. falcata* and *Q. phellos* yielded *catechol*, whereas with fused alkali the eight samples examined gave *protocatechuic acid*. Though all these compounds produce a violet colour on pine wood moistened with hydrochloric acid, phloroglucinol or other phenol was not detected among their decomposition products. Heated with 2 p.c. hydrochloric acid for two and a half hours, a phlobaphane separated, whereas the solution contained protocatechuic acid. Analyses of nine of these tannin preparations showed but little variation, the average being C=59·79; H=5·08, and approximately correspond with those of Etti (*l.c.*) for the tannin $C_{20}H_{20}O_9$ from *Q. pubescens*, and of Kraemer (Amer. J. Pharm. 1890, 236) for the tannin of *Q. alba*.

Oak wood tannin, *Quercin*, *Quercic acid*, *Quercinic acid* $C_{15}H_{12}O_9,2H_2O$ consists of a light brownish-yellow substance, and is distinguished from the quercitannic acid of oak bark in that its aqueous solution gives a blue, not green, coloration with ferric chloride, and does not yield a precipitate with bromine water (Böttinger, Ber. 1887, 20, 761).

With the object of isolating the tannin in a pure condition Böttinger acetylated a purified extract of the wood, and decomposed the acetyl compound $C_{15}H_7(C_2H_3O)_5O_9$ by heating it with water at 135°. By the action of sodium amalgam on the acetyl derivative, Böttinger (Annalen, 263, 110) obtained *hydroquercic acid* $C_{15}H_{18}O_7$ or $C_{15}H_{16}O_6$, *querlactone* $C_5H_6O_2$ and an acid which is probably trihydroxybutyric acid.

Hydroquercic acid is a grey-brown, bitter, hygroscopic powder, which forms the *acetyl* derivative $C_{15}H_{14}(C_2H_3O)_2O_6$, the *barium* salt $(C_{15}H_{15}O_6)_2Ba$, and the *lead* salt $(C_{15}H_{15}O_6)_2Pb$. Querlactone, on the other hand, forms the salt $(C_5H_7O_3)_2Pb$. As above noted, hydroquercinic acid could also be obtained in a similar manner from quercitannic acid.

Etti (Monatsh. 10, 647) isolated from the wood of the Slavonian oak a tannin $C_{16}H_{14}O_9$ which appeared to be a ketonic compound. This is present in wood in the form of a readily soluble salt (probably magnesium salt). Crystallised from alcohol, it forms brownish-red microscopic warty spherical masses, insoluble in water, and having the properties of a monobasic acid (*cf.* Fuchs, Monatsh. 9, 1132). With phenylhydrazine it gives the compound

$$C_{22}H_{20}N_2O_8,$$

forms a brown amorphous oxime $C_{16}H_{15}NO_9$ and with dilute sulphuric acid at 120°–130° yields *gallic acid* in addition to a red anhydride. Heated alone at 130°–135°, or in a sealed tube with water at 100°, anhydrides are also produced, which on boiling with hydriodic acid evolve methyl iodide. On long digestion of the tannin $C_{16}H_{14}O_9$ with hydrochloric acid at 100°, a methoxyl group is split off, with production of an acid $C_{15}H_{12}O_9$ of a yellow colour in which a methoxyl group is still present. This tannin is therefore probably the dimethyl ether of the ketonic acid formulated above.

On boiling the tannin with dilute sulphuric acid, the anhydride $C_{32}H_{24}O_{16}$ is produced, whilst on heating in a closed tube the anhydrides $C_{32}H_{20}O_{14}$ and $C_{32}H_{18}O_{13}$ were obtained.

The varied results of many of these workers with the oak tannins appear to be due, as suggested by Trimble, to the fact that in many cases they employed oak tannin extracts of doubtful authenticity. Thus it is possible that Etti, who in his earlier work describes the tannin as producing a blue coloration with ferric chloride, was in reality examining oak wood and not oak bark preparations, and again the peculiar insoluble property of certain of his tannins, also commented on by Trimble, suggests that in these cases he investigated an anhydride rather than the tannin itself. That oak barks contain only a phlobatannin appears to be certain from the investigations of Trimble, and it seems probable that in the wood a pyrogallol tannin alone exists. Though, as stated above by Etti in the case of the Slavonian oak, this yields phlobaphanes, Stiasny (private communication) has found that such is not usually the property of oak-wood extracts. An interesting point, moreover, apparently not stated in the literature, though well known to tanners, is that oak-wood extracts give some ellagic acid, and on this account impart to leather the 'bloom' so characteristic of this substance.

Oenotannin $C_{19}H_{16}O_{10}$ (?) was obtained by Gautier from red wine (Bull. Soc. chim. 1877, 27, 496), who describes it as a colourless substance readily soluble in water. It gives a green coloration with ferric chloride solution, by fusion with alkali *protocatechuic acid* and *phloroglucin*, and when exposed to moist air becomes converted into an insoluble red phlobaphane-like substance. According to Heise (Ber. Ref. 22, 823), oenotannin contains gallotannin and is a mixture of three substances.

Pistachia tannin is present in the leaves of the *Pistacia Lentiscus* (Linn.) in addition to some quantity of a gallotannin (Perkin and Wood, Chem. Soc. Trans. 1898, 73, 378), and consists of a pale-brown brittle mass which with iron alum solution give a blue-black coloration. With boiling dilute sulphuric acid a phlobaphane quickly separates, and when fused with alkali *gallic acid* and *phloroglucinol* are produced.

Phyllæscitannin is the name given by Rochleder to a tannin present in the small leaflets of the horse chestnut, as long as they remain enclosed in the buds (Zeitsch. Chem. 1867, 84). It is described as an amorphous red-brown substance of the formula $C_{26}H_{24}O_{13},H_2O$, having a strongly astringent taste.

Pinicortannic acid and **cortepinitannic acid** occur in the bark of the Scotch fir *Pinus sylvestris* (Linn.), and can be separated owing to the fact that in aqueous solution the former only is precipitated by means of lead acetate. Pinicortannic acid forms a reddish-brown powder of the composition $(C_{16}H_{18}O_{11})_2,H_2O$, which after drying is sparingly soluble in water. It gives a green coloration with ferric chloride, and when boiled with dilute acids gives the phlobaphane $C_{48}H_{50}O_{21}$ (Kawalier, Sitz. Ber. 11, 361).

Pinitannic acid and **oxypinitannic acid** occur in the needles of the Scotch fir *Pinus sylvestris* (Kawalier), and are distinguished from one another by the fact that the former only is precipitated by lead acetate solution. *Pinitannic acid*, according to Rochleder (Sitz. Ber. 29, 60), also present in the *Thuja occidentalis*, is a reddish-yellow substance which gives a red-brown coloration with ferric chloride and when boiled with dilute acids a sparingly soluble red product (phlobaphane).

Oxypinitannic acid, on the other hand, forms a green solution with ferric chloride (Kawalier).

Quebracho tannin or *Quebrachitannic acid*, see QUEBRACHO COLORADO.

Quinotannic acid or *Cinchonatannic acid* obtained from cinchona bark is a light yellow very hygroscopic substance, a solution of which gives a green precipitate with ferric salts. On digestion with boiling dilute sulphuric acid, it is converted into a sugar and cinchona red $C_{28}H_{22}O_{11}$ (Rembold, Annalen, 143, 270), and from the latter by fusion with alkali, *protocatechuic* and acetic acids are produced (Hlasiwetz, *ibid.* 143, 307). According to Schwarz (Sitz. Ber. 7, 250), quinotannic acid has the composition $C_{14}H_{16}O_9$, whereas cinchona red is to be represented as $C_{12}H_{14}O_6$.

Quinovatannic acid, contained in the bark of the *Cinchona nova*, in many respects resembles quinotannic acid (Hlasiwetz, Annalen, 79, 129). With ferric chloride it gives a dark green coloration and with boiling dilute acids quinova red $C_{12}H_{12}O_5$ is produced. On fusion with potash it yields *protocatechuic acid*.

Rhamnotannic acid (so called) present in buckthorn berries is, in reality, not a tannin matter.

Rhatany tannin $C_{20}H_{20}O_9$ from the bark of rhatany root, *Krameria triandra* (Ruis and Pav.) (Willstein, J. 1854, 656) is described by Raabe (*ibid.* 1880, 1060) as a light yellow powder, readily soluble in water. Its solution gives with ferric chloride a green coloration. When heated with dilute acids it yields rhatany red $C_{22}H_{22}O_{11}$ and a sugar (Grabowski, Annalen, 143, 274), whereas according to Raabe (*l.c.*) no sugar is thus produced and the red substance possesses the composition $C_{26}H_{18}O_8$. By dry distillation rhatany red yields catechol, *protocatechuic acid* and *phloroglucinol* when fused with alkali.

Rheotannic acid or *Rhubarb tannic acid* $C_{26}H_{26}O_{14}$, derived from rhubarb, forms a yellowish-brown readily soluble powder, the solution of which gives with ferric chloride a black green precipitate. With boiling dilute acids it gives *rheic acid* (rheumic acid) $C_{20}H_{16}O_9$ and a fermentable sugar (Kubly, Zeitsch. Chem. 1868. 308), although according to Tschirch and Neuberger (Schweiz. Wochenschr. Chem. Pharm. 1902, 282) in this manner *rheum-red* $C_{40}H_{32}O_{18}$, *cinnamic acid*, *gallic acid* and sugar are produced. According to Gilson (Chem. Zentr. 1903, i. 722, 882), two glucosides are present, *glucogallin* $C_{13}H_{16}O_{10}$, giving gallic acid and dextrose, and *tetrarin* $C_{32}H_{32}O_{12}$ from which *rheosurin* $C_{10}H_{12}O_2$, *cinnamic acid*, and *gallic acid* can be produced. According to Krembs (Inaugural Diss. 1903, Berne), a catechin is also present in rhubarb.

Rhodotannic acid $4C_{14}H_{12}O_7,3H_2O$, found in the leaves of *Rhododendron ferrugineum* (Linn.) is an amber coloured substance which gives a green coloration with ferric chloride solution. Heated with dilute mineral acids, a reddish-yellow precipitate of *Rhodoxanthin* $C_{14}H_{14}O_8$ is produced (Schwarz, Sitz. Ber. 9, 298).

Rubinic acid *v.* CATECHU.

Rubitannic acid $2C_{14}H_{22}O_{12}+H_2O$ was obtained by Willigt (Annalen, 82, 340) from the leaves of *Rubia tinctorum* (Linn.). It gives a green colour reaction with ferric chloride.

Sequiatannic acid $C_{21}H_{20}O_{10}$ was isolated from the cones of *Sequoia gigantea* (Torr) (California) by Heyl (Pharm. Centr. 1901, 42, 379) as a reddish-brown powder, soluble in water and yielding the salts $MgC_{21}H_{18}O_{10}$ and $CaC_{21}H_{18}O_{10}$. Boiled with dilute sulphuric acid, a *phlobaphane, gallic acid*, and a sugar are produced. The *hexa-acetyl* $C_{21}H_{14}O_{10}(C_2H_3O)_6$, *hexabenzoyl* $C_{21}H_{14}O_{10}(C_7H_5O)_6$ and *bromine* $C_{21}H_{15}O_{10}Br_5$ derivatives of this tannin are amorphous.

Sorbitannic acid from the juice of the ripe berries of the mountain ash *Sorbus Aucuparia* (Linn.) forms a thick syrupy mass, which gives a green coloration with ferric chloride solution. It yields *catechol* on dry distillation, and *protocatechuic acid* and *phloroglucinol* when fused with alkali (Vincent and Delachanal, Bull. Soc. chim. [ii.] 47, 492).

Spruce-bark tannin $C_{21}H_{20}O_{10}$ (?) gives, according to Böttinger, an unstable bromo derivative $C_{21}H_{14}Br_6O_{10}$. This reacts with hydroxylamine hydrochloride, and with hydrochloric acid at 180°–190° evolves *methyl chloride.* The penta-acetylpentabromo derivative

$$C_{21}H_{10}Br_5O_{10}(C_2H_3O)_5$$

was also prepared. With boiling dilute hydrochloric acid the tannin yields *spruce red* which yields the acetyl derivative $C_{42}H_{27}(C_2H_3O)_7O_{17}$, and when suspended in chloroform and treated with bromine the compound $C_{42}H_{24}Br_{10}O_{17}$ (Böttinger, Ber. 17, 1127).

Strawberry-root contains a tannin *fragarianin* (Phipson, J. 1878, 891), the solution of which gives a green colour with ferric chloride. Boiling dilute hydrochloric acid forms *glucose* and a red substance *fragiarin.* On dry distillation the tannin gives traces of *catechol*, and when fused with alkali *protocatechuic acid* is produced.

Tannecortepinic acid $C_{28}H_{26}O_{12}$, according to Rochleder and Kawalier (Sitz. Ber. 29, 23), can be isolated from the bark of young Scotch firs collected in the spring time. Ferric chloride gives a green coloration and boiling dilute acid a phlobaphane in addition to a little sugar.

Tannopinic acid $C_{26}H_{30}O_{12}$(?) is sometimes present in the needles of the Scotch fir gathered in the spring (Rochleder and Kawalier). In the winter time, oxypinitannic acid appears to take its place.

Tea-tannin is probably identical with the quercitannic acid of oak bark (Stenhouse, Phil. Mag. 23, 332; Rochleder, Annalen, 63, 205; and Hlasiwetz and Malin, J. pr. Chem. [i.] 101, 109).

Tormentilla tannin $C_{26}H_{22}O_{11}$, from the root of *Potentilla Tormentilla* (Neck.), is an amorphous reddish powder, which colours ferric chloride solution blue green. Boiled with dilute acids it produces *tormentil-red* without appreciable formation of sugar, and this appears to have the same composition as the tannin itself. With fused alkali *phloroglucinol* and *protocatechuic acid* are obtained. The root also contains a substance which yields *ellagic acid* when boiled with potash solution (Rembold, Annalen, 145, 5).

Viridic acid $C_{14}H_{20}O_{11}$ (?), which exists in coffee beans as a calcium salt (Rochleder, Annalen, 63, 197) and is obtained by the air oxidation of an ammoniacal solution of caffetannic acid, forms a brown amorphous mass, the alkaline solutions of which are green. The salts $Ba_2C_{14}H_{16}O_{11}$, $PbC_{14}H_{12}O_8$, and $PbC_{14}H_{14}O_9$ have been described (*cf.* also Vlaanderen and Mulder, J. 1858, 261).

Willow bark tannin. The bark of *Salix triandra* (Linn.) contains a glucoside tannin which gives a green colour reaction with ferric chloride, and when boiled with dilute sulphuric acid a brown-red precipitate (Stenhouse, Proc. Roy. Soc. 11, 403; Johanson, Arch. Pharm. [iii.] 13, 103).

Tannins are frequently accompanied in the plant by yellow colouring matters, and it has been pointed out by Perkin that a relationship is usually to be observed between these compounds in respect of the phenolic nuclei present in each. Thus catechu contains catechutannic acid and quercetin, both of which contain phloroglucinol and catechol groups, whereas both the cyanomaclurin and morin of Jâk wood (*Artocarpus integrifolia* (Linn.)) yield phloroglucinol and β-resorcylic acid. Again in sumach (*R. Coriaria* (Linn.)) *Pistacia lentiscus* (Linn.) (leaves) and *Hæmatoxylon campeachianum* (Linn.) (leaves), a gallotannin and myricetin exist, both of which are pyrogallol derivatives.

Other similar instances of this relationship could be cited; and where a divergence of this rule at first sight seems evident, this is frequently more apparent than real, as in the case of Young Fustic (*R. cotinus* (Linn.)) which is known to contain a gallotannin and fisetin (catechol and phloroglucinol). From the reactions of the wood extract, however, catechol tannin must also be present. A. G. P.

TANNISMUT, TANNOFORM, TANNOPIN, TANNOSAL, TANNOGUAIAFORM, TANNOCRESOFORM, TANNIGEN, TANNALBIN, TANARGAN, TANNOCASUM, TANNOTHYMAL, TANNYL, TANOCOL *v.* SYNTHETIC DRUGS.

TANTALITE. A heavy, black mineral consisting essentially of iron tantalate $FeTa_2O_6$, and crystallising in the orthorhombic system. The ferrous iron is usually in part, or sometimes almost wholly, replaced by manganous oxide, forming a passage to the variety known as *manganotantalite*. In the same way, tantalic acid is replaced isomorphously by columbic acid, forming a gradual passage into the species columbite (*q.v.*). The general formula for this isomorphous group is thus $(Fe,Mn)(Ta,Cb)_2O_6$. With the variation in the relative amounts of columbic and tantalic acids the sp.gr. ranges from 5·3 (columbite) to about 7·8 for nearly pure tantalite. In their other physical and crystallographic characters the two species are, however, remarkably similar. They are iron-black to brownish-black with a sub-metallic lustre, and a dark brown to black streak; H.=6. They are usually found as crystalline grains, or forming large rough masses by the sub-parallel grouping of prismatic crystals; well-formed crystals with brilliant faces are occasionally met with. They occur embedded in granitic rocks, more especially in pegmatite-veins intersecting these rocks: a common associated mineral is cassiterite. The columbium-rich members are of much more frequent occurrence than those at the tantalum end of the series.

Tantalite has long (since 1802) been known from several localities in Finland, and it has also been found in a few other countries. The greatly increased demand for tantalum since its introduction in the metallic filament electric lamps in 1904 has led to the discovery of several new localities, more particularly in Australia; and it is this continent that now supplies most of the raw material. It has been obtained in commercial quantities at Wodgina in the Pilbara gold-field, and at Greenbushes in the Blackwood Ranges, in Western Australia; and on the Finniss river near Port Darwin in Northern Territory. At Wodgina it occurs in pegmatite-veins, composed of quartz, felspar (mainly albite), mica (muscovite and lepidolite) and tantalite, the last-named in crystalline masses from the size of a shot to those weighing 5 cwts. The tantalite is collected from the surface soil, from the neighbouring alluvial deposits, and by quarrying the pegmatite. At Greenbushes it is found as grains and irregular lumps, reaching 13 lbs. in weight, in the alluvial deposits of tin-stone. On the Finniss river the mineral occurs with cassiterite scattered through a large intrusion of greisen.

Analyses: I. Tantalite ('skogbölite') from Skogböle, Kimito, Finland (A. Nordenskiöld, 1857). II. Grizzly Bear Gulch, Black Hills, South Dakota (W. P. Headden, Amer. J. Sci. 1891, 41, 98). III. Greenbushes, Western Australia (E. S. Simpson, Rep. Austr. Assoc. Adv. Sci., 1908, 11 (for 1907), 442; and Chem. News, 1909, 91, 49). IV. Manganotantalite from Wodgina, Western Australia (E. S. Simpson, *l.c.*). V. Manganotantalite from Finniss river, North Australia (Rep. Govt. Geologist, South Australia, 1905).

TANTALUM. Sym. Ta. At.wt. 181·5 (Balke). Shortly after the discovery of columbium by Hatchett, in 1801–2, a metal of similar properties was discovered by Ekeberg in certain Swedish minerals resembling those from which columbium had been isolated, and was called by him tantalum, on account of its extreme resistance to acids. Notwithstanding the fact that tantalite, the mineral which gave the largest yield of the new metal, was much heavier than columbite, Wollaston in 1809 concluded that the two metals were identical, and for many years they were indifferently termed columbium or tantalum. The similarity between the compounds of these metals, their invariable occurrence together in minerals, and the difficulty experienced in separating them from each other and the associated metals, prevented the large amount of work which was done upon them from yielding conclusive results, and it was not until the middle of the century that their true relations were established.

Although belonging to the group which includes vanadium, phosphorus, arsenic, antimony, bismuth, and nitrogen, tantalum and columbium have few properties in common with those elements, and invariably occur with minerals belonging to entirely different groups. Commercially speaking, they are members of a group of heavy metals, which includes tungsten, molybdenum, and uranium, found only in the oldest plutonic rocks. These metals are characterised by the power of improving and hardening steel when added in extremely small quantities, and it is interesting to note that the minerals carrying them commonly contain the metals of the rare earths, and rare alkaline earths, or are associated with minerals containing them. Zirconia, thoria, ceria, and even lithia, together with practically all the other rare earths and alkaline earths, occur in the same parent rocks, and it is probable that this common, indeed almost invariable association, is intimately connected with the origin of these metals.

The use of tantalum and columbium for hardening steel, their high melting-points, and the possibility of working the pure metals, either alone or in alloy with each other, into wire, and vessels of great acid-resisting properties, have recently given an impetus to the search for minerals containing them, which has resulted, for the moment, in the working of more deposits than the market can utilise. There is little doubt, however, that the larger output will ultimately result in an increased demand, as the uses to which the metals can be applied are so numerous. The value of apparatus made from these metals for chemical, physical, and surgical purposes in undoubted, and is likely to result in a demand for even larger quantities of the mineral than are at present available.

As regards the occurrence of tantalum in nature, the article on COLUMBIUM may be consulted. The two metals occur together and, although one may predominate in a mineral to an extent which renders it the characteristic metal, it is extremely exceptional to find one without a considerable proportion of the other.

For many purposes, it is probable that an alloy of tantalum and columbium is suitable, but it is usual to separate the oxides or salts before reduction to metal, and, as tantalum is preferred for most purposes, it is fortunate that its proportion in the minerals now worked largely predominates. Like columbium, tantalum occurs in nature only as the pentoxide, and all the minerals in which it is found may be regarded as tantalates or, in a few rare minerals, as silico-tantalates.

Although tantalum occurs as an essential, or at any rate invariable, constituent in a large number of the heavy rare minerals, the only one which is worked commercially is tantalite, essentially a tantalate of iron and manganese $Ta_2O_5(FeMn)O$, which may contain as much as 84 p.c. of Ta_2O_5, although seldom exceeding 70 p.c. The proportion between the iron and manganese varies considerably, and the tantalum may be largely replaced by columbium. In other words, tantalite may merge into *skogbolite* $Ta_2O_5\cdot FeO$, containing up to about 85 p.c. of Ta_2O_5, *manganotantalite* $Ta_2O_5\cdot MnO$ (up to 85 p.c. Ta_2O_5), *tapiolite* $Ta_2O_5\cdot Cb_2O_5\cdot FeO$ (up to 74 p.c. of Ta_2O_5), and other minerals containing widely varying proportions of Ta_2O_5, Cb_2O_5, FeO, and MnO. On reference to the article on TUNGSTEN, it will be seen that similar variations occur in the composition of wolfram, the tungstate of iron and manganese.

Tantalum also occurs as an apparently essential, although highly variable, constituent of between thirty and forty other minerals, including *microlite* $Ta_2O_5(CaO)_2$, containing up to about 70 p.c. of Ta_2O_5; *fergusonite*, a tantalate and columbate of yttrium, erbium, cerium, &c. (up to 43 p.c. Ta_2O_5); *yttrotantalite*, a tantalate and columbate of various rare earths (up to 47 p.c. Ta_2O_5); and *stibiotantalite*, a tantalate and columbate of antimony (up to 51 p.c. Ta_2O_5).

The principal localities where tantalum minerals occur have been detailed in the article on COLUMBIUM. At the present time, the main supply is obtained from Greenbushes, Pilbara, Wodgina, and elsewhere in Western Australia, where it occurs with tinstone and wolfram, partly in isolated masses which have escaped denudation during the weathering of the surrounding rocks, and largely in the form of alluvial material.

Metallic tantalum may be prepared in an impure state by reducing potassium tantalofluoride with potassium or sodium, or by reducing the pentoxide in the electric furnace with carbon. It was first prepared in a pure state by von Bolton, by reducing the tantalo-fluoride ($TaF_5\cdot 2KF$) with sodium and melting the washed, impure powder *in vacuó* in the electric furnace. The manufacture of the metal is entirely in the hands of Messrs. Siemens and Halske, and the exact present procedure is not known, but appears to be carried out according to von Bolton's method, the fusion *in vacuó* in the electric furnace being repeated with modification to remove all traces of impurity, and the preparation of the tantalo-fluoride being so conducted as to ensure its purity and freedom from columbium. The fusion *in vacuó* removes all traces of occluded gases, including the hydrogen and the oxygen (in the form of gas and of oxide) produced by the oxidation of the crude metal during the washing.

Another method devised by von Bolton consists in passing an electric current through rods of tantalum tetroxide Ta_2O_4 *in vacuô*. The intense heat produced by the current results in the expulsion of the oxygen and the production of brittle rods of impure metal which may be converted into pure tantalum by fusing and re-fusing *in vacuô* in the electric furnace as above. The tantalum tetroxide is prepared by shaping rods from a paste made of tantalum pentoxide and paraffin, and calcining them. The resultant metal possesses the same qualities as that made from the tantalo-fluoride, but the method is not employed on a commercial scale.

Wrought tantalum is a white metal, somewhat less bright than platinum, and usually showing a bluish tarnish from superficial oxidation. It has a sp.gr. of 16·8 (von Bolton); a specific heat, between 14° and 100°, of 0·033 (Dewar); and a m.p. of 2250°–2300° (von Bolton); 2798° according to tests made in 1912 at the University of Wisconsin. Its linear thermal coefficient of expansion between 0° and 60° is 0·0000079 according to tests made by the Imperial Standards Committee. It is about as hard as soft steel, but possesses a greater strength, the drawn wire having a tensile strength of 93 kilos per sq. mm. as against 80 kilos for good steel.

Tantalum is more malleable and ductile than columbium. It becomes progressively softer when heated, and can be hammered, rolled, or drawn into wire or seamless tubes similarly to steel, and is readily worked at a red heat. When heated in air, powdered tantalum readily oxidises, and both powder and thin wire burn at a red heat, the former with incandescence. Sheets of tantalum acquire a yellow tarnish at about 400° and, slowly at 500° or rapidly at 600°, become bluish, as in the case of steel when being tempered.

The worked metal possesses an extraordinary combination of toughness and hardness, and the slight superficial oxidation which is produced during working or by heating, enormously increases its property of resisting abrasion. So much is this the case that a diamond drill has but little penetrative power, although the metal is still capable of being rolled or drawn; the specially prepared metal has been found effective for the manufacture of pen nibs in place of iridium-pointed pens.

At a dull red heat, tantalum absorbs large quantities of hydrogen or nitrogen. At a yellow heat, about 740 volumes of hydrogen are thus absorbed. The metal is rendered brittle and fragile by the presence of either gas, but both can be expelled *in vacuô*. Three-fourths of the hydrogen can be driven off by heating to redness *in vacuô*, but the remainder can only be expelled by fusing *in vacuô* in the electric furnace, a treatment to which all metal now made is exposed, with a view to expelling all occluded gases and such other impurities as are volatile at the temperature at which tantalum melts.

The presence of occluded gases or small quantities of impurities completely alters the character of the metal, the value of which for all purposes to which it can be applied *as metal*, depends entirely on the extreme care taken in its purification after the preliminary stages of manufacture. The presence of even less than 0·1 p.c. of carbon renders it brittle, and it may be mentioned that the brittle metal obtained by Moissan in the electric furnace contained 0·5 p.c. The metallic nitride TaN, first prepared by Rose, is metallic in appearance, and was thought by him to be the metal itself.

Wrought tantalum is peculiarly resistant to all acids except hydrofluoric acid. It is absolutely unattacked by *aqua regia* even with prolonged boiling, and is not affected by organic acids or by the healthy or morbid secretions of the body, so that it is highly suited for the manufacture of dental and surgical instruments. Its extreme hardness permits of its use in place of steel, and the absence of corrosion and consequent ease of cleansing are resulting in an increased demand for such purposes.

Tantalum is readily attacked by fused caustic alkalis or alkaline nitrates and by sulphur. It alloys with iron, tungsten, molybdenum, and many other metals, but none of the alloys are of commercial importance excepting ferro-tantalum.

Ferro-tantalum is commonly prepared by the direct reduction of tantalite in the electric furnace, and is used to a small, but apparently increasing, extent in steel manufacture, for purposes similar to those for which ferro-tungsten, ferro-molybdenum, and ferro-vanadium are employed. The alloy commonly contains up to 50 p.c. of tantalum and columbium, the proportion of the latter being comparatively low and depending upon the amount which was present in the original tantalite.

Although the total output of metallic tantalum is under 2 tons per annum, its importance is considerable, especially in connection with the electric-lighting industry. Tantalum was the first metal to be used in commercial quantities for the manufacture of filaments. Its value depends on its great electrical resistance and high melting-point, and upon the fact that it can be drawn down to extremely fine wire (less than 0·03 mm.). The National Electric Lamp Association of the United States, in 1910 employed nearly five million feet of tantalum wire weighing under 100 lbs., for the manufacture of filaments.

According to Messrs. Siemens and Halske, taking the normal type of electric filament lamp of 25 c.p. at 110 volts, the filament for a lamp measures 650 mm., and has a diameter of 0·05 mm., so that 45,000 lamps could be made from 1 kilo of wire. This number is now largely exceeded, as it has been found possible to considerably reduce the diameter of the wire.

The electrical resistance (cold) of tantalum wire is 0·165 ohm per metre length of 1 sq. mm. section. When loaded to 1·5 watt per candle, the resistance of the same wire rises to 0·830 ohm.

G. T. H

COMPOUNDS OF TANTALUM.

Tantalum tetroxide Ta_2O_4, a porous dark-grey mass which scratches glass, is formed when the pentoxide is heated with magnesium in a carbon crucible. When powdered it is dark brown. It is not attacked by acids, but with chlorine gives a white readily volatile sublimate containing 18·5 p.c. chlorine. When heated it burns forming the pentoxide (Smith and Maas, Zeitsch. anorg. Chem. 1894, 7, 96).

Tantalum pentoxide Ta_2O_5 occurs in nature as the various *tantalites*, from which it may be obtained by fusing the finely-powdered mineral with three times its weight of acid potassium sulphate. The mass is boiled with water, and the residue is digested with ammonium sulphide, thus removing tin and tungsten and converting iron into sulphide. The residue is then washed and boiled with dilute hydrochloric acid and filtered; the mass consisting of the hydroxides of tantalum and columbium, and of titanic acid and silica, is washed with boiling water, dissolved in hydrofluoric acid, filtered, and heated to remove silicon fluoride; potassium fluoride is added to the solution which is then concentrated. The potassium tantalofluoride separates first; it is well washed, recrystallised, and heated to 400° with its own weight of concentrated sulphuric acid. The residue when boiled out with water gives the oxide and sulphuric acid. The acid adhering to the oxide may be removed from the oxide by heating with ammonium carbonate (Krüss and Nilson, Ber. 1887, 20, 1676; Moissan, Compt. rend. 1902, 134, 212). A more complete separation, which may be used for the estimation of tantalum, is described by Weiss and Landecker. The substance is fused with alkali bisulphite and the mass lixiviated with water. The solution is treated with sulphurous acid and boiled, when the tantalic, columbic, and titanic acids are precipitated quantitatively together with some tin, if present. The latter is removed by means of ammonium sulphide solution, and the residue is ignited and fused with a slight excess of sodium carbonate, and a small quantity of sodium nitrate is added towards the end of the operation, the mass being then gently heated until the nitrate is decomposed. The product is boiled with water and filtered from the titanium compound. After removing small quantities of the latter still present in the solution, it is treated with carbon dioxide or with a bicarbonate, whereby tantalic acid is precipitated quantitatively and, when heated to low redness, yields the pentoxide (D. R. P. 221429; J. Soc. Chem. Ind. 1910, 696; *see* also Zeitsch. anorg. Chem. 1909, 64, 65; Chesneau, Compt. rend. 1909, 149, 1132; also art. COLUMBIUM). Tantalum pentoxide is formed when the metal is treated with oxygen (Muthmann, Weiss and Riedelbauch, Annalen, 1907, 355, 58).

Tantalum pentoxide is a white amorphous, infusible powder, which, when strongly heated, becomes crystalline. It may also be obtained in rhombic prisms by igniting it with boron trioxide or melting it with microcosmic salt. Its sp.gr. varies with the intensity of the heat to which it has been subjected, and ranges from 7·055 to 8·257 (Marignac, Ann. Chim. Phys. 1866, [iv.] 9, 249). The ignited pentoxide is insoluble in acids, and is not acted on by hydrogen, but it may be reduced by heating strongly with carbon in the electric furnace. It forms double compounds with magnesium and the alkalis of the type $MgMTaO_8,xH_2O$ (M=alkali metal) (Balke and Smith, J. Amer. Chem. Soc. 1908, 30, 1637).

Tantalic acid $HTaO_3$ may be obtained as above or by mixing the chloride with water when it forms a gelatinous mass, which, when exposed to air, and then mixed with water containing ammonia, forms a crystalline powder. It is soluble in hydrofluoric, oxalic, and citric acids, but not in alkaline carbonates (Berzelius, Ann. Chim. Phys. [ii.] 3, 140).

Tantalates. For some naturally occurring tantalates and their extraction, *see* Rammelsberg, Chem. Soc. Trans. 1872, 25, 189. They are all insoluble, and are mostly derivatives of the above acid. In addition, *hexatantalates* are known of the formula $M_8Ta_6O_{19},xH_2O$, the alkali salts of which are soluble in water, and may be obtained by dissolving the acid in alkali hydroxide, or by fusing the pentoxide with the alkali hydroxide or carbonates. When tantalum pentoxide is ignited with the chlorides of calcium, magnesium and other metals, crystalline tantalates of these metals are formed (Joly, Compt. rend. 1875, 81, 266, 1266).

Pertantalic acid $HTaO_4,nH_2O$ is obtained by treating its potassium salt with dilute sulphuric acid. It is a white powder, fairly stable, decomposed only above 100°, but resembling percolumbic acid in other respects.

The *potassium salt* $K_3TaO_8,\frac{1}{2}H_2O$ is obtained by fusing tantalum pentoxide with potassium hydroxide, the mass is extracted with a little water, filtered, warmed with a little hydrogen peroxide, filtered, precipitated with alcohol, and the precipitate after washing with alcohol and ether, is treated with hydrogen peroxide and potassium hydroxide, and finally reprecipitated with alcohol. The corresponding sodium and barium salts, also the potassium calcium salt $KCaTaO_8,4\frac{1}{2}H_2O$, and the sodium salt

$$NaTaO_4,NaO{\cdot}TaO_4,13H_2O$$

have also been prepared by treating the corresponding tantalate with hydrogen peroxide (Melikoff and Pissarjewsky, Zeitsch. anorg. Chem. 1899, 20, 340; Balke, J. Amer. Chem. Soc. 1905, 27, 1155; Balke and Smith, *l.c.*).

Tantalum pentachloride $TaCl_5$, obtained by heating a mixture of the pentoxide and carbon in a current of chlorine, forms light yellow needles, m.p. 211°, b.p. 241·6°/753 mm., and volatilise at 144° (Deville and Troost, Compt. rend. 1867, 64, 294; *see* Willgerodt, J. pr. Chem. 1887, [ii.] 35, 391; Hermann, *ibid.* 1872, [ii.] 5, 66).

Tantalum pentabromide $TaBr_5$ can be prepared by passing bromine vapour over a strongly heated mixture of freshly-ignited tantalic oxide and pure sugar-carbon, air having been previously removed by heating the mixture in a current of dry carbon dioxide. It forms long yellow plates, m.p. about 240°, b.p. about 320°, fumes in moist air and reacts readily with methyl and ethyl alcohols.

Tantalum pentaiodide TaI_5 can be prepared by heating the bromide in a current of hydrogen iodide. It forms almost black plates, melts to a dark brown liquid, can be distilled in a current of carbon dioxide and fumes in moist air (van Haagen, J. Amer. Chem. Soc. 1910, 32, 729).

Bromotantalum bromide $(Ta_6Br_{12})Br_2,7H_2O$ has been obtained by reducing the pentabromide with sodium amalgam. It forms minute, black, hexagonal prisms giving a dark green powder. It is very stable and has tinctorial properties. A very minute quantity of the bromide is sufficient to give a beautiful emerald green colour to a considerable quantity of water and the solution imparts a stable pale-green colour to silk. Only two of the bromine atoms are in the ionic condition. When treated with caustic soda it is transformed into the *hydroxide* $(Ta_6Br_{12})(OH)_2,10H_2O$, thin hexagonal plates, which, on treatment with hydrochloric acid gives the *chloride*

$$(Ta_6Br_{12})Cl_2,7H_2O.$$

The *iodide* $(Ta_6Br_{12})I_2,7H_2O$ and the *chlorotantalum chloride* $(Ta_6Cl_{12})Cl_2,7H_2O$ have also been prepared (Chapin, J. Amer. Chem. Soc. 1910, 32, 323).

Tantalum pentafluoride TaF_5 is obtained by subjecting dry roughly powdered warmed tantalum contained in a boat inserted in a platinum tube, to the action of fluorine. The pentafluoride is purified by distilling it *in vacuô* at about 90°–100°. It forms colourless, strongly refractive prisms, m.p. 94° (corr.), b.p. 225°–226·5° (corr.), is very hygroscopic and is readily soluble in water. Caustic soda or ammonia precipitate tantalic acid containing a little fluorine from the solution. The fluoride attacks glass slowly at ordinary temperature, but rapidly when heated (Ruff, Zedner, Schiller, and Heinzelmann, Ber. 1909, 42, 492).

Tantalum pentafluoride forms a number of double fluorides with other metals (Balke, *l.c.* 1140; Smith, Chem. Zentr. 1905, ii. 1160; Ephraim and Heymann, Ber. 1909, 42, 4456), of which the

Potassium tantalofluoride $2KF,TaF_5$ is the most important. It is formed by bringing the two fluorides together in a dilute aqueous solution of hydrofluoric acid and consists of small anhydrous needles. On standing hydrofluoric acid is evolved. It is much more soluble in hot than in cold water, but when the solution is boiled an insoluble oxyfluoride $Ta_2O_5+2(2KF{\cdot}TaF_5)$ is precipitated (Krüss and Nilson, *l.c.*). The reactions of tantalum potassium fluoride are given in tabular form by Hall (J. Amer. Chem. Soc. 1904, 26, 1235). Tantalum pentafluoride also forms double salts with pyridine and other organic bases.

The following tantalum double salts with pyridine and quinoline have been prepared by the action of the base on an alcoholic solution of tantalum pentachloride containing hydrochloric acid

$$TaOCl_3,2C_5H_6NCl,2C_2H_6O\ ;$$
$$2TaOCl_3,3C_5H_6NCl,2C_2H_6O\ ;$$
$$Ta_2O_3Cl_4,4C_5H_6NCl\ ;\ \text{and}$$
$$TaOCl_3 2C_9H_8NCl,2C_2H_6O.$$

All these salts form colourless crystals soluble in alcohol, decomposed by water and becoming opaque on exposure to air (Weinland and Storz, Zeitsch. anorg. Chem. 1907, 54, 223).

Tantalum tetrasulphide Ta_2S_4 or TaS_2 may be prepared by passing a stream of sulphuretted hydrogen carrying carbon disulphide over tantalum pentoxide at 650°–900°. It is a very stable body not decomposed at 1300°, is scarcely attacked by boiling acids, readily absorbs moisture, and commences to be transformed into a crystalline variety at 1200° (Biltz and Kircher, Ber. 1910, 43, 1636).

Tantalum nitride Ta_3N_5 is obtained by heating the metal to 1000° in nitrogen (Muthmann, Weiss and Riedelbauch, Annalen, 1907, 355, 58), or by passing ammonia over tantalum chloride heated to a temperature not above that at which ammonium chloride volatilises. It is an amorphous yellowish-red mass, which, when heated to whiteness in dry ammonia forms the black *nitride* TaN (Joly, Compt. rend. 1876, 82, 1195).

Tantalum silicide $TaSi_2$ crystallises in iron-grey prisms, sp.gr. 8·83, with a metallic lustre; is decomposed readily by fused alkalis, dissolves in hydrofluoric acid, reacts with fluorine when heated gently, and is oxidised when heated in a current of oxygen (Hönigschmid, Monatsh. 1907, 28, 1017).

TAP CINDER. The basic iron silicate constituting the slag and flowing through the taphole of the puddling furnace, *v.* IRON.

TAPHOSOTE *v.* SYNTHETIC DRUGS.

TAPIOCA. A product obtained from the starch of cassava (*q.v.*) *Manihot utilissima* (Pohl) and other species of *Manihot.* The moist starch is heated and stirred until it agglutinates into little rounded, rugged masses, in which state it constitutes the tapioca of commerce. The starch granules become more or less swollen by this treatment, some of them preserving their original shape and character, while others gelatinise into shapeless or irregular masses. Tapioca usually contains from 10 to 14 p.c. of moisture with traces of nitrogenous matter and fat, but should be free from fibrous matter if properly prepared (Balland, J. Pharm. Chim. 1903, 17, 316).

The average of the analyses of seven samples of commercial tapioca (Bull. U. S. Dept. of Agric. 28, 1899) gave:

Water	Protein	Fat	N-free extract	Crude fibre	Ash
11·4	0·4	0·1	87·9	0·1	0·1

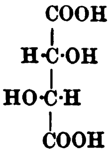
TARTAR EMETIC, *Potassium antimony tartrate v.* ANTIMONY.

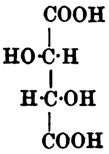
TARTARIC ACID, *Dihydroxysuccinic acid* (*Acide tartarique; Weinsaüre, Weinsteinsaüre, Tartarsaüre*), $C_4H_6O_6$.

The existence of the acid potassium salt of this acid in the deposit from fermented grape-juice was known to the Greeks and Romans, and the term 'tartarum' was applied to the deposit by Paracelsus, but it was generally considered to be an acid and to contain no base, although an alkali was known to be present in the ash. The production of an alkali by boiling tartar with lime was noticed by Kunkel in 1677, but the acid was not isolated until 1769, when Scheele obtained it by boiling tartar with chalk and decomposing the product with sulphuric acid.

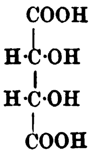
Tartaric acid contains two asymmetric carbon atoms and hence exists in four modifications, *viz.*: *d*-tartaric acid and *l*-tartaric acid which rotate the plane of polarised light to the right and left respectively; *r*-tartaric acid or racemic acid which is optically inactive, being a racemic mixture of the above two acids; *i*-tartaric acid or mesotartaric acid which is also optically inactive, as the lower half of the molecule is the mirror image of the upper half. Racemic acid is said to be 'externally compensated' and mesotartaric acid 'internally compensated.' The configurations of *d*-, *l*-, and *i*-tartaric acids are shown below :—



d-Acid.

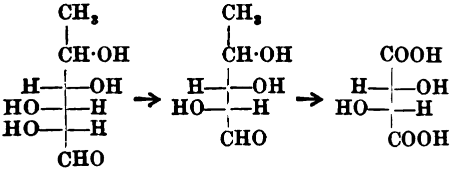


l-Acid.



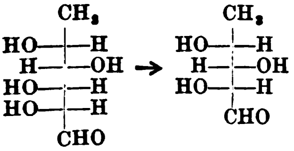
i-Acid.

The relative configuration of *d*- and *l*-tartaric acids to the sugars has been determined by Fischer (Ber. 1896, 29, 1377). The configuration of the *d*-acid was determined by converting rhamnose into rhamno-tetrose by the Wohl degradation and oxidising the methyl tetrose to *d*-tartaric acid with nitric acid.

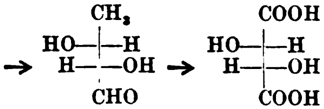


d-Rhamnose. *d*-Rhamno-tetrose. *d*-Tartaric Acid.

Similarly the configuration of the *l*-acid was determined from *l*-gulose.



l-Gulose. *l*-Xylose.



l-Threose. *l*-Tartaric Acid.

Physico-chemical data.—The following table compares some of the constants of the four acids :—

—	M.p.	Sp.gr.	Mol. of water of cryst.	No. of grams dissolved by 100 grams H_2O.	Affinity constant.
d-Tartaric acid	168°–170°	1·755	—	132·2	0·097
l-Tartaric acid	168°–170°	1·754	—	132·2	0·007
r-Tartaric acid	205°–206°	1·697	1 H_2O	17·07	0·097
i-Tartaric acid	140°	1·666	1 H_2O	125·0	0·06

The specific gravity of solutions of *d*-tartaric and racemic acids of equal concentration are in close agreement up to concentrations of 10 p.c. Between concentrations of 10 p.c. and 14 p.c. the solution of racemic acid has a smaller specific volume than that of one of tartaric acid of the same concentration as shown in the following table :—

Percentage of acid in solution.	Sp.gr. of tartaric acid solution.	Sp.gr. of racemic acid solution.	Sp. vol. of tartaric acid solution (d_1).	Sp. vol. of racemic acid solution (d_2).	$d_1 - d_2$.
10·666	1·04950	1·04969	0·95283	0·95266	0·00017
14·018	1·06600	1·06623	0·93809	0·93788	0·00021

The specific gravities of 4 p.c. solutions of *d*- and *l*-tartaric acids are 1·01770 and 1·01767 respectively. On mixing the two solutions to obtain racemic acid the values obtained in two experiments were 1·01769 and 1·01766. Hence there is no change in specific gravity. All these values are compared with water at 4° and reduced to vacuum (Marchlewski, Ber. 1892, 25, 1556). According to Jahn (Wiedemann's Annalen, 1891, 43, 306) when *d*- and *l*-tartaric acids are mixed to give racemic acid, no heat is evolved. Also the heat of neutralisation of *d*- and *l*-tartaric acids by optically active bases is the same. The following data are given by Berthelot (Compt. rend. 1891, 112, 827). When solutions of the sodium salts of *d*- or *l*-tartaric acids are mixed with calcium chloride solution, at first heat is developed, but no precipitate is formed. After a few minutes a precipitate separates with a further development of heat. The values for *d*-tartaric acid are +0·98 Cals. and +2·68 Cals., and for *l*-tartaric acid +0·92 Cals. and +2·61 Cals. When the sodium salts of *d*- and *l*-tartaric acid are mixed to give sodium racemate, there is no development of heat. The heats of neutralisation of the four tartaric acids by sodium hydroxide are practically identical under similar conditions of temperature and concentration, *viz.* +12·7 Cals. per equivalent. The rates of diffusion of *d*- and *l*-tartaric acids are the same (Marchlewski, Ber. 1893, 26, 983). For relation between the optical activity and absorption spectra of the tartaric acids, *v.* Stewart, Chem. Soc. Trans. 1907, 1037.

Physiological action. According to Chabrié (Compt. rend. 1893, 116, 1410) the order of toxicity of the tartaric acids as determined by experiments on guinea pigs is *l*-tartaric acid, *d*-tartaric acid, racemic acid, and mesotartaric acid, the *l*- acid being twice as poisonous as the *d*- acid. Karczag examined the effect of the four acids on the cardio-inhibitory and vaso-motor centres and on the isolated cardiac and ventricle by intravenous injection (Zeitsch. Biol. 1909, 53, 218). On the cardio-inhibitory and vaso-motor centres, *l*-tartaric acid is the most reactive and *d*-tartaric acid the least, racemic and mesotartaric acids occupying intermediate positions. Mesotartaric acid has the least action on the isolated cardiac and ventricle. When dogs are fed with *d*- or *l*-tartaric acid or with racemic acid, the acids pass unchanged into the urine. Hence there is no evidence that *d*- or *l*-tartaric acids are consumed at different rates in the body (Neuberg and Saneyoshi, Biochem. Zeitsch. 1911, 36, 32). According to Brion, *l*-tartaric and mesotartaric acids are most completely oxidised in the organism of a dog, the *d*- acid much less so, and racemic acid least of all. Hence racemic acid is not resolved into *d*- and *l*-tartaric acids in its passage through the organism (Zeitsch. physiol. Chem. 1898, 25, 283).

More carbon dioxide is evolved in the earlier stages of the reaction between yeast and *d*-tartaric acid than is the case when *l*-tartaric acid is used. Racemic acid occupies an intermediate position, while mesotartaric acid acts similarly to *d*-tartaric acid (Karczag, Biochem. Zeitsch. 1912, 38, 516).

Separation of the tartaric acids. Holleman (Rec. trav. chim. 1898, 17, 66) has devised the following method for the separation of *d*-tartaric acid, racemic acid, and mesotartaric acid. The aqueous solution of the free acids is evaporated on the water-bath until crystallisation commences and the liquid is then left for 24 hours in a cool place. The racemic acid separates quantitatively and the crystals are carefully drained, dried, and weighed. The mother liquor is diluted to 20 c.c., and 10 c.c. of this are exactly neutralised with potassium hydroxide and the other 10 c.c. are added and the liquid is left overnight, when potassium hydrogen *d*-tartrate separates out and is filtered, washed with a very little water, dried and weighed. The filtrate is neutralised with ammonia, made slightly acid with acetic acid, boiled and treated with calcium chloride solution. After leaving for a further 24 hours the calcium mesotartrate, which has separated, is filtered, dried, and weighed.

d-TARTARIC ACID.

d-Tartaric acid has been obtained together with racemic acid by the oxidation of saccharic acid, dextrose, cane sugar, milk-sugar, starch, gum arabic and sorbin with nitric acid (Dessaignes, Annalen, Suppl. 2, 242; Hornemann, J. 1863, 38; Kiliani, Annalen, 1880, 205, 175). It can also be obtained by the resolution of racemic acid and its salts into their optical antipodes (*v. infra*). For asymmetric synthesis from *d*-bornyl fumarate by the action of potassium permanganate. *v.* McKenzie and Wren, Chem. Soc. Trans. 1907, 1215. According to Zinno tartaric acid can be synthesised by the following methods: (i.) by oxidising succinic acid in cold concentrated aqueous solution with hydrogen peroxide; (ii.) by oxidising calcium succinate with calcium hypochlorite; (iii.) by treating glyceric acid of 26° B. with a solution of potassium hydroxide of sp.gr. not greater than 1·134 at 15°, and finally with carbon dioxide under a pressure of 3 atmos., whereby cream of tartar is produced; (iv.) by heating *l*-malic acid with hydrogen peroxide at 120°; if an ethereal solution of *l*-malic acid is used, a mixture of *d*-tartaric and racemic acids is obtained (Mon. Sci. 1902, 16, 493; L'Orosi, 1902, 25, 293).

Occurrence. Tartaric acid occurs in nature in the free state, or, more often, as the acid potassium salt and to a small extent as the calcium salt in association with oxalic, malic, citric, and probably racemic acid, in tamarinds, mulberries, sorrel, cucumbers, and many other plants. It occurs in large quantity in the juice of the grape, which furnishes practically all that is found in commerce. According to Winter (Zeitsch. ver. Rübenzucker Ind. 1888, 38, 380) it does not exist in the juice from the sugar-cane, but it is found in the precipitated calcium salts obtained in the treatment of beet juice (Lippmann, Ber. 1894, 24, 3299). Metzger states that tartaric acid is present in oak wood (Bied. Zentr. 1897, 26, 678). When tartaric acid is added to a solution containing potassium malate, succinate, pectinate, acetate, hydrogen sulphate, or hydrogen phosphate or a mixture of these salts, potassium hydrogen tartrate is always precipitated. Hence Carpené concludes that tartaric acid cannot exist in the free state in wines in the presence of these salts (Selmi, 1894, 4, 13).

A possible explanation of the occurrence of tartaric acid in nature has been given by Genvresse (Compt. rend. 1892, 114, 555). By the action of nascent hydrogen glyoxylic acid is converted into racemic acid. The former acid occurs in nature in unripe grapes, gooseberries, &c., and it may be that the tartaric acid is produced from the glyoxylic acid in an analogous manner.

When the grape juice ferments, the potassium hydrogen tartrate is gradually deposited, on account of its less solubility in the alcohol produced, partly as a crystalline crust on the sides of the vat and partly with the 'lees' which consists of yeast and the various suspended matters of the must. The crust is known as 'argol,' and when recrystallised produces 'tartar,' which by further crystallisation is converted into 'cream of tartar,' technically known as 'cream.'

The quality of lees, argol, and tartar varies enormously. Superior argols are equal to tartar, while inferior varieties are little better than lees. The tartaric acid in argols varies from 40–70 p.c., and that in lees averages about 25 p.c., but varies within wide limits. Lees from 'plastered wines,' *i.e.* from those in which baked gypsum or 'yeso' has been trodden with the grapes, as in Spain, Cyprus, and the Greek Islands, the Marsala district of Sicily, and the South of France, contain very little tartar, the acid being mostly present as the calcium salt.

The best class of coloured tartars consist of nearly pure potassium hydrogen tartrate. That of Messina usually contains 76 p.c. of tartaric acid, 1½–3½ p.c. of which is present as the calcium salt, whilst that from St. Antimo contains 74–75 p.c., of which the calcium salt constitutes 3–4½ p.c. Vinaccia tartar, which is obtained from the skins and solid matters of grapes, contains about 70–73 p.c. of tartaric acid, 5–7 p.c. being calcium salt. Occasionally much greater quantities of calcium tartrate are formed in crude tartar. The table (p. 405) shows the composition of tartars and lees from different localities (Warington, J. Soc. Arts. 1876, 370).

The following table shows the general composition of lees (Warington, *l.c.*):—

—	Tartaric acid as		Total tartaric acid.
	Potassium hydrogen tartrate.	Calcium tartrate.	
Italian (33 samples)	24·10	6·1	30·2
Greek (14 samples)	19·90	11·8	31·7
French (9 samples)	17·30	6·0	23·3
,, (30 samples)	5·30	20·5	25·8
Yellow Spanish (59 samples)	8·70	18·2	26·9
Red Spanish (17 samples)	8·80	17·4	26·2

—	Messina tartar.	St. Antimo tartar.	French lees (plastered).	Spanish lees (plastered).	Spanish lees (unplastered).
Tartaric acid as acid tartrate	74·05	69·34	4·48	5·27	22·66
Tartaric acid as neutral tartrates	2·60	4·66	21·34	19·13	11·67
Tartaric anhydride	67·408	65·120	22·721	21·472	30·210
Sand	0·140	0·425	4·600	4·900	4·730
Silica	0·055	0·130	2·130	1·960	
Ferric oxide	0·053	0·086	0·394	0·351	0·214

	100·000	100 000	100·000	100·000	100·000

The lees often contain calcium carbonate; also Spanish earth (a native aluminium magnesium silicate used in fining wine); gypsum when the wine has been plastered therewith; a resin when obtained from the Greek Islands. The vegetable matter contains considerable quantities of nitrogen. The lees are used for the manufacture of tartaric acid, either in the moist condition or after being dried. The moist pasty lees are removed from tuns into sacks and pressed. They contain varying amounts of potassium hydrogen tartrate and calcium tartrate with some alcohol and higher esters. They are mixed with water and distilled, the distillate yielding the so-called Lager brandy and wine oil or Cognac oil. The residue, which is used for the manufacture of tartaric acid, contains from 1–8 p.c. of the acid. Lees containing a higher percentage of tartaric acid, which only occurs after the first stage of the fermentation, are well pressed and dried, usually by the heat of the sun, and sold as dried wine lees.

Preparation and manufacture. Scheele's process for preparing the acid consisted in merely neutralising the solution of the tartar with chalk, and decomposing the precipitated tartar with sulphuric acid. By this process, however, only half the acid was extracted, the rest remaining in solution as potassium tartrate:—

$$2C_4H_5O_6K+CaCO_3$$
$$=C_4H_4O_6K_2+C_4H_4O_6Ca+H_2O+CO_2.$$

The first improvement on this process consisted in the replacement of chalk by lime, which produced a larger yield although a portion of the calcium tartrate was retained in solution by the potassium hydroxide produced. Lowitz next suggested the precipitation of the residual tartrate from the solution, after the treatment with chalk, by addition of calcium chloride (Aitkin's Dict. of Chemistry, 1807, ii. 405). This was in turn superseded by a process attributed to Desfosses, and consisting in the replacement of the calcium chloride by the precipitated calcium sulphate obtained by treatment of calcium tartrate with sulphuric acid.

The methods in use vary according to the nature of the crude material. A suitable mode of procedure in the case of an argol is to mix the powdered argol with water, add hydrochloric acid and boil (4–5 cub. metres of water and 110–120 kilos. of crude hydrochloric acid of 20°–22°B. with 500 kilos. of argol). The solution is nearly neutralised with milk of lime, whereby calcium tartrate is precipitated and potassium tartrate and calcium chloride remain in solution. The potassium tartrate is decomposed either by boiling with a sufficient quantity of calcium sulphate or by adding calcium chloride solution, an excess of the precipitant being avoided in either case. The small amount of potassium hydrogen tartrate purposely left in the liquid, when treating the latter with milk of lime, is decomposed with pure precipitated calcium carbonate. The object of not adding sufficient milk of lime to neutralise the solution is to avoid the precipitation of iron oxide and alumina. The liquid must still remain slightly acid after the addition of the calcium carbonate. After cooling to about 40°C. the liquid is filtered off with the aid of a suction pump and the residue washed with water. The calcium tartrate is then mixed with water and decomposed with dilute sulphuric acid, a portion of the solution being tested at intervals to ascertain when sufficient acid has been added; the reagent employed is calcium chloride, which gives no precipitate with the calcium sulphate contained in the solution, but precipitates the free acid.

The gypsum resulting from the decomposition is washed on a vacuum filter, and the liquors are evaporated in steam-heated leaden pans, or in vacuum pans. After partial concentration the liquor is run off from the gypsum which has deposited on the sides of the pan, and is concentrated to the crystallising-point, when it is run into a tub and continuously agitated by a mechanical stirrer to produce a granular 'salt.' This system of crystallisation separates the salt in about a fifth of the time required for crystallisation by standing. The mother-liquor from the 'salt' is concentrated and a second and third crop of crystals are obtained by 'granulation' as above; the residual dark-coloured impure solution is known as 'old liquor.' The granular salt is re-dissolved, heated with animal charcoal which has been freed from calcium phosphate by digestion with hydrochloric acid; the solution is filtered, concentrated, and crystallised in cylindrical leaden pans about 2 feet deep. Tartaric acid thus prepared always contains lead. The crystallisation is assisted by the addition of sulphuric acid, in which the acid is less soluble than in water (*v. infra*).

The mother-liquors are diluted and precipitated with milk of lime, and thus produce a further quantity of calcium tartrate, which is worked up as above. It is found, however, that the iron, alumina, and phosphoric acid introduced in the tartar, charcoal, whiting, &c., gradually accumulate in the liquors, and greatly reduce their power of crystallising so that continuously more and more sulphuric acid must be added to induce crystallisation. According to Carles (Bull. Soc. chim. 1910, [iv.] 7, 326) the iron may be removed by precipitation with potassium ferrocyanide and filtration, when crystallisation is much facilitated. The old liquor finally becomes thick and yields no tartaric acid, although a considerable quantity remains in solution, together with a large amount of decomposition products, principally due to the action of the sulphuric acid. A process has been patented for obtaining the potassium salts which are present in the calcium tartrate mother-liquors (Alberti, Fr. Pat. 402925; J. Soc. Chem. Ind. 1909, 1313).

The manufacture of tartaric acid from lees and low argols may be carried out by Scheurer-Kestner's process which consists in dissolving the lees, &c., in hydrochloric acid, which separates it from most of the organic impurities and colouring matter. The solution is precipitated by whiting or lime and treated as above (Scheurer-Kestner, Wurtz, Dict. of Chem. iii. 263). This extraction, however, is incomplete. If the filtration of the lees is attempted, the pores of the filter become clogged and even under a pressure of four or five atmospheres no liquid will pass through. Dietrich and Schnitzer overcame this difficulty by heating the lees under a pressure of 4 or 5 atmospheres for 6 hours, whereby the albuminoid substances are coagulated. Wet lees, when thus treated, can be readily filtered. Dried lees or argols are crushed, stirred in a tank with water, and heated by steam for half an hour, and then transferred to the pressure boiler. The lees are then treated with the requisite quantity of hydrochloric acid (21°–22°B.), filtered, pressed, and washed. The tartaric acid is precipitated with lime and calcium carbonate and the remaining operations are the same as in the treatment of argols with the exception that there is no need to add calcium chloride or sulphate.

Many modifications of the above processes have been patented. J. B. Lawes & Co. mix chalk and lime with a 27–35 p.c. solution of anhydrous calcium chloride and stir the tartar into the mixture. The amount of calcium chloride used should be greater than that of the chalk and the lime, and after the tartar has been added the chalk and lime should be in slight excess. After settling, the liquid is again treated with the calcium chloride mixture. The solid residue is decomposed with sulphuric acid in the usual manner (Eng. Pat. 11694; J. Soc. Chem. Ind. 1910, 1488). Schmitz and Toenges boil argols or crude tartars with slight excess of alkali carbonate and treat the warm lye with sodium hypochlorite until the colour has changed from brown to light yellow. The solution is neutralised with acetic or hydrochloric acid and the tartaric acid is precipitated with calcium chloride. The calcium tartrate thus obtained is boiled with alkali carbonate and treated as above. If cream of tartar is required, after boiling the calcium tartrate with potassium carbonate, the calcium carbonate is filtered off and a suitable acid added to precipitate the cream of tartar (Eng. Pat. 21178; *ibid.* 1897, 799). Another process, whereby a saving of 50 p.c. in reagents is claimed, consists in dividing the crude material into two parts and treating one portion with alkali and the other with acid. To the acid portion is added an amount of oxalic acid equivalent to the calcium salts present and to the alkali portion potassium chloride or other potassium salt, so that on mixing the two solutions all the tartaric acid is precipitated as potassium hydrogen tartrate and all the calcium salts as calcium oxalate. The precipitate, after being filtered, is treated with hot water containing a small quantity of oxalic acid and on filtering and cooling the solution, potassium hydrogen tartrate separates out. The oxalic acid can be recovered and used again (Cantoni, Chautemo et Cie et Degrange, Fr. Pat. 426714; *ibid.* 1911, 956). Another method, having the same object in view, is that of Moszczenski (U.S. Pat. 1000433; *ibid.* 1911, 1115). The crude material is made into a paste with water and lime is added, whereby potassium tartrate is formed in solution, leaving calcium tartrate in the residue. The liquid is filtered off and tartaric acid obtained from the residue by the addition of sulphuric acid. On mixing the two solutions, potassium hydrogen tartrate is precipitated. Perigny and Mazet treat the crude material electrolytically and by the use of suitable anodes, obtain metallic tartrates. The yield is improved by esterifying one or both of the alcoholic hydroxyl groups with boric or antimonious acid and subsequently hydrolysing the product (Fr. Pat. 382824; *ibid.* 1908, 296, 470).

Methods for the treatment of lees have been patented by Auzies, Secheyron and Subra (Fr. Pat. 429008; *ibid.* 1911, 1253), and by Martignier and Montpellier (Eng. Pat. 20078; *ibid.* 1891, 253). The former add sulphuric acid to the lees and sufficient hot water to dissolve the potassium sulphate and tartaric acid thus formed. On cooling the potassium sulphate separates out and the tartaric acid may be obtained from the mother-liquors by concentration and crystallisation. If much pectic substance is present the tartaric acid is best obtained by dialysis. The latter neutralise the lees and add an excess of a saturated solution of potassium sulphate, calcium sulphate being precipitated, and potassium tartrate going into solution. The filtered solution is decolorised with animal charcoal and sulphuric acid added to precipitate the potassium hydrogen tartrate.

If grape marcs form the crude material, they are usually only pressed or extracted with hot water, since after this treatment they can be sold as fodder for cattle, whereas if acid has been used, they become valueless for this purpose (Janson, Chem. Ind. 1909, 32, 719). Most processes for utilising grape marcs as a source of tartaric acid also aim at recovering the alcohol they contain. Salat extracts the marcs with water or with a liquid which has previously been obtained in the process. Sufficient sulphuric acid is added to the extract to decompose all calcium tartrate, and enough oxalic acid to dissolve all the potassium hydrogen tartrate. After 6 hours the alcohol is distilled off and the residual liquid is treated, while hot, with enough potassium sulphate to convert all the tartaric acid into potassium hydrogen tartrate and immediately afterwards with sufficient lime or chalk to neutralise the sulphuric and oxalic acids. After standing for 30 minutes the liquid is filtered and potassium hydrogen tartrate separates from the filtrate on cooling (Fr. Pat. 421730; *ibid.* 1911, 441). Barbet lixiviates the marcs in a battery with water made alkaline with sodium carbonate. To the extract is added an amount of sulphuric acid exactly equivalent to the sodium carbonate used. After a few days the liquid is filtered and the alcohol distilled off. The cream of tartar is then obtained as such by evaporation or as calcium tartrate by precipitation with calcium chloride (Fr. Pat. 379038; *ibid.* 1907, 1211). Ciapetti charges a series of diffusion vessels with the marcs, drives off the alcohol by steam and then acts on them with an aqueous solution of sulphurous acid under pressure. This treatment decolorises the solution and gives potassium hydrogen sulphite and tartaric acid in solution. After this solution has passed through the series of vessels, it is heated to 80°, whereby sulphur dioxide is expelled and cream of tartar is precipitated (Fr. Pat. 330951; *ibid.* 1903, 1099). Jude dissolves out the tartaric acid by the addition of an acid to the marcs and treats the filtrate with a potassium salt, such as the chloride, and a carbonate in quick succession so as to obtain a precipitate rich in potassium hydrogen tartrate (Fr. Pat. 402999; *ibid.* 1909, 1326; *cf.* Carles, Fr. Pat. 365034; *ibid.* 1906, 952).

A preliminary treatment of the crude material to render the colouring matters which are present insoluble, forms the subject of several patents. The crude lye may be boiled for 45 minutes after treatment with formalin (*ibid.* 1909, 913); if the proportion of albuminous material in the lye is low, blood, white of egg, casein or glue, &c., is added and then formalin and the substance taken to dryness at 140° (Garin and David, Fr. Pat. 374276; *ibid.* 1908, 712). Crude tartrates are treated with 1–2 p.c. of formalin or trioxymethylene and dried; the liquids obtained subsequently by extraction have very little colour (Garin, Annemasse and David, Fr. Pat. 8375; *ibid.* 1907, 778). Faucheux and Boissière submit the crude material to a slight roasting by means of hot gases from a furnace, whereby all organic matter other than tartrates is decomposed and the iron and aluminium compounds which are present, are rendered insoluble (Fr. Pat. 338735; *ibid.* 1904, 680). Vigneaux adds acid to the crude material and then zinc or some other metal to remove the excess of the acid, the hydrogen evolved decolorising the liquid. When the acid has been neutralised, potassium hydrogen tartrate is first deposited and finally calcium tartrate (Fr. Pat. 430883; Eng. Pat. 11558; *ibid.* 1911, 1382).

Fermaud extracts the crude substance with a hot solution of aluminium chloride or nitrate and claims thereby to get a purer product (D. R. P. 247452; *ibid.* 1912, 773). Special boilers for extracting the crude material have been patented by Roux (Eng. Pat. 7363; Fr. Pat. 328713; *ibid.* 1903, 1014) and Chauvin (Fr. Pat. 385103; *ibid.* 1908, 591). Cornette and Faucheux have patented a process for centrifugating out the potassium hydrogen tartrate after extracting the crude material with water (Eng. Pat. 5759; Fr. Pat. 435915; *ibid.* 1912, 386, 1125).

Other sources of tartaric acid than the grape have been proposed. Brehier and Talbot treat cellulose, saccharic or amylaceous substances with alkaline permanganate in the presence of chlorine. The nascent oxygen reacts on the glucose bodies and a tartaric acid liquor is produced from which the tartaric acid may be obtained by the usual methods (Eng. Pat. 3240; *ibid.* 1891, 751). Ellis treats a solution of a saccharic substance electrolytically and by anodic oxidation in the presence of substances yielding insoluble compounds with tartaric acid, obtains insoluble tartrates which are immediately removed from the field of oxidation (U.S. Pat. 789269; *ibid.* 1905, 635).

The crude tartrates obtained by any of these methods may be further purified by one of the following methods. Scarlata decomposes them with hydrofluosilicic acid yielding a residue of potassium fluosilicate while tartaric acid and calcium fluosilicate go into solution. After filtering, a slight excess of sulphuric acid is added to decompose the calcium fluosilicate and the precipitate of calcium sulphate having been removed, the tartaric acid is crystallised out (Mon. Sci. 1899, 783). Another method is to convert the crude tartrate into an alkali salt and add sulphuric acid. The filtered liquid is treated with aluminium sulphate in quantity sufficient to form an alum, and the latter is removed by evaporation and crystallisation. The tartaric acid is recovered from the mother liquors (Sir J. McDougall and F. L. McDougall, Eng. Pat. 4613; U.S. Pat. 898253; J. Soc. Chem. Ind. 1907, 1215). To obtain colourless cream of tartar, crude calcium tartrate is decomposed with sulphuric acid which has been freed from arsenic with sulphuretted hydrogen. After filtration the liquid is treated with purified animal charcoal and a small quantity of sodium thiosulphate, which prevents any iron or aluminium compounds being precipitated subsequently. After agitation the solution is again filtered and potassium carbonate added to precipitate the potassium hydrogen tartrate (Condouris and Tassopoulos, Fr. Pat. 366058; *ibid.* 1906, 1003; Tassopoulos, Eng. Pat. 16047; *ibid.* 1908, 876; *cf.* also Martignier, Eng. Pat. 27328; *ibid.* 1899, 1154).

Properties. Tartaric acid crystallises in large anhydrous monoclinic prisms having sp.gr. 1·755 (Walden, Ber. 1896, 29, 1701) and m.p. 168°–170° (Bischoff and Walden, *ibid.* 1889, 22, 1814). The crystals become luminous in the dark when rubbed. They often contain traces of lead owing to their having been crystallised in lead pans. The solubility of tartaric acid in water is given in the following table, the values being the same for *d*- and *l*-tartaric acids (Leide, Zeitsch. anal. Chem. 1883, 22, 269). The second column gives the number of parts of tartaric acid dissolved by 100 parts of water.

Temp.	Solubility	Temp.	Solubility
0°	115·04	55°	205·83
5°	120·0	60°	217·55
10°	125·72	65°	230·16
15°	132·20	70°	243·66
20°	139·44	75°	258·05
25°	147·44	80°	273·33
30°	156·20	85°	289·50
35°	165·72	90°	306·56
40°	176·0	95°	324·51
45°	185·06	100°	343·53
50°	195·0		

100 parts of 90 p.c. alcohol dissolve 29·146 parts of tartaric acid, whilst 100 parts of absolute alcohol at that temperature dissolve 20·385 parts (Bourgoin, Bull. Soc. chim. 1878, [ii.] 29, 244; *cf.* Schiff, Annalen, 1860, 113, 189). 100 parts of ether dissolve 0·393 part at 15° (Bourgoin, *l.c.*). A solution of tartaric acid saturated at 15° contains 57·9 parts of the acid (Gerlach, J. 1859, 44) or 57·75 parts (Maisch, *ibid.* 1865, 392). The table of specific gravities in the next column contains Gerlach's results (*cf.* Maisch, *l.c.*; Schiff, *l.c.*; Marchlewski, Ber. 1892, 25, 1560; Přibram and Glücksmann, Monatsh. 1898, 19, 123).

Strong solutions of tartaric acid contract on dilution. Thus 500 c.c. of a solution of sp.gr. 1·338 require 505·508 volumes of water to produce 1000 volumes (Warington, Journ. Chem. Soc. 1875, 942). The presence of much free sulphuric acid diminishes the solubility of tartaric acid at ordinary temperatures and increases the difference between the solubility at low and high temperatures. A cold saturated solution of tartaric acid, when mixed with half its volume of strong sulphuric acid and cooled, gives an abundant white precipitate of tartaric acid, whilst a hot solution of the acid in one volume of water and one and a half volumes of sulphuric acid (sp.gr. 1·713) deposits 70 p.c. of the tartaric acid on cooling. Thus a much larger proportion of tartaric acid is obtained in one crystallisation when sulphuric acid is present (Grosjean, Chem. Soc. Trans. 1883, 334).

Sp.gr. at 15°	Per cent. of acid in solution	Sp.gr. at 15°	Per cent. of acid in solution

The optical rotation $[\alpha]_D$ of aqueous solutions of the acid is given in the following table (Thomsen, J. pr. Chem. 1885, [ii.] 32, 318; *cf.* Kanonnikoff, J. Russ. Phys. Chem. Soc. 1890, 22, 369; Přibram and Glücksmann, *l.c.*).

Per cent. of acid	10°	15°	20°	25°	30°
50	5·93	6·67	7·38	8·03	8·64
40	7·58	8·26	8·91	9·51	10·07
30	9·22	9·85	10·45	10·99	11·50
20	10·87	11·44	11·98	12·47	12·93

In supersaturated aqueous solutions the rotation falls to 0°, and finally becomes lævorotatory (Lepeschkin, Ber. 1899, 32, 1180). In a mixture of dry ether and acetone the rotation is also lævorotatory (Landolt, *ibid.* 1880, 13, 2329). For rotation in solutions of ether and alcohol *v.* Přibram, Monatsh. 1888, 9, 488. According to Aignan tartaric acid exists in solution as the polymeride $(C_4H_6O_6)_2$ which is partially dissociated (Compt. rend. 1891, 112, 951). Affinity constant, k=0·097 (Walden, Ber. 1896, 29, 1701); dissociation constants, $k_1=970{\cdot}0\times10^{-6}$; $k_2=59{\cdot}0\times10^{-6}$ (Smith, Zeitsch. physikal. Chem. 1898, 25, 193). Molecular refraction *v.* Gladstone and Hibbert, Chem. Soc. Trans. 1897, 824. Conductivity *v.* Bischoff and Walden, *l.c.*; Ostwald, Zeitsch. physikal. Chem. 1889, 3, 371.

On heating tartaric acid at its melting-point some *ditartaric acid* is stated to be produced together with a variety of tartaric acid known as *metatartaric acid*. This acid is an amorphous deliquescent mass, the solution of which regenerates *d*-tartaric acid on boiling. It yields salts of greater solubility than the *d*-tartrates into which they are converted on boiling with water (Grosjean, Chem. Soc. Trans. 1883, 334; Erdmann, Annalen, 1837, 21, 9; Laurent and Gerhardt, *ibid.* 1849, 70, 348; Braconnot, Ann. Chim Phys. [ii.] 68, 299). By heating at 180°, or for a considerable time at 150°, *ditartaric acid* (*tartralic acid*) is obtained, while the further action of heat yields *tartrelic acid* (*soluble tartaric anhydride*) and *tartaric anhydride.* Ditartaric acid $C_8H_{10}O_{11}$ is an amorphous very deliquescent substance which readily combines with water, especially on boiling, to regenerate tartaric acid. Tartrelic acid $C_4H_4O_5$ forms yellow deliquescent crystals which are converted by boiling water first into ditartaric acid and then into tartaric acid. Tartaric anhydride $C_4H_4O_5$ is a colourless powder, insoluble in water, alcohol, or ether, but is converted by boiling water first into tartrelic acid, then into ditartaric acid and finally into tartaric acid (Warington, *l.c.*; Frémy, Annalen, 1839, 29, 444; Laurent and Gerhardt, Compt. rend. 1848, 27, 318; Schiff, Annalen, 1863, 125, 129).

The dry distillation of tartaric acid yields pyruvic acid, pyrotartaric acid, pyrotritaric acid, $C_7H_8O_7$, uvitic acid $C_7H_8O_3$, and acetic acid. These decompose yielding carbon monoxide, carbon dioxide, acetaldehyde, acetone, formic acid, and other compounds (Völckel, Annalen, 1854, 89, 57; Bourgoin, Bull. Soc. chim. 1878, [ii.] 29, 309; Pelouze, Ann. Chim. Phys. [ii.] 46, 297; Böttinger, Ber. 1876, 9, 670; Liebermann, *ibid.* 1882, 15, 428). Fusion with potassium hydroxide yields acetic and oxalic acids. By destructive distillation with potassium hydrogen sulphate an acid isomeric with pyrotritaric acid is obtained (Simon, Compt. rend. 1900, 131, 586). By heating tartaric acid with water, hydrochloric acid or alkali, racemic and mesotartaric acids are obtained in varying proportions (*v. Racemic acid, infra*). By oxidation with chromic acid, potassium permanganate or sulphuric acid, carbon dioxide and formic acid are obtained, whilst if slowly oxidised with nitric acid, tartronic acid is the product. Phosphorus and hydriodic acid reduce tartaric acid to malic and succinic acids. Phosphorus pentachloride yields chlorofumaric chloride.

By oxidising tartaric acid in the presence of a ferrous salt *dihydroxymaleic acid* $C_4H_4O_6,2H_2O$ is obtained. On reduction of the latter the final product is succinic acid, whilst on oxidation with glacial acetic acid and bromine *dihydroxytartaric acid* is produced, which is a good reagent for the detection of sodium salts (Fenton, Chem. Soc. Trans. 1895, 48; 1896, 546; 1898, 71, 472; Eng. Pat. 26259).

On exposure of a solution of tartaric acid to light for a year in a stoppered flask, Otto found that part was converted into pyruvic acid, although no micro-organisms were present (Ber. 1895, 27, 838, 1264). It is stated by Wehmer that a mould develops in pure tartaric acid solutions and is capable of existence in the presence of large amounts of acid. This mould produces citric acid fermentation in sugar solutions (Bied. Zentr. 1898, 27). On exposure of a 5 p.c. aqueous solution containing 1 p.c. uranium oxide to the action of sunlight, the first products are oxalic acid and a compound $C_2H_4O_2$ which reduces cupric salts. The oxalic acid is then converted into water, carbon dioxide and carbon monoxide and the last-named reduces part of the tartaric acid to malic acid and then to succinic acid. At the same time part of the malic acid is converted into oxalic acid and acetaldehyde and the succinic acid into propionic acid and carbon dioxide (Seekamp, Annalen, 1894, 278, 810).

Yeast ferments tartaric acid solutions yielding butyric and propionic acids, the latter being probably formed through the intermediate production of glyceric, malic, and succinic acids. Acetaldehyde is also present in small quantity (Karczag, Biochem. Zeitsch. 1912, 43, 44). On the purification of brewing yeast from wild yeasts by tartaric acid, *v.* Hansen, Zeitsch. Brauwesen, 1892, 2; Lindner, Wochenschrift Brauerei, 12, 316).

By the interaction of tartaric acid and trioxymethylene or formaldehyde under suitable conditions monomethylene- and dimethylene-tartaric acids can be obtained (Henneberg and Tollens, Annalen, 1896, 292, 53; van Ekenstein, Proc. K. Akad. Wetensch. Amsterdam, 1900, 3, 400; Rec. trav. chim. 1901, 20, 331; Sternberg, Pharm. Zeit. 1901, 46; Chem. Fabr. auf Aktien von E. Schering, D. R. P. 130346, Chem. Soc. Abstr. 1902, i. 705; de Bruyn and van Ekenstein, Rec. trav. chim. 1902, 21, 310). Tartaric acid gives a dinitrate in 81 p.c. yield on treatment with nitrogen pentoxide (Gibson, Proc. Roy. Soc. Edinburgh, 1908, 28, 705). When iron is placed in a solution of tartaric acid, hydrogen is evolved and the compound $C_4H_2O_6Fe_2$ is produced, showing that both the carboxylic and alcoholic hydrogen atoms have been replaced (Ulsch, Chem. Zeit. 1899, 23, 658).

Uses. Tartaric acid is used in certain photographical processes for printing and developing. It is also employed medicinally and for the production of baking powders, effervescent drinks, Seidlitz powders, &c. It is used by the calico printer to liberate chlorine from bleaching powder, and in the production of a number of dyestuffs; as a 'resist' for aluminium and other mordants and in the discharge colours for Turkey-red. It is also used in the mordant bath in dyeing wool; for brightening the colour of silk after dyeing; and for tendering cotton fibre.

Salts. Tartaric acid contains four hydrogen atoms which can be replaced by metals, but only two of these are in carboxyl groups, and hence the acid is dibasic forming two series of salts, the tartrates and the hydrogen tartrates or 'bitartrates.' Few of the salts are readily soluble in water and all are insoluble in alcohol.

Potassium hydrogen tartrate, cream of tartar, $C_4H_5O_6K$, occurs in the juice of the grape and is deposited on fermentation on account of its lesser solubility in alcohol, partly as a crystalline crust known as 'argol' and partly with the 'lees.' For composition of argol and lees *v.* pp. 404–405. The argol, &c., when heated with water, yields slightly coloured crystals of the purer salt which is known as 'tartar.' This may be further purified by any of the methods given under the manufacture of tartaric acid.

Potassium hydrogen tartrate crystallises in aggregates of small hard rhombic prisms, having a sp.gr. of 1·973 (Schiff, Annalen, 1859, 112, 89; *cf.* Schabus, J. 1850, 377; Buignet, *ibid.* 1861, 15; Cooke, *ibid.* 1880, 805). Its solubility in water and aqueous alcohol is given in the following table (Roelofsen, Amer. Chem. J. 1894, 16, 466; *cf.* Wenger, *ibid.* 1892, 14, 624; Blarez, Compt. rend. 1891, 112, 434, 808; Noyes and Clement, Zeitsch. physikal. Chem. 1894, 13, 413; Magnanini, Gazz. chim. ital. 1901, 31, ii. 542).

Temperature	Milligrams of $C_4H_5O_6K$ in 10 c.c.

The alteration of the solubility in water caused by the presence of other substances has been determined by Warington (Journ. Chem. Soc. 1875, 947; *cf.* Magnanini, *l.c.*; Noyes and Clement, *l.c.*; Blarez, *l.c.*). The following table gives the solubility at 14° in acid solutions of equal acidity, *i.e.* of such strength that equal volumes require the same amount of alkali for neutralisation; and in potassium acetate and citrate.

—	Grms. of acid or salt in 100 c.c.	Grms. of KHTa dissolved in 100 c.c.
Water . . .	—	0·422
Acetic acid . .	0·8106	0·422
Tartaric acid .	1·0331	0·322
Citric acid . .	0·8448	0·546
Sulphuric acid .	0·6853	1·701
Hydrochloric acid .	0·5037	1·949
Nitric acid . .	0·8445	1·969
Potassium acetate	1·3875	0·744
Potassium citrate .	1·3966	0·843

The solubility is thus diminished by the presence of tartaric acid and increased by the presence of other acids. These results are of great importance in the estimation of tartaric acid as potassium hydrogen tartrate. Mineral acids should not be present, nor any large excess of potassium acetate or citrate. The solubility of potassium hydrogen tartrate in water is greatly diminished if potassium sulphate, nitrate, or, especially, chloride be present. Grosjean showed that while the solubility in water at 12° was 1 in 262, the solubility in a 5 p.c. solution of potassium chloride was 1 in 3213, and in a 10 p.c. solution 1 in 4401. For conductivity of aqueous solutions, *v.* Walden, Zeitsch. physikal. Chem. 1891, 8, 466.

Potassium hydrogen tartrate has been proposed as a standard for acidimetry and alkalimetry (Bornträger, Zeitsch. anal. Chem. 1892, 31, 43; 1894, 33, 713; Zeitsch. angew. Chem. 1894, 54; Kollo, Pharm. Zentr-h. 1909, 50, 315; Hefelman, *ibid.* 334). To prepare pure potassium hydrogen tartrate for this purpose, white cream of tartar is heated with dilute hydrochloric acid, the solution cooled and stirred, and the precipitate filtered, washed, and recrystallised from hot water. Or a solution of tartaric acid may be divided into two equal parts, one portion being neutralised with potassium carbonate and the other portion added to it. The precipitate is washed and recrystallised from hot water. It is quite pure when the alkali obtained by calcining a weighed quantity exactly neutralises an equal weight of the uncalcined substance, neutral litmus paper being used as an indicator.

When heated, potassium hydrogen tartrate yields a mixture of carbon and potassium carbonate used as a reducing agent under the name of 'black flux.' Potassium hydrogen tartrate is used in the preparation of effervescing drinks, baking powders, &c., and in medicine; also in the mordant bath for wool dyeing, in conjunction with alum, iron salts, stannous chloride, &c., apparently producing double salts which are more effective as mordants.

Cream of tartar dissolves readily in a solution of boric acid or borax (Le Fèvre, Mémoires de L'Acad. Royale, Paris, 1732), and the product is used medicinally under the name 'soluble cream of tartar.' It is best prepared by dissolving a mixture of 4 parts of cream of tartar and 1 of boric acid in 24 parts of water and heating until most of the water is driven off. The salt prepared with boric acid is a white powder, which is permanent in the air, whereas that prepared with borax, and known in the German Pharmacopœia as 'Boraxweinstein' is deliquescent.

Potassium hydrogen tartrate dissolves many oxides, forming double tartrates; tartar emetic is a compound of this nature (*v.* ANTIMONY). Other double salts which have been prepared in a similar manner are the *titanitartrates* and *stannitartrates* (Henderson, Orr and Whitehead, Chem. Soc. Trans. 1899, 556; *cf.* Rosenheim and Schütte, Zeitsch. anorg. Chem. 1901, 26, 239); *molybdotartrates* (Henderson and Barr, Chem. Soc. Trans. 1896, 1455; *cf.* Rosenheim and Itzig, Ber. 1900, 33, 707; Itzig, *ibid.* 1901, 34, 1372); *glucinotartrates* (Rosenheim and Woge, Zeitsch. anorg. Chem. 1897, 15, 299); *tartrarsenites* (Henderson and Ewing, Chem. Soc. Trans. 1895, 103). The *tungstotarates* are prepared by boiling tungstic acid in a solution of a normal alkali tartrate (Rosenheim and Itzig *l.c.*).

Potassium ferric tartrate is prepared by adding precipitated ferric hydroxide to potassium hydrogen tartrate and treating with cold water. It is the *ferrum tartaratum* of pharmacy, and should yield 30 p.c. of Fe_2O_3 on ignition, as estimated from the weight of ash insoluble in water. It forms ruby-red transparent scales soluble in about 4 parts of water.

Potassium tartrate $C_4H_4O_6K_2,\frac{1}{2}H_2O$ is prepared by neutralising potassium hydrogen tartrate with potassium carbonate or hydroxide. It forms colourless, monoclinic crystals, which have sp.gr. 1·973 (Schiff, Annalen, 1859, 112, 89) and are soluble in 66 parts of water at 14°, the solubility decreasing with rise of temperature. When a solution of this salt is treated with acid, potassium hydrogen tartrate is precipitated. By the electrolysis of a concentrated aqueous solution of potassium tartrate potassium hydrogen tartrate, carbon dioxide, carbon monoxide, a little formaldehyde and formic acid, but no acetic acid are produced (Miller and Hofer, Ber. 1894, 27, 468).

Sodium hydrogen tartrate $C_4H_5O_6Na,H_2O$ and *sodium tartrate* $C_4H_4O_6Na_2,2H_2O$ crystallise in rhombic crystals (Dumas and Piria, Annalen, 1844, 44, 88). They are both very soluble; the normal salt dissolves in 2·28 parts of water at 24°, and the sp.gr. of the crystals is 1·794.

Potassium sodium tartrate, Rochelle salt $C_4H_4O_6NaK,4H_2O$ is prepared by neutralising potassium hydrogen tartrate with sodium carbonate or hydroxide. It forms large rhombic prisms of sp.gr. 1·767 (Schiff, *l.c*), and is soluble in 1·70 parts of water at 6° (Fresenius, Annalen, 1845, 53, 234). Above 40° a saturated solution deposits crystals of Rochelle salt and sodium tartrate, and above 55° a mixture of potassium and sodium tartrates (van Leeuwen, Zeitsch. physikal. Chem. 1897, 23, 33). Addition of acetic acid to the solution precipitates potassium hydrogen tartrate, this reaction distinguishing Rochelle salt from sodium tartrate. Seidlitz powders contain Rochelle salt, which is sometimes replaced wholly or partly by sodium hydrogen carbonate. Some powders also contain about 0·001 grain of tartar emetic.

Ammonium hydrogen tartrate $C_4H_5O_6NH_4$ and *ammonium tartrate* $C_4H_4O_6(NH_4)_2$ have similar properties to those of the corresponding potassium salts (Pasteur, J. 1853, 415; 1854, 395; Schiff, *l.c.*). *Ammonium potassium tartrate* $C_4H_4O_6K(NH_4)$ and *ammonium sodium tartrate* $C_4H_4O_6Na(NH_4),4H_2O$ resemble Rochelle salt in their properties.

Ammonium ferric tartrate, which is employed in medicine, is prepared according to the U.S. Dispensatory, 14th ed., p. 1214, by dissolving 6 oz. of tartaric acid in 2 pints of water and neutralising it with ammonium carbonate, 6 oz. of tartaric acid being then added. Ferric hydroxide, precipitated from a solution of ferric chloride, is then stirred in at 140°F. until no more will dissolve. The solution is then filtered, evaporated to a syrup at a temperature below 140°F. and dried on a glass plate. It forms transparent garnet-red scales of sweetish taste, which are slowly but extremely soluble in water to a neutral solution, but insoluble in alcohol or ether.

The normal and acid tartrates of *lithium, caesium,* and *rubidium* are all readily soluble. The rubidium salt crystallises from aqueous solutions in anhydrous, hexagonal, trapezohedral crystals, having sp.gr. 2·694 at 14°; they are lævorotatory (Traube, Sitzungsber. Berl. Akad. 1895, 10, 195).

Magnesium tartrate $C_4H_4O_6Mg,4H_2O$ is obtained as a crystalline crust by evaporating a solution of magnesium carbonate in tartaric acid, and is soluble in 123 parts of water at 15·6°. The acid salt $(C_4H_5O_6)_2Mg$ is obtained by dissolving magnesium carbonate in excess of tartaric acid. It is a crystalline substance, soluble in 53 parts of water at 15·6°. Double salts with the alkali metals are known.

Calcium tartrate $C_4H_4O_6Ca,4H_2O$ occurs in small quantities, together with the acid potassium salt, in many plants and is always found in argol and lees as described previously. It may be prepared by adding excess of calcium chloride to a solution of a tartrate. It crystallises in rhombic prisms or pyramids, but is frequently deposited from dilute solutions in aggregates of fine radiating needles, which gradually become converted into isolated pyramids or prisms. The solubilities of the tartrates of calcium, strontium, and barium are given in the following table (Cantoni and Zachovers, Bull. Soc. chim. 1904, [iii.] 31, 1121; *cf.* Enell, Zeitsch. anal. Chem. 1899, 38, 368):—

Temp.	Grms. of salt in 100 c.c. water		
	$C_4H_4O_6Ca,4H_2O$	$C_4H_4O_6Sr,3H_2O$	$C_4H_4O_6Ba$

Strong acids and potassium hydrogen tartrate dissolve calcium tartrate, and hence it is frequently present in purified tartars. It is precipitated from these solutions by ammonium hydroxide immediately or after some time. It is soluble in ammonium chloride and cold alkali, being reprecipitated from the latter on boiling. Alkali chlorides dissolve it more readily than does water (Cantoni and Jolkowsky, Bull. Soc. chim. 1907, [iv.] 1, 1181). A hot neutral solution of copper chloride converts it on digestion into insoluble copper tartrate, this reaction distinguishing it from calcium citrate; this test, however, will not detect calcium tartrate in the presence of much calcium citrate. Unlike calcium racemate and calcium oxalate, calcium tartrate is soluble in acetic acid.

Crude calcium tartrate is liable to undergo decomposition either by an anaerobic ferment, which yields formic, acetic, butyric, and higher fatty acids, but not propionic acid; or by an aerobic ferment yielding calcium carbonate as the ultimate product (Ordonneau, *ibid.* 1911, [iv.] 9, 398; *cf.* Emmerling, Centr. Bakt. Par. 1908, [ii.] 21, 317). *Bacillus Tartaricus*, which is capable of anaerobic and aerobic life, but which is more active in the latter state, decomposes calcium tartrate with the formation of acetic and succinic acids, hydrogen and carbon dioxide (Grimbert and Ficquet, J. Pharm. Chim. 1898, [vi.] 7, 97).

Calcium hydrogen tartrate $(C_4H_5O_6)_2Ca$ is formed by dissolving the normal salt in tartaric acid, and is much more soluble than the normal salt, 100 parts of water dissolving 0·71 parts of the acid salt at 15·6°.

Strontium tartrate $C_4H_4O_6Sr,3H_2O$ and *barium tartrate* $C_4H_4O_6Ba$ are more soluble than the calcium salt (p. 411). A tribasic barium tartrate has been prepared by Quartaroli (Staz. sperim. agrar. ital. 1910, 43).

Aluminium tartrate $(C_4H_4O_6)_3Al_2$ is formed by dissolving alumina in tartaric acid and is a gummy non-deliquescent mass soluble in water; the solution is capable of dissolving considerable quantities of alumina without becoming alkaline. A double salt of potassium and aluminium appears to be formed by dissolving alumina in cream of tartar. It forms an amorphous mass not precipitated by alkalis, and probably constitutes the active ingredient of the mixture of alum and cream of tartar used in the mordant bath for dyeing wool.

Ferrous tartrate $C_4H_4O_6Fe$ is obtained as a white, almost insoluble, crystalline powder by boiling iron filings with tartaric acid. 100 parts of water at 15·6° dissolve 0·877 parts of the salt (Dulk, Annalen, 1832, 2, 62).

Ferric tartrate $(C_4H_4O_6)_3Fe_2$ is obtained by dissolving the precipitated hydroxide in tartaric acid. The solution deposits a basic salt on warming, but is not precipitated by addition of alkalis on account of the production of a double salt (*cf.* Rosenthaler and Siebeck, Arch. Pharm. 1908, 246, 51).

Nickel tartrate and *cobalt tartrate* and double salts with potassium tartrate are described by Tower (J. Amer. Chem. Soc. 1900, 22, 501; *cf.* Werther, J. pr. Chem. 1844, [i.] 32, 400; Fabian, Annalen, 1857, 103, 248).

Zinc tartrate $C_4H_4O_6Zn.2H_2O$ is prepared by the action of tartaric acid on zinc acetate (Schiff, Annalen, 125, 146) or by boiling tartaric acid with zinc (Frisch, J. 1866, 401). The solubility of zinc, copper, and lead tartrates is given in the following table (Cantoni and Zachovers, Bull. Soc. chim. 1905, [iii.] 33, 754; *cf.* Partheil and Hübner, Arch. Pharm. 1903, 241, 413):—

Temp.	Grms. of salt in 100 c.c. water		
	$C_4H_4O_6Zn,2H_2O$	$C_4H_4O_6Cu,3H_2O$	$C_4H_4O_6Pb$

Copper tartrate $C_4H_4O_6Cu,3H_2O$ is obtained as a greenish-blue crystalline powder on addition of copper sulphate to a soluble tartrate. It dissolves in alkalis and ammonia with formation of double tartrates and the deep blue solution is reduced, with precipitation of cuprous oxide, by heating with glucose and many other organic compounds (*v.* FEHLING'S SOLUTION). For solubility *v. supra.*

Lead tartrate $C_4H_4O_6Pb$ is prepared by the addition of tartaric acid to a soluble lead salt when it forms a white crystalline powder (sp.gr. 3·871) almost insoluble in water (*v. supra*), but readily dissolved by alkalis. It is also obtained by boiling lead acetate with tartaric acid (Heintz, J. 1860, 261; Frisch, *ibid.* 1866, 400). By boiling an ammoniacal solution of the normal tartrate, the insoluble basic tartrate $C_4H_2O_6Pb_2$ is obtained (Erdmann, Annalen, 1837, 21, 19).

Silver tartrate v. SILVER.

Antimony tartrate v. ANTIMONY.

Bismuth tartrate. According to Baudran on boiling bismuth hydroxide with tartaric acid, bismuthotartaric acid $C_4H_5O_6(BiO),H_2O$ is obtained, and by replacement of a hydrogen atom by potassium, an emetic is produced. Similar salts may be obtained containing manganese, iron, or chromium in place of bismuth (Ann. Chim. Phys. 1900, [vii.] 14, 506). Telle states that the compound forms small needles and has the constitution $C_8H_8O_{12}Bi,3H_2O$ and that it may also be obtained by adding tartaric acid to the hydrated lactate of bismuth (Arch. Pharm. 1908, 246, 484). It is almost insoluble in water. Fischer and Grützner state that by boiling freshly precipitated bismuth hydroxide with tartaric acid the compound $C_4H_4O_6,2Bi(OH)_2$ is formed as a white, amorphous, electrical precipitate (*ibid.* 1894, 232, 460).

Esters. The normal esters of tartaric acid may be prepared (i.) by saturating a solution of tartaric acid in the alcohol required with hydrogen chloride; (ii.) by heating an alkyl hydrogen tartrate in a sealed tube with the corresponding alcohol; (iii.) by the action of an alkyl iodide on silver tartrate. If the last method be used a small quantity of the alkyl dialkyloxy compound is also formed, and this has a high rotation (Rodger and Brame, Chem. Soc. Trans. 1898, 301; Purdie and Lander, *ibid.* 1899, 156).

Methyl tartrate $C_4H_4O_6(CH_3)_2$ is a crystalline solid, m.p. 48°; b.p. 280°; 163°/23 m.m.; sp.gr. 1·3403 at 15° (in liquid state); $a_D + 2·74°$. It remains liquid below its boiling-point for a considerable time (Anschütz and Pictet, Ber. 1880, 13, 1176; Anschütz, *ibid.* 1885, 18, 1399; Frankland and Wharton, Chem. Soc. Trans. 1896, 1310).

Ethyl tartrate $C_4H_4O_6(C_2H_5)_2$ is a colourless liquid, b.p. 280°; 162°/19 mm.; sp.gr. 1·2097 at 14° (Anschütz and Pictet, *l.c.*; *cf.* Frankland and McCrae, *ibid.* 1898, 73, 310); $a_D^{20°} + 9·30°$ (Frankland and Wharton, *l.c.*). The influence of solvents, temperature, &c., on the rotation of ethyl tartrate has received considerable attention, *v.* POLARIMETRY and following references: Frankland, *ibid.* 1899, 349; Patterson, *ibid.* 1901, 167, 477; 1903, 765; 1905, 313; 1908, 1836; Patterson and McMillan, *ibid.* 1907, 504; Patterson and McDonald, *ibid.* 1908, 936; 1909, 321; Patterson and Montgomerie, *ibid.* 1130; Patterson and Anderson, *ibid.* 1912, 1833; Purdie and Barbour, *ibid.* 1901, 971; Grossmann, Zeitsch. physikal. Chem. 1910, 73, 148. By passing hydrogen chloride into ethyl alcohol and then adding methyl tartrate and finally boiling under a reflux apparatus, ethyl tartrate is produced. The reverse reaction may also be accomplished (Patterson and Dickinson, Chem. Soc. Trans. 1901, 280). Alkyl metallic salts of the type $C_4H_4O_6RM$ have been prepared.

Methyl hydrogen tartrate $C_4H_5O_6·CH_3$ is prepared by boiling methyl alcohol (1 mol.) with tartaric acid (1 mol.). It forms rhombic crystals containing $1H_2O$ (Tannhaüser, Zeitsch. Kryst. Min. 1908, 45, 183; Marckwald and Karczag, Ber. 1909, 42, 1518).

Ethyl hydrogen tartrate $C_4H_5O_6·C_2H_5$ is prepared by dissolving tartaric acid in an equal quantity of absolute alcohol in a retort at 60°–70°, diluting with water and crystallising the product. It forms rhombic prisms, m.p. 90° (Guerin, *l.c.*).

Detection. Tartaric acid and tartrates char when heated, giving a smell resembling that of burnt sugar. Tartrates leave a residue consisting of the oxide or carbonate of the metal. Tartaric acid and tartrates char very readily when heated with strong sulphuric acid. To distinguish from citric acid or citrates, the substance is heated with pure concentrated sulphuric acid at 100° for 40 minutes. In the presence of tartaric acid the liquid becomes blackened, even as little as 1 p.c. in the substance treated giving a brown shade, whereas citric acid only imparts a yellow colour.

With neutral solutions of tartrates calcium chloride gives a white crystalline precipitate of calcium tartrate. This precipitation only takes place after some time from dilute solutions and may be accelerated by scratching the sides of the containing vessel with a glass rod. If calcium acetate be used as the reagent, solutions containing 0·1 p.c. of tartaric acid give a precipitate, but by adding a few drops of *l*-tartaric acid or its ammonium salt a precipitate is formed in solutions containing only 0·0001 p.c. of tartaric acid, since calcium racemate is less soluble than calcium tartrate (Brönsted, Zeitsch. anal. Chem. 1903, 42, 15). For microscopical detection of calcium tartrate, *v.* Sullivan and Crampton, Amer. Chem. J. 1906, 36, 419.

Potassium acetate and acetic acid, when added to solutions of tartrates or of tartaric acid, yield a colourless precipitate of potassium hydrogen tartrate (de la Source, Compt. rend. 1895, 121, 774).

Silver nitrate gives with neutral solutions of tartrates a white precipitate of silver tartrate. A silver mirror is obtained by heating an ammoniacal solution of silver tartrate. The procedure is as follows: The silver tartrate is treated with ammonium hydroxide in a clean test tube, until it is nearly all dissolved. A crystal of silver nitrate is placed in the bottom of the test tube, which is then transferred to a beaker of boiling water. In a short time a silver mirror is produced on the sides of the tube.

If a few centigrams of resorcinol are heated with about 2 c.c. of concentrated sulphuric acid until vapours are evolved, and a small quantity of a tartrate is added, a bright-red coloration is produced. Or 2 grams of resorcinol may be dissolved in dilute sulphuric acid (0·5 c.c. to 100 c.c. of water) and this used as the reagent. Two or 3 drops are added to 2 c.c. of concentrated sulphuric acid, and to this a very small quantity of the substance (liquid or solid). The solution is then heated at 115°–140° (Denigès, J. Pharm. Chim. 1895, [vi.] 1, 586; Bull. Soc. chim. 1909, [iv.] 5, 19; Mohler, *ibid.* 1890, [ii.] 4, 728). If pyrogallol is substituted for resorcinol, a violet-blue coloration is produced, whilst with β-naphthol the colour is blue in the cold, changing to an intense green on heating, and on dilution with 15–20 volumes of water, a permanent reddish-yellow colour is obtained (Piñerua, Compt. rend. 1897, 124, 291).

On adding a few drops of ferrous sulphate solution followed by a small quantity of hydrogen peroxide to a solution of a tartrate, a yellow coloration is produced, changing to violet on the addition of alkali hydroxide. The colour is discharged by acids and restored by alkalis (Fenton, Chem. Soc. Proc. 1893, 113).

If a few c.c. of cobalt nitrate solution be added to a solution of an alkali tartrate, a red colour is obtained which is discharged by alkali hydroxide. On boiling a blue coloration is produced, which disappears on cooling and reappears on heating (Tocher, Pharm. J. 1906, 77, 87).

Another test consists in boiling the neutral solution with minium. After filtering, a few drops of a 2 p.c. solution of potassium thiocyanate are added. On standing the liquid darkens owing to a precipitation of lead sulphide In testing wines a brownish-violet precipitate is obtained (Ganassini, Boll. Chim. Farm. 1903, 42, 513; Tagliavini, *ibid.* 1907, 46, 493).

Estimation. Since all tartrates leave an oxide or carbonate on gentle ignition, they may be estimated by dissolving the residue in standard acid and determining the amount of acid thus neutralised with standard alkali.

For the estimation of free tartaric acid, alone or in the presence of citric acid, Allen recommends the following process (Chem. News, 1875, 31, 277): 2 grams of the sample are dissolved in 20 c.c. of proof spirit, and the filtered solution is diluted to 45 c.c. with proof spirit, treated with 5 c.c. of a cold saturated solution of potassium acetate, and stirred for 10 minutes. The crystalline precipitate of potassium hydrogen tartrate is filtered off, washed with proof spirit, and, to remove any citrate carried down by the tartrate, is rinsed from the filter by a cold saturated solution of potassium hydrogen tartrate and digested therewith for a few hours. It is then again filtered, washed with proof spirit, rinsed with hot water into a weighed dish, and weighed after evaporating off the water at 100°. The precipitate may be dissolved and titrated with decinormal alkali and phenolphthalein instead of being weighed.

Tartaric acid liquors. These are the liquids obtained by the decomposition of calcium tartrate by sulphuric acid and are of a very complex nature. They contain free tartaric acid; other organic acids; sulphuric acid, and calcium, potassium, aluminium, and iron sulphates; phosphates and bodies of an indefinite nature. The analyst is usually required to estimate the tartaric acid, free sulphuric acid, and in some cases the total organic acids.

For the estimation of tartaric acid potassium acetate is the best reagent for pure liquors, but cannot be used in the presence of iron or aluminium. In the latter case potassium citrate is used. A quantity of liquor containing 2–4 grams of tartaric acid (about 30–40 c.c.) is treated drop by drop with constant stirring with a saturated solution of potassium citrate until, the sulphuric acid having been converted into potassium sulphate, the citrate commences to react with the tartaric acid, which is precipitated as potassium hydrogen tartrate in streaks on the sides of the vessel. If much sulphuric acid is present a fine precipitate of potassium sulphate precedes the appearance of the bitartrate. When the streaks begin to appear, a cubic centimetre of the citrate solution is added for every gram of tartaric acid supposed to be present, in all cases avoiding a great excess of the reagent. If a gelatinous precipitate should appear, the estimation is repeated with the previous addition of some citric acid. After stirring continuously for 10 minutes at a temperature not exceeding 15°, the precipitate is washed two or three times with 25 c.c. of a 5 p.c. solution of potassium chloride, saturated with potassium hydrogen tartrate. The precipitate is then collected on a small filter and washed with the same solution until the acidity of the filtrate is only slightly greater than that of the washing solution. The filter and precipitate are then transferred to a beaker and the amount of tartaric acid estimated by titration against standard alkali, phenolphthalein or litmus being used as an indicator. Sometimes a potassium hydrogen citrate is carried down with the tartrate and is difficult to separate. The best method is to dissolve the precipitate in 50 c.c. of hot water, add 5 grms. of potassium chloride, and cool the liquid quickly to 15° with continuous stirring for 10 minutes. This purified precipitate is then washed with the washing liquid and treated as above, but a correction of 0·5 p.c. must be added to the percentage of tartaric acid so found to allow for unavoidable losses in the purification process. From very old liquors containing much sulphuric acid potassium alum may be precipitated owing to its sparing solubility in solutions of potassium sulphate. To prevent this phosphoric acid should be added before the citrate solution, and the liquid filtered immediately after stirring. For further details *v.* Allen's Commercial Organic Analysis, 1911, i. 541.

To estimate the free sulphuric acid, 20 c.c. of the liquid are made up to 200 c.c. with alcohol and allowed to remain overnight. The liquid is then filtered through a dry filter, and the alcohol evaporated from 100 c.c. of the filtrate. The sulphuric acid is then estimated as barium sulphate in the usual manner (Allen, *ibid.* 549).

To estimate the total organic acids, a known volume of the liquor is exactly neutralised with standard alkali and the liquid evaporated to dryness. The residue is ignited at a very low temperature until the carbon is nearly all burnt away. The ash is heated with a known volume of standard sulphuric acid, the solution decanted and the insoluble residue heated with more standard acid, concentrating the solution, if necessary, to dissolve the phosphates. To the mixed cold concentrated solutions, sufficient sodium potassium tartrate is added to keep any aluminium in solution and the solution titrated with standard alkali using litmus as an indicator. Each c.c. of normal sulphuric acid neutralised by the ash is equivalent to 0·075 grm. of organic acid, expressed in terms of tartaric acid (Warington. J. Chem. Soc. 1876, 28, 982).

Lees, argols, and *tartars.* About 8 grms. of the lees or argol (or 3 grms. of tartar) are heated on the water-bath with a little water for 5 minutes. Two grams of potassium oxalate are added and the mixture heated for a further 15 minutes. While hot the solution is nearly neutralised with a 3·5 p.c. solution of potassium hydroxide, the quantity of alkali being about 0·5 p.c. below that required for complete neutralisation, as determined by a preliminary experiment (*v. infra*). The solution is then heated on the water-bath for 30 minutes and the precipitate filtered off with the aid of a filter pump. The precipitate is washed ten times with water, using 3 c.c. each time, and the filtrate should have a volume of 50 c.c.; to this solution are added 5 grms. of potassium chloride and 2·5 grms. of citric acid, and after stirring continuously for 10 minutes, the solution is allowed to stand for 30 minutes. The precipitated potassium hydrogen tartrate is filtered off and washed with a 10 p.c. solution of potassium chloride saturated with potassium hydrogen tartrate, the acidity of which has been previously determined with N/10 alkali. When the acidity of the washings is the same as that of the washing solution the precipitate is dissolved in hot water and titrated with N/10 potassium hydroxide. The preliminary determination of the acidity of the sample is carried out as follows: Exactly 3 grms. of the sample are extracted with boiling water, the liquid decanted off and the operation repeated. The residue is transferred to a filter paper and washed until the washings are no longer acid. The solution is then titrated with 3·5 p.c. potassium hydroxide solution, using neutral litmus paper as an indicator (Allen, *ibid.* 546; Warington, *l.c.*; Grosjean, Chem. Soc. Trans. 1879, 34).

Total tartaric acid. Many methods have been proposed for the analysis of tartar and at the Seventh International Congress of Applied Chemistry, the method of Goldenberg, Geromont

& Co. was adopted as being most suitable (Zeitsch. anal. Chem. 1908, 47, 57). A weighed amount of the sample (6 grms. if the tartaric acid yield is likely to be above 45 p.c.; 12 grms. if below that percentage) is digested with 18 c.c. of hydrochloric acid of sp.gr. 1·1 for 10 minutes. The whole mass is then washed into a 200 c.c. graduated flask, made up to the mark with distilled water, shaken well and filtered through a dry filter into a dry flask. 100 c.c. of the filtered liquid are then poured into a 300 c.c. beaker, containing 10 c.c. of potassium carbonate solution (66 grms. of pure carbonate in 100 c.c.). The solution is brought to boiling and kept at that point for 20 minutes until the calcium carbonate has separated in a crystalline form. The liquid and precipitate are rinsed into a 200 c.c. flask, made up to the mark and filtered through a dry filter. 100 c.c. of the filtrate are transferred to a porcelain basin and evaporated to 15 c.c. While the liquid is still hot, 3·5 c.c. of glacial acetic acid are added gradually with constant stirring, which is maintained for 5 minutes after the acid has been added. After standing for 10 minutes, 10 c.c. of 95 p.c. alcohol are added and the liquid stirred for another 5 minutes. The liquid is allowed to stand for a further 10 minutes and then filtered with the aid of a pump and washed with alcohol until the washings are no longer acid (*v. infra*). The filter and precipitate are transferred by means of 200 c.c. of hot water into a porcelain basin, the liquid brought to boiling and titrated with N/5 alkali, using neutral litmus paper as the indicator. The alkali must have been standardised against pure potassium hydrogen tartrate, using the same paper as indicator. A correction has to be made since the volume of undissolved matter has not been allowed for in making the solution up to the various volumes. It was agreed that for samples containing less than 45 p.c. of acid, 0·8 should be deducted.; for those containing from 45 p.c. to 60 p.c., 0·3; from 60 p.c. to 70 p.c., 0·2; and for those containing over 70 p.c. no deduction should be made. To control the washings 30 c.c. of the alcohol is titrated with standard alkali, using phenolphthalein as indicator. The washing is continued until 30 c.c. of the filtrate require the same amount of standard alkali to give the colour that was produced in the test with the original 30 c.c.

This method has been criticised by Heczko (Zeitsch. anal. Chem. 1911, 50, 12), Tobler and Caramelli (J. Soc. Chem. Ind. 1911, 207), Ordonneau (Bull. Soc. chim. 1910, [iv.] 7, 1034) and Beys (Compt. rend. 1910, 150, 1250; Bull. Soc. chim. 1910, [iv.] 7, 697). According to Heczko the results obtained are influenced by the amount of calcium salts present, as they are not completely precipitated by potassium carbonate in the presence of tartrates. Also the insolubility of potassium hydrogen tartrate depends on the temperature and concentration of the solution from which it is precipitated. Tobler and Caramelli state that the error introduced by making the solution up to 200 c.c. after treatment with potassium carbonate increases with the amount of precipitated calcium carbonate, and the suggested corrections do not adequately allow for it. Ordonneau has made a series of determinations by the Goldenberg method, using for the purpose of analysis pure potassium hydrogen tartrate and calcium tartrate to which known quantities of the impurities which occur in tartars were added. He concludes that the error when litmus is used as indicator is double that obtained with phenolphthalein and that the best results are obtained with the latter indicator at 50° after boiling and cooling to that temperature. His results are tabulated below:—

Impurities added to potassium hydrogen tartrate	Total tartaric acid	Percentage of impurity	Loss of tartaric acid		Loss of tartaric acid per gram of impurity.	
			Litmus	Phenolphthalein	Litmus	Phenolphthalein
Calcium phosphate (tribasic) . .	75·80	5	2·35	1·60	0·47	0·32
Ferrous phosphate	75·80	5	6·15	3·68	1·22	0·73
Ferric phosphate	75·80	5	7·95	3·98	1·59	0·79
Aluminium phosphate	75·80	5	4·65	2·20	0·93	0·44
Alumina, pure anhydrous . . .	75·80	5	19·35	8·80	3·87	1·76
Ferric chloride, dry (≡ 4·92 grms. Fe_2O_3)	71·81	10	13·38	7·21	2·71	1·46
Calcium tartrate	78·69	5	1·77	0·99	—	—
Calcium tartrate	77·57	10	1·85	1·04	—	—
Calcium tartrate (alone) . . .	57·69	—	2·08	2·00	—	—

Lead in tartaric acid. The following method is due to W. A. Davis (Allen's Commercial Organic Analysis, 1911, i. 550, 569; *cf.* Wilkie, J. Soc. Chem. Ind. 1909, 28, 637). The reagent is freshly prepared colourless ammonium sulphide, obtained by diluting 2 c.c. of 0·880 ammonia to 10 c.c. and saturating with well-washed hydrogen sulphide. Standard lead solutions are made by dissolving 5 grams of pure lead in nitric acid, evaporating to remove all but the last traces of nitric acid and diluting to 1000 c.c. For use portions of it are taken, diluted 100 times and treated in the usual manner for colour comparisons.

Ten grams of tartaric acid are dissolved in 25 c.c. of hot water, cooled, and to the solution are added 2 c.c. of N/10 sodium thiosulphate solution. The solution is heated nearly to boiling, cooled, and 1 c.c. of a 10 p.c. solution of potassium cyanide is added. Then ammonia (0·880) is added until the liquid has a faint smell of the reagent. The liquid is boiled until it is colourless, poured into a tall cylinder, made up to 100 c.c. and treated with 2 drops of the freshly prepared reagent. The tint obtained is compared with tints produced by solutions made from pure lead-free tartaric acid to which known amounts of the lead nitrate solution have been added, so as to give comparisons of the order of 5 parts per 1,000,000, 10 parts per 1,000,000, &c. If it is desired to test cream of tartar, 10 grams should be dissolved in hydrochloric acid and after the addition of sodium thiosulphate, the above method can be used.

Wines. For estimating tartaric acid in wines the method of Kling may be used (Compt. rend. 1910, 150, 616; Bull. Soc. chim. 1912, [iv.] 11, 886). 25 c.c. of the solution, diluted or concentrated so as to contain 3–4 grms. of tartaric acid per litre, are added to 100 c.c. of water. To the solution are added 25 c.c. of a solution of *l*-potassium sodium tartrate (16 grms. per litre) and 20 c.c. of a solution of calcium acetate (30 grms. per litre). The precipitated calcium racemate is filtered off, washed, and dissolved in 20 c.c. of hydrochloric acid (40 grms. per litre). The solution is diluted to 150 c.c. and 40 c.c. of a solution of sodium acetate (10 p.c.) and calcium acetate (1 p.c.) is added and the liquid heated to boiling. After cooling the racemate is collected, washed, dissolved in boiling dilute sulphuric acid and titrated at the boiling-point with potassium permanganate solution (16 grms. per litre), which has been standardised against potassium hydrogen tartrate. In the presence of considerable amounts of iron or aluminium salts, &c., the initial precipitation must be performed in the presence of ammonium citrate (Kling and Florentin, Ann. Falsif. 1912, 5, 518). For other methods of estimation in wines, *v.* Gowing-Scopes, Analyst, 1908, 33, 315; von Florentz, Chem. Zeit. 1907, 31, 1118.

l-Tartaric Acid.

This acid, which has also been called *anti-tartaric acid*, was first obtained by Pasteur (Ann. Chim. Phys. 1850, [iii.] 28, 56) by the crystallisation of a solution of sodium ammonium racemate. The product was found to consist of a mixture of hemihedral crystals, some having the hemihedral faces developed to the right and others to the left, the former being dextrorotatory, and the latter lævorotatory. The acid obtained from the former was *d*-tartaric acid, while the latter yielded a lævorotatory acid, *l*-tartaric acid (*cf.* Bichat, Bull. Soc. chim. 1886, [ii.] 46, 54; Jungfleisch, J. 1883, 1084). The best method of preparation is that due to Marckwald (Ber. 1896, 29, 42; *cf.* Kling, Bull. Soc. chim. 1910, [iv.] 7, 774). To a boiling aqueous solution of racemic acid is added gradually half the amount of cinchonine necessary to form the acid salt and sufficient water to give a clear solution. After standing for one day cinchonine *l*-tartrate crystallises out, from which *l*-tartaric acid can be obtained in the usual manner. The yield is two-thirds of that demanded by theory. For asymmetric synthesis by the action of potassium permanganate on *l*-bornyl fumarate, *v.* McKenzie and Wren, Chem. Soc. Trans. 1907, 1215.

Properties. *l*-Tartaric acid forms anhydrous rhombic crystals, m.p. 168°–170° (Bischoff and Walden, Ber. 1889, 22, 1820; Zeitsch. physikal. Chem. 1891, 8, 466). It resembles *d*-tartaric acid in most of its physical properties (*v.* p. 403), but the two acids are oppositely pyroelectric and also solutions of the same concentration rotate the plane of polarised light an equal amount, but in opposite directions. Solutions of *l*-tartaric acid are destroyed by *Schizomycetes.* The salts of *l*-tartaric acid have the same number of molecules of water of crystallisation and the same crystalline form as those of *d*-tartaric acid. They exhibit opposite hemihedry, opposite rotation and are oppositely pyroelectric. They are also somewhat more soluble than the corresponding salts of the *d*-acid (Jungfleisch, Bull. Soc. chim. 1884, [ii.] 41, 223). There are differences between the compounds of the two acids with optically active substances. Thus a partially racemic compound is obtained by the combination of ammonium *d*-tartrate and ammonium *l*-malate, whilst ammonium *l*-tartrate does not undergo this combination (*v.* Racemism). The compounds with optically active bases also are different, thus cinchonine *d*-tartrate crystallises with $4H_2O$, whilst the *l*- salt only has $1H_2O$, but the affinity constants of *d*- and *l*-tartaric acids for optically active bases are the same (Marckwald and Chwolles, Ber. 1898, 31, 783).

Racemic Acid.

This acid, which is also known as r-*tartaric acid* or *paratartaric acid*, was discovered by Kestner in the mother liquors of tartaric acid obtained from the vintage of 1822 (Compt. rend. 1849, 29, 526, 557) and was examined by Gay-Lussac (Schweiger's J. 48, 381), Walchner (*ibid.* 49, 238), Berzelius (Pogg. Annalen, 19, 319), and Biot (Ann. Chim. Phys. [ii.] 69, 22), of whom the last-named pointed out its optical inactivity. Pasteur investigated its properties further and decomposed it into *d*- and *l*-tartaric acids (Compt. rend. 1853, 36, 19; 37, 162). Racemic acid appears to exist to some extent in grape juice, but is produced chiefly during the fermentation. It is produced to a certain extent in the tartaric acid works in the process of purification, and after crystallising cream of tartar, potassium ammonium racemate can be extracted from the mother liquors.

Preparation. Most methods for the production of racemic acid result also in the formation of mesotartaric acid, from which it may be separated by the method given on p. 404. The following are the chief methods for the interconversion of the tartaric acids. When *d*-tartaric acid is heated for 30 hours at 170° with one-seventh to one-tenth of its weight of water, racemic acid is the main product, whilst by heating *d*-tartaric acid (or racemic acid) with 4 c.c. of water for 2 days at 165°, mesotartaric acid is produced (Jungfleisch, Bull. Soc. chim. 1872, [ii.] 18, 203; 1873, [ii.] 19, 101; 1874, [ii.] 21, 146; 1878, [ii] 30, 191; *cf.* Dessaignes, *ibid.* 1863, [i.] 5, 356). According to Meisner, the yield of mesotartaric acid is only 5·5 p.c. by this method, and if 100 grms. of *d*-tartaric acid are heated with 350 grms. of sodium hydroxide, and 700 grms. of water during 8 hours in a copper flask, racemic acid is obtained almost free from mesotartaric acid, only 1·3 p.c. of the latter being produced (Ber.

1897, 30, 1574). Holleman states that by heating *d*-tartaric acid for 8 hours with boiling alkali, 24 p.c. of mesotartaric acid is produced, the maximum yield of 31 p.c. being obtained after only 2 hours' heating (Rec. trav. chim. 1898, 17, 66; *cf.* Bosekin, *ibid.* 224). Holleman also heated 6 grms. of *d*-, *r*-, and *i*-tartaric acids wth 4 c.c. of N-hydrochloric acid in sealed tubes and obtained the following results. *d*-Tartaric acid below 140° yielded *i*-tartaric acid almost entirely, but after 42 hours at 155°, 6·7 p.c. of *r*-tartaric acid and 18 p.c of *i*-tartaric acid were obtained. *r*-Tartaric acid, after 100 hours at 140°, yielded 19 p.c. of *i*-tartaric acid, and the latter under similar conditions gave 10 p.c. of the *r*-tartaric acid. Finally when *d*- and *l*-tartaric acids are mixed in equal quantities in solution, racemic acid is the sole product.

By heating dibromosuccinic acid or dibromo*iso*succinic acid with 200 parts of water, a mixture of mesotartaric and racemic acids is obtained, the former yielding chiefly mesotartaric acid and the latter racemic acid (Lossen and Riebensahm, Annalen, 1896, 292, 295; *cf.* Pasteur, Annalen, Suppl. 2, 242). A similar result is obtained by using the silver salt (Perkin and Duppa, Quart. J. Chem. Soc. 1861, 13, 112; Kekulé, Annalen, 1860, 117, 121). By heating an alcoholic solution of glyoxal with a 5 p.c. excess of alcoholic hydrocyanic acid, a mixture of the nitriles of racemic and mesotartaric acids is produced (Pollak, Monatsh. 1894, 15, 469; Strecker, Zeitsch. Chem. 1868, 216; Schöyen, Annalen, 1864, 132, 168; Staedel, Ber. 1878, 11, 752). When phenol is oxidised with potassium permanganate in alkaline solution a mixture of *r*- and *i*-tartaric acids is obtained (Doebner, Ber. 1891, 24, 1755).

Racemic acid may be obtained by reducing glyoxylic acid with zinc and acetic acid, glycollic acid also being produced (Genvresse, Compt. rend. 1892, 114, 555); by oxidising fumaric acid with potassium permanganate (Kekulé and Anschütz, Ber. 1880, 13, 2150; Annalen, 1884, 226, 191; *cf.* Tanatar, Ber. 1879, 12, 2293); by treating piperic or sorbic acid with dilute potassium permanganate solution (Doebner, *ibid.* 1890, 23, 2374); by the action of nitric acid on fructose, mucic acid, and inulin, the first-named also yielding mesotartaric acid (Kiliani, *ibid.* 1881, 14, 2530); and together with *d*-tartaric acid by the action of nitric acid on dulcitol, mannitol, milk sugar, cane sugar, and saccharic acid (Carlet, J. 1860, 249; 1861, 367; Hornemann, J. pr. Chem. 1861, [i.] 89, 283).

Properties. Racemic acid crystallises in large plates belonging to the triclinic system and which contain 1 mol. of water of crystallisation. It is less soluble in water or alcohol than tartaric acid, and has m.p. 205°–206°; sp.gr. 1·697 (Walden, Ber. 1896, 29, 1701). The reactions which it undergoes are the same as those of tartaric acid.

The racemates resemble the tartrates in most respects, but differ in their solubility and in the number of molecules of water of crystallisation which they contain. Thus *potassium racemate* crystallises in the rhombic system with $1H_2O$, or in the monoclinic with $2H_2O$ (van 't Hoff and Müller, Ber. 1899, 32, 857), whilst the *rubidium salt* crystallises in the monoclinic system with $2H_2O$ at low temperatures; at higher temperatures the solution deposits crystals of rubidium *d*- and *l*-tartrates (Traube, Sitzungsber. Berl. Akad. 1895, 10, 195; Wyrouboff, Chem. Zentr. 1901, ii. 764; *cf.* van't Hoff and Müller, Ber. 1898, 31, 2206). *Calcium racemate* crystallises in fine needles containing $4H_2O$, and is obtained by adding calcium sulphate to a soluble racemate or racemic acid. It is even less soluble than calcium tartrate, and use is made of this fact in Kling's method for the estimation of tartaric acid (*v.* p. 416). For distinction from calcium tartrate *v.* p. 412. The *barium salt* crystallises with $2\frac{1}{2}H_2O$ and with $5H_2O$ (Lossen and Riebensahm, Annalen, 1896, 292, 313; Mügge, Chem. Zentr. 1899, ii. 245). For resolution of racemates into *d*- and *l*-tratrates, *v.* RACEMISM.

MESOTARTARIC ACID.

Mesotartaric acid, which is also known as i-*tartaric acid*, was first obtained by Pasteur, together with racemic acid, by heating cinchonine *d*- or *l*-tartrate for some time at 170°. Most of the methods of preparation result also in the production of racemic acid, the best being that of Holleman (*v. Racemic acid*). It may also be obtained by treating mesodiaminosuccinic acid with nitrous acid (Farchy and Tafel, Ber. 1893, 26, 1986; *cf.* Lehrfeld, *ibid.* 1881, 14, 1819), or by oxidising sorbin (Dessaignes, Annalen, Suppl. 2, 242), erythritol (Przybtek, J. Russ. Phys. Chem. Soc. 1880, 12, 209) or glycerol (*ibid.* 1881, 13, 330) with dilute nitric acid.

It crystallises in rectangular plates containing 1 mol. of water of crystallisation, and has m.p. 140° and sp.gr. 1·666 (Bischoff and Walden, Ber. 1896, 29, 1702). It is slightly less soluble in water than tartaric acid. Its affinity constant is 0·060. The mesotartrates resemble the tartrates except in their solubility and in the number of molecules of water of crystallisation which they contain. Thus the *calcium salt* contains $3H_2O$ and, like the potassium salt, is more soluble than the corresponding salt of tartaric acid. Marckwald and Karczag (Ber. 1909, 42, 1518) have prepared two optically active methyl hydrogen mesotartrates by boiling mesotartaric acid with methyl alcohol and resolving the resulting racemic ester with strychnine.

TARTRAZINE *v.* PYRAZOLONE COLOURING MATTERS.

TARTRONIC ACID, *hydroxymalonic acid* $HO{\cdot}CH(CO_2H)_2$, discovered by Dessaignes in 1853 as a decomposition product of an aqueous solution of dinitrotartaric acid and hence named *tartronic acid* (Annalen, 1852, 82, 363; 1854, 89, 339; compare Demole, Ber. 1877, 10, 1788); is also obtained by reducing mesoxalic acid with sodium amalgam (Deichsel, Zeitsch. Chem. 1865, 69); by the action of baryta water or of silver oxide on monobromomalonic acid (Pinner, Ber. 1875, 8, 963; Petrieff, *ibid.* 1878, 11, 414); by hydrolysing ethyl monochloromalonate with potassium hydroxide and decomposing the calcium salt with oxalic acid (Conrad and Bischoff, *ibid.* 1880, 13, 595); by the action of baryta water on dibromopyruvic acid (Grimaux, Bull. Soc. chim. 1877, [ii.] 27, 440); or of dilute sodium hydroxide on ethyl trichlorolactate (Pinner, 1885, Ber. 18, 752). Tartronic acid can be obtained by the careful oxidation of glycerol with nitric acid (Sadtler, *ibid.* 1875, 8, 1456) or potassium permanganate (Campani and Bizzarri, Gazz. chim. ital. 1880, 10, 489; compare *ibid.* 1883, 13, 490); and it has been synthesised by treating glyoxylic acid with potassium cyanide and boiling the product with baryta water (Böttinger, Ber. 1881, 14, 729). Tartronic acid is most conveniently prepared by heating an aqueous solution of dihydroxytartaric acid until carbon dioxide ceases to be evolved and finally evaporating the solution (Fenton, Chem. Soc. Trans. 1898, 73, 73; compare Grüber, Ber. 1879, 12, 514).

Tartronic acid crystallises from water in large, hard, anhydrous prisms; it sublimes when carefully heated at 110°–120° (Conrad and Bischoff, *l.c.*); melts at 158°–159° (Fenton, *l.c.*; Skinner, Chem. Soc. Trans. 1898, 73, 489); at 155° (Grüber, *l.c.*; Massol, Compt. rend. 1892, 114, 422); at 145°–160° (Grimaux, *l.c.*); melts and decomposes at 185°–187° (Conrad and Bischoff, *l.c.*); at 178°–180° (Campani and Bizzarri, Gazz. chim. ital. 1882, 12, 1); at 184° (Pinner, *l.c.*); at 183° (Böttinger, *l.c.*). It has electrical conductivity $\mu_D=357$ (Ostwald, Zeitsch. Physikal. Chem. 3, 369), affinity constant $K=0{\cdot}107$ (Skinner, *l.c.*); for heats of neutralisation compare Gal and Werner (Compt. rend. 1886, 103, 871, and Massol (*l.c.*). It is readily oxidised by hydrogen peroxide in the presence of ferrous salts into mesoxalic acid (Fenton, Chem. Soc. Trans. 1900, 77; 71).

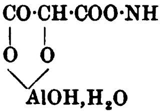
Salts. Tartronic acid forms both normal and acid salts, which, with the exception of the salts of the alkali metals, are insoluble or only sparingly soluble in water (Pinner, Ber. 1885, 18, 752). The following salts are described:—*Ammonium* $C_3H_2O_5(NH_4)_2$ and $C_3H_3O_5(NH_4)$ (Dessaignes, *l.c.*); *sodium* $C_3H_2O_5Na_2$ is deliquescent and becomes anhydrous at 110°, the *acid* salt is unstable; *potassium* $C_3H_2O_5K_2$ and

$$C_3H_3O_5K,\tfrac{1}{2}H_2O$$

(Conrad and Bischoff, *l.c.*; Massol, *l.c.*); *barium* $C_3H_2O_5Ba,2H_2O$; *calcium* $C_3H_2O_5Ca,2\tfrac{1}{2}H_2O$ (Pinner, *l.c.*); *zinc* and *mercury* salts are white precipitates, *cobalt* salt is a red flocculent precipitate; the *copper* salt bluish-green crystals (Conrad and Bischoff, *l.c.*); *lead* salts $C_3H_2O_5Pb$ and $(C_3HO_5)_2Pb_3,2H_2O)$; *cadmium* salt $C_3H_2O_5Cd$ (Grüber, *l.c.*); *silver* salt $C_3H_2O_5Ag_2$ is crystalline (Conrad and Bischoff, *l.c.*); *manganese* salt

$$[CO_2H{\cdot}CH(OH){\cdot}COO]_2Mn$$

crystallises in the triclinic system (Campani and Bizzarri, *l.c.*); the aluminium in the complex *aluminium* compound



$$\begin{array}{c} CO{\cdot}CH{\cdot}COO{\cdot}NH_4 \\ |\quad\;\; | \\ O\quad O \\ \diagdown\diagup \\ AlOH,H_2O \end{array}$$

is not precipitated by ammonia (Hamus and Quadrat, Zeitsch. anorg. Chem. 1909, 63, 306).

Derivatives. The *ethyl ester* $HO{\cdot}CH(COOEt)_2$ has m.p. 2°, b.p. 120·5°–121°/15 mm. (Filippo, Rec. trav. chim. 1910, [ii.] 14, 113; Freund, Ber. 1884, 17, 780; Pinner, *l.c.*); it forms an *acetate* $CH(OAc)(CO_2Et)_2$, b.p. 235°–245° under atmospheric pressure, or 158°–163°/60 mm.; of which the *ethyl* derivative $CEt(OAc)(CO_2Et)_2$ has b.p. 151°–153°/30 mm. (Conrad and Brückner, Ber. 1891, 24, 2997); the *phenyl ether*

$$CH(OPh)(CO_2Et)_2$$

has b.p. 230°–240°/60 mm., and yields the crystalline *acid* $CH(OPh)(COOH)_2$ on hydrolysis. The *methyl ester* $HO{\cdot}CH(CO_2Me)_2$ has m.p. 44·5°–45°, b.p. 122°/19 mm. (Filippo, *l.c.*); the *chloro* derivative $HO{\cdot}CCl(CO_2Me)_2$ has m.p. 42°, is unstable and converted into methyl dihydroxymalonate on exposure to moist air; the *bromo* derivative $HO{\cdot}CBr(CO_2Me)_2$, m.p. 30° (decomp.) dissociates at 40° into hydrogen bromide and methyl mesoxalate; the *anilino* derivative $PhNH{\cdot}C(OH)(CO_2Me)_2$ has m.p. 102° and yields methyl phenyliminomalonate $NPh:C(CO_2Me)_2$ by the action of phosphoric oxide (Curtiss and Spencer, J. Amer. Chem. Soc. 1909, 31, 1053).

Tartronamic acid $CO_2H{\cdot}CH(OH)CONH_2$ prepared by boiling freshly prepared sodium dialurate with water, forms large needles or prismatic crystals, m.p. 160° (decomp.), and yields crystalline *barium* $(C_3H_4O_4N)_2Ba,H_2O$, *lead* $(C_3H_4O_4N)_2Pb,\tfrac{1}{2}H_2O$; *potassium*

$$C_3H_4O_4NK,H_2O$$

and *silver* $C_3H_4O_4NAg$ salts (Menschutkin, Annalen, 1876, 182, 82).

Tartronamide $HO{\cdot}CH(CONH_2)_2$ has m.p. 195°–196° (Pinner, *l.c.*), 198° (Freund, *l.c.*) and gives the biuret reaction (Schiff, Ber. 1896, 29, 298, 1354). *Tartrono-dimethylamide*

$$HO{\cdot}CH(CONHMe)_2$$

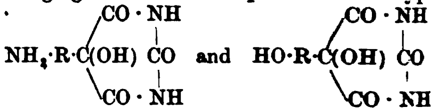
has m.p. 153°–154° (Filippo, *l.c.*).

Alkyl substituted tartronic acids. Methyltartronic acid $HO{\cdot}CMe(CO_2H)_2$ has m.p. 175° (Schmöger, J. pr. Chem. [ii.] 14, 77; 19, 168; 24, 38; Böttinger, Ber. 1881, 14, 87, 148; 1884, 17, 114); *ethyltartronic acid* $HO{\cdot}CEt(CO_2H)_2$ has m.p. 98° (Guthzeit, Annalen, 1881, 209, 232); iso*butyltartronic acid* $HO{\cdot}C(C_4H_9)(CO_2H)_2$ has m.p. 110°–114° (Conrad and Bischoff, Annalen, 1881, 209, 218), *benzyltartronic acid*

$$CH_2Ph{\cdot}C(OH)(CO_2H)_2$$

has m.p. 143°; all these acids decompose at their melting-point, yielding the corresponding member of the acetic acid series.

Aryl substituted tartronic acids. Alloxan condenses with aromatic amines, phenols or polyhydric phenols in the presence of condensing agents to form compounds of the types



$$NH_2{\cdot}R{\cdot}C(OH)\begin{cases}CO{\cdot}NH \\ \qquad\;\; CO \\ CO{\cdot}NH\end{cases} \text{ and } HO{\cdot}R{\cdot}C(OH)\begin{cases}CO{\cdot}NH \\ \qquad\;\; CO \\ CO{\cdot}NH\end{cases}$$

and these are readily hydrolysed by alkali to give the alkali salt of the corresponding substituted tartronic acid

$$NH_2{\cdot}R{\cdot}C(OH)(COOK)_2$$

and $HO{\cdot}R{\cdot}C(OH)(COOK)_2$ from which the acid is usually easily obtained. The following acids obtained by these methods are described in the patent literature (D. R. PP. 107720, 112174, 113722, 114904, 115817):—p-*ethylaminophenyltartronic acid*

$$NHEt{\cdot}C_6H_4{\cdot}C(OH)(CO_2H)_2,$$

m.p. 163° (decomp.); p-*diethylaminophenyltartronic acid* $NEt_2{\cdot}C_6H_4{\cdot}C_3H_3O_5$, m.p. 107°–108° (decomp.); p-*benzylaminophenyltartronic acid* $C_7H_7NH{\cdot}C_6H_4{\cdot}C_3H_3O_5$, m.p. 137° (decomp.); *potassium hydrogen* p-*ethylbenzylaminotartronate* $C_7H_7NEt{\cdot}C_6H_4{\cdot}C_3H_2O_5K$; p-*phenylaminophenyltartronic acid* $NHPh{\cdot}C_6H_4{\cdot}C_3H_3O_5$, m.p. 125°–127° (decomp.); p-*iminodiphenyltartronic acid*

$NH(C_6H_4{\cdot}C_3H_3O_5)_2$ as potassium hydrogen salt only; p-*amino*-m-*tolyltartronic acid*

$$NH_2{\cdot}C_7H_6{\cdot}C_3H_3O_5,$$

m.p. 194°–195° (decomp.); p-*ethylamino*-m-*tolyltartronic acid* $NHEt{\cdot}C_7H_6{\cdot}C_3H_3O_5$; p-*amino*-m-*methoxyphenyltartronic acid*

$$NH_2{\cdot}C_6H_3(OMe)C_3H_3O_5,$$

m.p. 187°–188° (decomp.); p-*methylamino*-m-*methoxyphenyltartronic acid*

$$NHMe{\cdot}C_6H_3(OMe)C_3H_3O_5,$$

m.p. 135° (decomp.); p-*amino*-m-*ethoxyphenyltartronic acid*, m.p. 150° (decomp.); p-*amino*-o-*chlorophenyltartronic acid* $NH_2{\cdot}C_6H_3Cl{\cdot}C_3H_3O_5$, m.p. 198°–199° (decomp.); p-*dimethyl*- and p-*diethyl-amino*-o-*chlorophenyltartronic acids* as potassium hydrogen salts only; p-*ethylenediaminodiphenyltartronic acid* $C_2H_4N_2H_2(C_6H_4{\cdot}C_3H_3O_5)_2$ decomposes at 400°; o-*hydroxyphenyltartronic acid* $HO{\cdot}C_6H_4{\cdot}C_3H_3O_5$, m.p. 118°–120° (decomp.); p-*hydroxy*-m-*methoxy-phenyltartronic acid*; o-*hydroxy*-m-*tolyltartronic acid*; and m-p-*dihydroxyphenyltartronic acid*. M. A. W.

TASMANITE *v.* RESINS.

TAURINE, *a-amino-β-ethanesulphonic acid*

$$NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}SO_3H,$$

in combination with cholic acid forms one of the chief constituents of the bile of oxen and other animals, whence it was obtained by Gmelin in 1826; it was afterwards investigated by Demarçay (Annalen, 1838, 27, 286) and by Dumas and Pelouze (*ibid.* 292), who overlooked the fact that it contained sulphur and gave it the formula $C_2H_7NO_5$. Redtenbacher (*ibid.* 1846, 57, 170), remarking on the strangely inert behaviour towards strong acids of a compound containing so large a proportion of oxygen, reinvestigated the compound, and on fusion with alkali obtained evidence of the presence of sulphur, and gave it the correct formula $C_2H_7NO_3S$. Taurine occurs in the muscles and organs of Bojanus of *Mytilus edulis* (Kelly, Beitr. chem. Physiol. Path. 1904, 5, 377); in the extract of muscle and the hepato-pancreas of various marine gasteropods (Mendel, *ibid.* 582); and in meat extract (Micko, Zeitsch. Nahr. Genussm. 1908, 15, 449; Zeitsch. physiol. Chem. 1908, 56, 180). The source of the taurine in the animal economy is the cystine of the ingested protein, the oxidation occurring in the liver; experiments on dogs serve to show that the administration of cystine leads to an increase in the output of taurine (Von Bergmann, Beitr. chem. Physiol. Path. 1903, 4, 192); and experiments on cats show that if artificial cystinuria is produced there is a consequent fall in the taurine of the bile (Gibson, Proc. Amer. Soc. Biol. Chem. 1908, 16).

Synthesis. Taurine can be synthesised from ethylene by the following series of reactions:—ethylene dibromide is converted by the action of antimony pentachloride into ethylene chlorobromide, which on treatment with potassium thiocyanate yields ethylene chlorothiocyanate; this is converted by oxidation into chloroethylsulphonic acid, the silver salt of which reacts with ammonia at 100°–120°, yielding taurine

$$C_2H_4 \rightarrow C_2H_4Br_2 \rightarrow C_2H_4ClBr \rightarrow C_2H_4Cl(CNS)$$
$$\rightarrow C_2H_4Cl{\cdot}SO_3H \rightarrow C_2H_4(NH_2)SO_3H$$

(James, Chem. Soc. Trans. 1879, 35, 810; compare Kolbe, Annalen, 1862, 122, 33). Taurine can also be readily prepared from cysteic acid (*a*-amino-*β*-sulphopropionic acid) by heating it with water in a sealed tube at 235°–240°

$$SO_3H{\cdot}CH_2{\cdot}CH(NH_2)CO_2H \rightarrow SO_3H{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2$$

(Friedmann, Beitr. Chem. Physiol. Path. 1903, 3, 1).

Taurine crystallises in large tetragonal plates, that decompose on heating above 240°; it is soluble in 15·5 parts of water at 12°, or in 25,000 parts of 90 p.c. alcohol at 17° (Stutzer, Zeitsch. anal. Chem. 1892, 31, 503).

When taurine is administered to human subjects or to dogs, it is eliminated partly unchanged and partly in the form of taurocarbamic acid (*v. infra*; Salkowski, Ber. 1873, 6, 744); when fed to fowls a considerable portion reappears unchanged in the excreta, the remainder is oxidised to sulphuric acid (Čech, *ibid.* 1877, 10, 1461).

Salts. Taurine has a neutral reaction, and forms salts with bases, the *silver* $C_2H_6NSO_3Ag$; *lead* $(C_2H_6NSO_3)_2Pb$ and

$$2[(C_2H_6NSO_3)_2Pb],Pb(OH)_2;$$

sodium $C_2H_6NSO_3Na$ and *calcium* $(C_2H_6NSO_3)_2Ca$ salts are crystalline and soluble; the *cadmium* salt $(C_2H_6NSO_3)_2Cd$ is a sparingly soluble white powder, and *mercury* salt $(C_2H_6NSO_3)_2Hg$ is insoluble in cold and sparingly soluble in hot water and is well adapted for the preparation of pure taurine and for its detection (Lang, Ber. 1876, 9, 853; Bull. Soc. chim. 1876, [ii.] 25, 180)

Derivatives. *Ethanesulphonimide* or *anhydrotaurine*  $C_2H_4\left<\begin{matrix}NH\\|\\SO_2\end{matrix}\right.$ obtained by the action of ammonia on *β*-chloroethylsulphonic chloride is a gum-like solid, m.p. 45°–50°; is not decomposed on heating with water at 150°, and yields a mercury derivative  $\left[C_2H_4\left<\begin{matrix}N\\|\\SO_2\end{matrix}\right.\right]_2Hg$ with HgO (James, Chem. Soc. Trans. 1886, 49, 486).

The mono-, di- and tri-substituted taurines are obtained by heating the amine salt of *β*-chloroethylsulphonic acid with the necessary quantity of the amine at 160° in a sealed tube for 10 hours.

Methyltaurine $NHMe{\cdot}C_2H_4{\cdot}SO_3H$, m.p. 241°–242°, forms lustrous prisms belonging to the anorthic system; *ethyltaurine* $NHEt{\cdot}C_2H_4{\cdot}SO_3H$ rhombic prisms, m.p. 147°; *allyltaurine*

$$NH(C_3H_5)C_2H_4{\cdot}SO_3H$$

rhombic prisms, m.p. 190°–195°; *phenyltaurine* $NHPh{\cdot}C_2H_4{\cdot}SO_3H$, thin silky leaves, m.p. 277°–280° (decomp.). *Dimethyltaurine*

$$NMe_2{\cdot}C_2H_4{\cdot}SO_3H,H_2O$$

darkens at 270°–280° and finally decomposes; *diethyltaurine* $NEt_2{\cdot}C_2H_4{\cdot}SO_3H$, m.p. 151°; *methylphenyltaurine* $NMePh{\cdot}C_2H_4{\cdot}SO_3H$. *Trimethyltaurine* is an analogue of betaïne and probably has the constitution represented by the formula  $C_2H_4<\begin{matrix}NMe_2\\{\cdot}SO_2{\cdot}\end{matrix}>O$, since it yields pure trimethylamine when boiled with excess of baryta, and does not give any trace of methyl iodide on heating with hydrogen iodide; it crystallises in rhombic plates that remain unchanged at 300° (James, Chem. Soc. Trans. 1885, 47, 367; 1886, 49, 486; Dittrich, J. pr. Chem. 1878, [ii.] 18, 63). *Taurocyamine*

$$NH{:}C(NH_2)NH{\cdot}C_2H_4{\cdot}SO_3H$$

obtained by heating taurine and cyanamide at 100°–120° forms soluble white prisms, m.p. 224°–226°; *methyltaurocyamine*

$$NH:C(NH_2)NMe{\cdot}C_2H_4{\cdot}SO_3H,H_2O$$

similarly formed from methyltaurine crystallises in large monoclinic prisms that become anhydrous at 110° and turn brown at 285° (Dittrich, *l.c.*). *Phenyltaurocyamine* forms glistening leaves that do not melt at 300°; *dimethyltaurocyamine* $(CH_3)_2(CN{\cdot}NH_2)C_2H_4{\cdot}SO_3H$ has m.p. 248° (decomp.) (James, Chem. Soc. Trans. 1885, 47, 367).

Taurine condenses with benzoic and with phthalic anhydride to form the *compounds* $C_{15}H_{20}N_2S_2O$, m.p. 175°, and

$$C_{25}H_{29}N_2S_2O_{16},7H_2O\ (?),$$

m.p. 50°, respectively (Tauber, Beitr. chem. Physiol. Path. 1903, 4, 323).

Taurocarbamic acid, a-carbamido-β-ethanesulphonic acid, $NH_2{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}CH_2{\cdot}SO_3H$ occurs in the urine after the administration of taurine, and probably also in normal urine. The potassium salt is readily prepared from taurine and potassium cyanate (Salkowski, Ber. 1873, 6, 1191). The acid is also prepared by oxidising ethylenepseudothiourea with bromine water (Gabriel, *ibid.* 1889, 22, 1142); or by condensing taurine with urea in the presence of barium hydroxide (Lippich, *ibid.* 1908, 41, 2068).

Taurocarbamic acid forms prismatic crystals that begin to decompose in a closed tube at 160°, the mass again becoming crystalline and melting at 300° with decomposition. M. A. W.

TAUROCHOLIC ACID $C_{26}H_{45}NO_7S$ occurs in the form of its sodium salt as one of the chief constituents of the bile salts. It yields taurine and cholic acid on hydrolysis; and has been synthesised by condensing the azide of cholic acid $C_{23}H_{39}O_3{\cdot}CON_3$ with an alkaline solution of taurine (Bondi and Müller, Zeitsch. physiol. Chem. 1906, 47, 499; compare Tauber, Beitr. chem. Physiol. Path. 1903, 4, 323), *v.* BILE.

TAXINE $C_{37}H_{52}NO_{10}$ (?) is an alkaloid which is supposed to form the poisonous constituent of the leaves, shoots, and fruit of the yew tree (*Taxus baccata* (Linn.)). It was discovered by Lucas (J. 1856, 550; Arch. Pharm. 1857, 85, 145), but was first prepared more or less pure by Marmé in 1876 (Hilger and Brande, Ber. 1890, 23, 464). It may be obtained by extracting the powdered leaves and seeds with ether or hot alcohol, and after distilling off most of the latter, treating the residue with dilute acid and then precipitating with ammonia, the last two processes being repeated until the product becomes colourless. A better yield is said to be obtained by extracting the leaves, &c., with water acidified with sulphuric, tartaric, or oxalic acid (Vreven, Pharm. J. 1896, 4, 215; Sauvan, *ibid.* 177; Thorpe and Stubbs, Chem. Soc. Trans. 1902. 874; Moss, Sci. Proc. Roy. Dublin Soc. 1909, 12, 92. *See* also Amato and Capparelli, Gazz. chim. ital. 10, 349; Marmé, Chem. Zentr. 1876. 166).

From two specimens of the leaves of a female Irish yew, Moss obtained 0·323 p.c. and 0·623 p.c.; from the seeds of the fruit of the same, 0·079 and 0·082 p.c.; whilst from the leaves of a male specimen he obtained 0·082 p.c. The fleshy part of the berries, however, contained no taxine. In the common yew, both male and female, Thorpe and Stubbs obtained about 0·18 p.c. taxine.

Taxine is a dull, white, amorphous powder, m.p. 82° (slight decomposition). By microscopic examination, Moss detected signs of softening at 60°. It is odourless, has a very bitter taste, is almost insoluble in water, and in light petroleum, but is readily soluble in ether, alcohol, acetone, chloroform, or benzene, also in dilute acids and to a slight extent in excess of ammonia. When heated in a glass tube, a white cloud appears and drops of oil condense and then solidify on the cool parts of the tube. When treated with hydrochloric acid, it decomposes readily (Thorpe and Stubbs, *l.c.*; Moss, *l.c.*). With sulphuric acid it gives a brown to purplish-blue colour; whilst if nitric acid is present the colour is a very deep pink. With reagents generally it gives the characteristic alkaloid reactions. When heated with soda lime, ammonia is evolved. Taxine forms a series of soluble salts with acids and characteristic double salts with a number of metallic salts.

Taxine depresses the action of the heart in frogs, rabbits, cats and dogs. It interferes with the respiration and causes death in a short time through suffocation.

Taxicatin $C_{13}H_{22}O_7$, an inodorous slightly bitter substance, m.p. 166°–167°; when combined with 2 molecules of water its m.p. is 165°; $[a]_D - 72{\cdot}9°$; is also found in *Taxus baccata* (Lefebvre, J. Pharm. Chim. 1907, 26, 241).

TCHA-LAN. A blue powder containing copper; used by the Chinese for obtaining a blue colour on porcelain (Ebelmen and Salvétat, Ann. Chim. Phys. [iii.] 35, 338).

TEA. This term is usually understood to signify both the dried leaves of certain plants belonging to the natural order *Ternstrœmiaceæ* (notably two species of *Thea—T. chinensis* and *T. assamica*, or of hybrids between these two); and also the aqueous infusion prepared from them.

Tea has been used in China for many centuries. Reference to it is said to have been made by a Chinese writer who lived 2700 years B.C. as well as in poems edited by Confucius, about 500 B.C. It appears at first to have been used only medicinally, but Yo Lu, a writer who lived during the latter part of the Tang dynasty, which lasted from 618 to 906 A.D., says that it was drunk in the sixth century, and that during the eighth century it became so common that a tax was levied on it. Arab writers speak of it in China in the ninth century, and it seems to have been introduced into Japan in 810, where its cultivation was commenced early in the thirteenth century. There was no knowledge of tea in Europe until after 1517, when intercourse began between Portugal and China. It was first brought to Europe in 1610 by Dutch merchants, and some years later was introduced into England. A Mr. Wickham, the agent of the East India Company in Japan, wrote to an officer-friend named Eaton, in 1615, asking for 'a pot of the best sort of chaw' (tea), and in Mr. Eaton's own accounts occurs the item, 'Three silver porringers to drink chaw in.' Pepys mentions having tasted it, and writes in his diary, 28th September, 1660, 'I did send for a cup of tee (a China drink), of which I had not drank before,' and, June 28th, 1667, 'Home and there find my wife making of tee, a drink which Mr. Pelling the Potticary tells her is good for her cold and defluxions.' The East India Company presented 2 lbs. of tea to Catherine, the Queen of Charles II., in 1664, and in 1669 they imported it directly from China. Garway, the first tea-dealer in London, issued in 1659 a broad-sheet headed, 'An exact description of the growth, quality, and virtues of the leef of Tea.' In 1660 he bought a lot, and sold it according to quality at from 15*s*. to 50*s*. per lb. He had the infusion 'made according to the directions of the most knowing merchants and travellers into those Eastern countries.' Much prejudice had to be overcome, however, before tea became a popular beverage in England, owing to the fashion of tea drinking being a foreign one, and Jonas Hanway, one of the leading opponents of the new custom, describes it, in his Essay on Tea, published in 1707, as 'pernicious to health, obstructing industry and impoverishing the nation.' In 1666, there were not more than 100 lbs. of tea brought to Europe, and its price was as high as 60*s*. per lb., but about ten years later, the quantity imported from China by the East India Company had reached nearly 5000 lbs. By 1725, the price had fallen to from 13*s*. to 20*s*. for black tea, and to from 12*s*. to 30*s*. for green tea. In 1745 the amount brought to England alone was 730,000 lbs., and in 1800 the infusion had become a very general beverage in this country. The following table gives some idea of the growth of the consumption of tea in the British Isles during the last century :—

Year	Amount consumed (lbs.)	Amount per head of population (lbs.)
1800	23 million	1·4
1850	51 „	1·8
1860	77 „	2·6
1870	118 „	3·7
1880	158 „	4·5
1890	194 „	5·0
1900	250 „	6·0
1910	287 „	6·3
1912	296 „	6·4

The reduction of duty has no doubt aided this rapid increase. From about 1833, when the monopoly of the East India Company was withdrawn, the high duty of 6*s*. or 8*s*. per lb. was gradually reduced until in 1865 it was 6*d*. per lb. Mr. Goschen reduced it to 4*d*. in 1890, since when it has varied between 8*d*. in 1904, to 5*d*. per lb., which is the duty at the present time (1913).

China and Japan were formerly the only great tea-producing countries, although the plant was known as far back as 1780 to be growing in India. In 1788, Sir Joseph Banks pointed out the advantages that would follow from the cultivation of tea in India, and in 1820 Mr. David Scott sent leaves to Calcutta from wild tea-plants growing in the districts that Sir J. Banks had named as suitable for tea-planting; but owing to some doubt as to the true character of the leaves no action was taken in the matter.

Mr. C. A. Bruce noticed the tea-plant growing wild in the jungles of Assam, and in 1839 he received a gold medal from the Society of Arts for this discovery, and for successfully growing and preparing China tea in India. Mr. Bruce's right to this medal was disputed by Captain Charlton, who said that he had pointed out the indigenous Assam tea-plant in 1832. The honour of its discovery has also been claimed for Moneram Dewan, a native. Lord William Bentinck, when Governor-General, formed a committee to introduce the cultivation of tea into India; and in 1834 Dr. Wallish admitted that David Scott had been correct with regard to the leaf. The Government committee at first sent to China for seed and for skilled manufacturers, but Captain Jenkins again pointed out the indigenous *Thea assamica*, and this was used for some years.

In 1836, 1 lb. of tea was sent from India to London; in 1837, 5 lbs.; in 1838, 12 small boxes; in 1839, 95 boxes. In 1839 the Assam Tea Company was formed, which in 1840 bought one of the Government tea-gardens that had failed, and the cultivation has been carried on by private enterprise ever since. The Government, however, was not satisfied with the amount of success attained, and a few years afterwards sent Mr. Robert Fortune to China to study the cultivation and manufacture of tea, and to bring seeds and plants thence to India. He found excellent tea grown and made in the Chusan Islands, and in the neighbourhood of Ning-po and of the Temple of Tein-tung, twenty miles inland; but as this was only for home consumption, he determined also to see and get seeds and plants from the districts of the interior, though this was forbidden to foreigners by Chinese law.

In 1849 he took his young tea plants to Hong Kong, and sent them in four different vessels to Calcutta. In April, 1850, he returned to Shanghai and the north to get implements and engage manufacturers to accompany him. Altogether he introduced more than 12,000 plants into India, and went carefully over the chief tea districts there, travelling up the Ganges and beyond Allahabad. The plantations over the principal tea districts there lay about 29° and 30°N. lat. and 78° and 79°E. long. and were chiefly in the neighbourhood of Almorah, situated about 4000 and 5000 ft. above the sea. The principal districts now are: Upper and Lower Assam, Bheel, Cachar, Chota Nagpore, Chittagong, Darjeeling, Dooars, Dehra Doon, Neilgherry, Sylhet, Terai, and Travancore.

Although in India the native plant or a hybrid is now used (*v. Cultivation*), Fortune's introduction of Chinese growers and manufacturers to teach methods to the natives must have greatly aided the Indian industry.

The rapid increase in the amount of Indian tea imported into England may be seen from the fact that in 1857 we received from India only 121,000 lbs., whilst half a century later the amount was over 150 million lbs. In 1889 the supply of Indian tea to the United Kingdom for the first time exceeded that from China, which was also surpassed by Ceylon tea in 1891, and the excess has been maintained ever since, with a corresponding diminution in the importation of China tea.

Many attempts at the cultivation and manufacture have been made in Ceylon. In 1868, the coffee plants were diseased and the crop failed, and attention was therefore turned to the cultivation of other crops suitable to the climate as cacao, cinchona and tea. The latter industry has grown enormously, as may be seen from the table below.

Ceylon tea combines some of the good qualities of Indian and of Chinese tea, and it does not require blending, but it does not keep so well. In this respect Chinese tea is much the best, and it is customary therefore to store smaller quantities of Indian or Ceylon tea than of Chinese. In comparison with Indian tea, Chinese is also more uniform in quality. Some Indian and Ceylon growers are apparently inclined to attend more to quantity than to quality. Our increased importation from India and Ceylon is partly owing to the heavy transit and export duties levied on tea by the Chinese Government, also to the faulty and often objectionable methods of manufacture, chiefly by hand labour, followed in China, as compared with the more scientific methods and almost universal employment of machinery in India and Ceylon.

IMPORTS TO THE UNITED KINGDOM
(In million lbs.).

—	China	India	Ceylon	Other countries	Total
1873	135	20	(23 lbs.)	8¾	163¾
1875	170	26	(1400 „)	1½	197½
1880	158¼	45½	(150,000lbs.)	3¼	207
1885	140	64¾	3¾	4	212½
1890	69¼	100½	47	6¾	223½
1895	40	123½	83½	8½	255½
1900	21½	153½	114½	9½	299
1905	7¾	179	106¼	15½	308½
1910	19	180¼	107½	25	331¾
1912	20½	192½	112½	35½	361

From the above table it will be seen that, the rapid increase in the imports of Indian and Ceylon tea was arrested during the period 1905–1910, whilst the importations from China and other countries showed a marked tendency to increase. This is due partly to the fact that Indian tea is gradually displacing China tea in markets such as Russia, the United States, and Canada, hitherto favourable to the teas of China and Japan, so that the supply of Indian tea is at present barely equal to the demand. In Ceylon, moreover, a considerable amount of tea has, in recent years, gone out of cultivation for the more profitable cultivation of rubber. Also, the Chinese have been making strenuous efforts to regain some of their lost trade by fiscal changes and by attention to improved methods of cultivation and manufacture. The returns for 1912 showed a revival of the Indian and Ceylon tea trade with the United Kingdom.

The European nations who consume most tea are Great Britain, Holland, and Russia. Next to Great Britain, the United States import more than any other country, but reckoned by the amount drunk per head the people of Australia and New Zealand are the greatest tea-drinkers in the world. The following table shows the amount of tea consumed per head per annum in the principal tea-drinking countries:

Australia and New Zealand	6·8 lbs.	Russia .	. 1·3 lb.
United Kingdom	6·4 „	United States	1·1 „
Canada .	. 4·5 „	Persia .	. 0·8 „
Netherlands	. 1·7 „	Chile .	. 0·7 „
		Argentina	. 0·6 „

Europe is supplied chiefly by China and India, and North America by Japan; but China black tea and Japan green tea are being rapidly supplanted in Canada and the United States by Indian black and Ceylon green tea respectively.

The methods of making the infusion vary in different countries. In China a pinch of tea is put into the cup, boiling water is poured on it, and the infusion is drunk at leisure, even after it is cold, and without milk or sugar. The water to make it is got from a running stream if possible, otherwise from a spring, *not* from a well, and is boiled slowly. The methods prevailing in Japan are described further on. In England the old fashion of letting the tea 'brew' and constantly adding hot water to the same leaves, is dying out; and the best tea makers pour boiling water on to the leaves, which have been put into a heated pot, let it stand on them for about five minutes, and then pour off the infusion or take out the leaves. The reason for this method is, that by that time, most of the theine and essential oil but not more than a third of the astringent tannin have been extracted. In Russia, lemon-juice is added to the infusion. In Germany, rum is sometimes added, as well as cinnamon or vanilla. In Spain, lemon-verbena leaves are added.

Botany. The tea-plant (*Thea assamica* or *Camellia Thea*) belongs to the order *Ternstrœmiaceæ*.

Leaves. Lanceolate, serrate, acute, and thick. They are alternate, and their stalks are short. Their upper surface is green and glabrous, and their under surface sometimes hairy on the nerves. The veins from the midrib go nearly to the edge, and then unite to form an intra-marginal vein. The leaves are dotted with pellucid oil glands, and numerous unicellular hairs are found on the under surface, especially of young leaves. The hairs, after emerging from the epidermis, bend suddenly at a right angle in a direction parallel to the surface of the leaf, and are very characteristic. The stomata are very numerous and are bordered by two special cells of reniform shape. Stellate crystals of calcium oxalate occur in the internal tissues or mesophyll, as well as thick-walled sclerenchymatous cells of very irregular shape giving support to the upper and lower layers of the leaf, and known as 'sclerites' or 'idioblasts.' These serve to distinguish tea from most other leaves likely to be used for the purpose of adulteration.

Flowers. White or slightly yellow, or rose tinted, axillary, regular and hermaphrodite. Bracts, two or three below the calyx. There are five round and convex sepals, and five obovate obtuse petals (more rarely, six or more). The stamens are indefinite, monadelphous, and adhere to the petals by their base. The styles are three in number, with simple stigmas. The ovary is superior and three-celled, each cell containing from four to five pendulous anatropous ovules.

Fruit. Woody, forming a three-celled loculicidal capsule, which remains green for a long time. Each cell contains one exalbuminous seed, the remaining ovules never ripening.

Cultivation. Our chief authority on the cultivation and manufacture of tea in China is

Robert Fortune, who in his Journey to the Tea Countries of China gives many interesting particulars about the cultivation and manufacture of tea, and of his adventures in getting to the interior disguised as a mandarin.

He states that the parts of the world best suited by climate for the cultivation of the tea plant are China, Japan, India, Ceylon, South America, parts of Australia, the shores of the Mediterranean, the middle of France, and even Ireland. Java is now one of the chief tea producing countries, and amongst other countries where tea is more or less successfully cultivated at the present time may be mentioned Burmah, the Straits Settlements, Natal, Nyassaland, Mauritius, Queensland, the Fiji Islands, Brazil, and the Caucasus.

A warm climate is essential. In the best districts in China the ordinary range of the thermometer in the summer at 3 P.M. is between 80° and 90°F.; it sometimes reaches 100°, and it rarely falls below 32° in winter.

The best position for a tea-plantation, if other conditions are favourable, is a slope facing the south, because on sloping ground there is natural drainage, and the soil does not get too wet; it ought never to be as wet as in rice fields. If flat ground is used, the tea-gardens are often artificially raised, and are always carefully drained. The spring rains are most beneficial, provided the drainage be efficient. There must be a constant supply of water, either from natural sources or by irrigation. Hilly districts are suitable, because the vegetable matter washed down from above enriches the gentler slopes and the level ground below. Increased altitude (within limits) appears to improve the flavour of tea, but with a diminution of the quantity of leaf produced. The plant flourishes best in rich loam mixed with sand and gravel. Oak-bearing land is considered extremely good for tea plants.

The seed—which is in appearance like a hazel nut, having an outer and an inner shell inclosing a kernel, and ripens about a year after the flower has faded—is gathered in October, and kept in sand and earth, in which it germinates, until March, when it is sown in rows. Holes are dug and left for about two weeks, then filled with surface soil, and three seeds are put into each hole about six inches apart. The best plant remains in the hole, and the others are transplanted to vacancies. The plants are about 4 ft. apart, and the same distance separates the rows. About 26 lbs. of seed are required for an acre, yielding about 2500 shrubs. Sometimes the seeds are sown more thickly in corners of the tea-farm or in nurseries, and the plants transplanted when a year old at the beginning of the rainy season.

The wild plant (originally, probably, the *Thea assamica* of the forests of Northern India) may grow to a height of from 30 to 50 ft., but the cultivated plants are pruned and kept to a height of from 3 to 6 ft., so that they become well-spread, bushy shrubs resembling somewhat the 'Portugal laurel' in appearance. The leaves are not picked until the plant is three years old. It does not yield its full quantity until its sixth or seventh year, and in China leaves are seldom gathered from a plant more than twelve years old. A good cultivator takes care that some portion of his farm shall be resown every year.

In India, only those plants are allowed to *flower* which are to be kept for producing seed, the leaves of which are not to be made use of. Fortune introduced Chinese seed into India; but it has been found that the indigenous plant, or a cross between it and the Chinese varieties, yields better tea in India. The Chinese plant makes the best green tea, whilst hybrids are best for black. Only such seeds as are used in India are imported into Ceylon.

The raw leaves yield only about one-fifth of their weight of manufactured tea. The plants give in their third year not more than a *maund* (80 lbs.), but in their fifth year about 280 lbs. of tea per acre. The amount increases from the fifth to the twelfth year, but varies greatly in different districts, and it also depends on the plucking, whether 'fine' or 'coarse.' In the richest years, the amount in some places (*e.g.* Sylhet) may reach 1000 lbs. per acre. A tea bush from 8 to 12 years old will yield ¼ lb. of manufactured tea, and taking 2500 bushes per acre, the average yield in India is thus over 600 lbs. per acre.

Manufacture. The two great classes of tea are *green* and *black*, the differences between them depending solely on the mode of manufacture. Sub-divisions depend on the *age of the leaves*, *i.e.* the time of the year they are gathered, and the *way they are rolled*.

The chief sub-divisions are as follows:—

Green Varieties.

Hyson. Leaf-buds and first leaf; picked in April. The young leaves, which are very uniform in size, are carefully twisted and rolled longitudinally into a spiral form.

Skin Hyson consists of the inferior leaves of hyson rolled transversely and longitudinally and frequently enclosing the débris of other green teas. It is often merely tea refuse, and the coarser kinds are known in the vernacular as 'tea bones.'

Gunpowder. According to Dujardin-Beaumetz, this is simply carefully selected hyson. According to Johnston and Church, it is from a special plantation, and flavoured with *Olea fragrans*, the sweet-scented olive. The leaves are cut transversely in three or four parts before being rolled into pellets.

Pearl or *Imperial.* Dujardin-Beaumetz describes this as a kind of hyson, but coarser than the true hyson, and of a silver-green colour. Johnston and Church say that the true Imperial, which is excellent, is rarely sent to Europe, and that what we call 'Imperial' is a tea from the Chusan Archipelago flavoured with the *Olea fragrans*. The tea occurs in the form of pellets made by rolling the leaves first longitudinally, then transversely.

Black Varieties.

The different kinds of black tea are usually classified according to the age of the leaf. The youngest leaves give the best tea, and the order, commencing with the youngest when plucked, is as follows:—

(*a*) *Flowery Pekoe* (*b*) *Orange Pekoe* (*c*) *Pekoe*	'Poco' refers to the white down of the young leaf.

(*d*) *First Souchong* } 'Souchong' means
(*e*) *Second Souchong* } 'small plant.'

(*f*) *Congou.* 'Congou' means 'labour,' and is intended to express the great care required in the preparation of this tea. (*a*) (*b*) (*c*) mixed make *Pekoe*; (*d*) and (*e*) mixed with *a, b, c* give *Pekoe-Souchong.*

Pekoe. Youngest leaf and leaf-buds; picked in April. This is sometimes flavoured by the addition of orange, rose, or jasmine flowers. When with the first-named, it is called *Orange Pekoe.*

Souchong. The strongest and perhaps finest of the black leaf teas. It consists of the larger of the young leaves, and is suitable for use either alone or in blends.

Congou. The younger leaves from the third crop, older and larger than *Souchong.* This constitutes the ordinary beverage of the inhabitants of China and Russia.

Bohea. The commonest variety of tea, consisting of the older leaves of the third crop or a mixture of various leaves, stalks, and dust.

Caper (plain-scented). Various teas or tea dust made into hard grains by means of gum or rice-water, sometimes polished with graphite or coloured with indigo, &c.

Broken Pekoe. Siftings of various Pekoes.

Fannings. Siftings of Congou.

There are other special varieties of teas as Twankay (green), Kaisow (red leaf), Moning and Oolong (black, with more or less of the flavour of green), used chiefly for giving 'life' to blends.

The leaves are plucked three times a year. In April (that is in China just before the spring rains); at the end of May or beginning of June; and towards the end of June, or, according to some authorities, in July. Sometimes there is a fourth gathering in the late summer or early autumn, but leaves of such a size and age as they are then make only the common and coarser kinds of tea. In South Australia there are always four, and sometimes in wet seasons a fifth gathering. Women are generally, if not always, employed in India, and sometimes in China, for the picking.

The plants are picked as successive 'flushes' appear, a 'flush' being the throwing-out of new shoots and leaves; and the number of flushes in a season—that is, in from seven to nine months—varies from 18 to 25, according to the soil and climate. In Ceylon, the flushing continues all the year round. Up to a certain point the more a plant is picked the more new shoots it throws out. At the end of the season each shrub is 3½ or 4 ft. high, and about 5 ft. in diameter. It is then pruned down to a height of 2 feet and a diameter of 3 ft., and thus it remains until the spring.

In the manufacture of *green tea* the object is to keep the colour and prevent fermentation; it is necessary, therefore, to roast as soon as possible after picking, and finish the whole process quickly.

In the manufacture of *black tea*, on the contrary, the leaves are dried slowly before manipulation, and one of the processes is that of fermentation (*cf.* Eighth Int. Cong. Appl. Chem. 1912, Sect. VIII.).

Processes of manufacture of green tea.
Chinese methods.

The methods and apparatus employed in China are very simple and primitive. The tea farms are very small, seldom exceeding five acres, and almost every cottager grows sufficient tea to supply the wants of his family and possibly secure other necessaries of life by selling the surplus to the travelling tea-merchants who periodically visit the country districts for that purpose.

The principal processes are as follows:—

Steaming. To get rid of the raw flavour, and preserve the colour, the leaves are spread out in bamboo trays and fitted into a bamboo box, the bottom of which is a boiler. Here the leaves remain for an hour or two. They then are exposed on tiled floors, or in shallow bamboo trays out of doors in the shade, to prevent their turning yellow and becoming hard and brittle by drying too rapidly as they would if placed in the sun, and are meanwhile separated from stalks and dirt.

Roasting. Half a pound of leaves at a time is put into a *kno* or iron pan, 10 ins. deep and 16 ins. in diameter, which is set in a brick stove over a brisk wood fire. Here the leaves are kept 4 or 5 minutes, and stirred rapidly with the hand. When taken out they are moist and flaccid, although much vapour has been given off.

Rolling. The object of this is to break the cells, contents of which come out and spread over the surface of the leaf, so that a fine aroma is produced. This is done on the rattan table, where the leaves are rolled by hand into balls, shaken out again, and rolled once more, passing from hand to hand until they reach the head workman, who sees whether they have the proper twist. If they are right they are shaken out on flat trays or sieves, and allowed to cool for a few minutes.

The second roasting is done over a slow charcoal fire for an hour or an hour and a half, at the end of which the green colour is fixed, dull at first, but gradually growing brighter. During the second roasting one man moves and occasionally rolls the leaves, while another fans.

Sifting. This is first done by means of sieves of different sizes; then the leaves are winnowed on large bamboo trays, and finally they pass through the winnowing machine. This gets rid of dirt and impurities, and separates the different kinds of tea, according to size and twist of leaf.

During the sifting the leaves undergo a *third roasting* or *re-firing.* It was about 5 minutes before the end of this last roasting that the manufacturer used to add the Prussian blue, &c., for colouring. This was done for the foreign market only, as this highly coloured tea was prized in Europe until it was discovered to be faced. The whole manufacturing process takes about 10 hours. Sometimes the sorting and re-firing take place at Canton before exportation instead of in the interior.

Japanese methods.

The principal kinds of Japanese green tea are Gyokuro and Sencha, which are those chiefly used by the Japanese themselves, and exported to the United States of America, Canada, and Australia.

The methods of manufacture are very much the same as in China, but whilst machinery is now almost universally employed in Japan for teas intended for exportation, yet owing to a prevalent idea that the use of machinery is detrimental to the development of the finest aroma, the superior qualities of tea are still prepared by the old-fashioned hand processes.

Indian methods.

Machinery is used almost exclusively in India for the manufacture of tea, as insuring 'more cleanliness and uniformity' than the method by hand. Each process appears to be gone through once without necessity for repetition.

There seems to be less difference between the Indian and the Chinese mode of manufacturing green tea than there is between the methods of the two countries in making black. The Indian method of making green tea is as follows:—

The leaves are picked twice a day. Those which are brought in at 1 p.m. are partly manufactured the same day; those which come in at night are spread six inches thick until next morning. The various processes are:

1. *Drying* (if necessary).
2. *Roasting.* This is done in pans over fires until the temperature is 160°F., and the leaves are meanwhile vigorously stirred for seven minutes.
3. *Rolling.* This is done four times in succession, the leaves being dried in the sun between each rolling.
4. *Second roasting.* The leaves are returned to the pans, and roasted at the same temperature as before.
5. *Beating.* Bags are filled with the leaves, which are then beaten heavily. They remain in the bags all night.
6. *Third roasting.* During the stirring this time the temperature gradually falls from 160°F. to 120°F.
7. *Sifting and sorting.* The sieves are round and made of brass wire or cane, with wooden sides 3½ ins. high. Before sifting, any red leaves there may be are carefully picked out.

The method of manufacture in *Ceylon* is the same as that in India.

Processes of manufacture of black tea.
Chinese methods.

A little of the soft stalk is picked with the young leaves and leaf-buds for black tea.

Withering. The leaves are spread on large bamboo trays or mats, and exposed out-of-doors for some hours. If leaves are gathered during the wet season, this first drying takes place indoors on frames standing some feet above pans of hot charcoal. This process renders the leaves soft and pliable; the stalks bend without breaking, and do not crackle when compressed.

Tossing and fermentation. In a cool building, or in the shade out-of-doors, the leaves are then tossed and gently patted till they are soft and flaccid. They then lie in heaps, covered with a cloth, and are carefully watched until they get a slightly reddish tinge, and give out a fragrant smell.

First roasting and rolling. This roasting is for 5 minutes in shallow iron pans over wood fires. The rolling is on rattan tables, the same as for green tea. Sometimes the rolling takes place first, and sometimes the roasting.

Exposure out-of-doors. The leaves are now shaken out thinly on sieves, and put out-of-doors on bamboo frames for about 3 hours. In the black-tea districts they are seen in front of all the cottages; and workmen go from one to another turning and separating the leaves. The day should be fine and dry, but not too hot. When dry enough, they are removed to the factory.

Second roasting and rolling. This roasting is in the same shallow iron pan as before, and the rolling on the same table.

Drying and rolling. The leaves are spread to a depth of about 1 in. in sieves, and these are put into tubular baskets called poey-longs, which are slightly contracted in the middle, and are 2½ ft. long and 1½ ft. broad, somewhat like a dice-box in shape. There are cross-wires a little above the contraction of each basket on which the sieve stands. The poey-long, the mouth of which is covered by a bamboo tray, stands upright over a low stove built on the ground, and containing a small quantity of charcoal, so that the tea-sieve is about 14 ins. above the stove. These stoves are built round three sides of a long narrow room, and are 2 or 3 feet deep, and 5½ ins. high. While the rolling goes on, the balls of leaves are left standing in heaps until all are done. The drying and rolling go on alternately, either two or three times, until the leaves are dry and crisp and have the right dark colour.

Sifting. This is done by means of large circular bamboo trays, and the large leaves, if necessary, are picked out by hand.

Final drying. The fires are covered to reduce the heat. The leaves are placed much more thickly in the baskets, and the workman makes a hole with his hand through the centre of those in each sieve, to equalise the heat and allow the charcoal vapours to escape. Here the leaves remain over a slow fire for 2 hours or longer. The mouth of the basket is quite closed by a tray. For home consumption in China tea is not dried quite so much, and it is kept for a year before use.

Japanese methods.

The manufacture of black tea in Japan has not hitherto been very successful, owing probably to imperfect fermentation, a process to which the native leaf does not appear to be so well adapted as the China leaf.

The mode of manufacture is the same in principle as that of China, but differs in the order of the processes and the time of their duration.

Large quantities of tea of the Oolong variety are shipped from Formosa. This, although similar in appearance to black tea, has the flavour of green tea.

All teas in Japan are re-fired in the 'godowns' of the exporters. This is to drive off any excessive moisture, tea being extremely hygroscopic, and to destroy any germs which might, especially in the presence of moisture, cause the tea to decay on its voyage to other parts of the world. According to Kozai, the amount of moisture in ordinary Japanese tea is from 10 to 11 p.c., but it is reduced by re-firing before exportation to 3 or 4 p.c.

It has been proved by experiments with leaves of other plants in Japan that steaming not only preserves their colour but prevents fermentation. This may be because the heat of the steam destroys the enzymes which produce fermentation. Hence, for black tea, the leaves must on no account be steamed, but withered, and then allowed to ferment. For green tea the leaves are steamed to prevent fermentation and preserve colour, and are manufactured quickly.

In Japan, other kinds of tea are manufactured exclusively for home consumption called respectively *bancha kamairii* or *pan-roasted tea* and *yencha* or *flat tea.* The former is a very inferior tea consisting of old leaves from the last year's crop mixed with broken stalks and twigs. Kamairii is made simply by alternate roasting in an iron or bronze pan, and rolling on a table seven or eight times over. Until 250 years ago all tea was made so, but now it is rare. According to Y. Kozai this is sometimes made in China, and is known there as '*sencha*' (*v. supra*). For *flat tea* the leaves are supplied from a special plantation. They are not rolled or touched by the hand at all, but are spread on stiff paper for firing by means of bamboo sticks, and are alternately collected and spread out until nearly dry. Then they are taken from the furnace, all the broken or yellow leaves removed, and fired again. The final drying lasts all night at a gentle heat, and the leaves are then separated into three classes. For use they are ground to a powder of the fineness of flour, drunk with the infusion. This tea ('yencha') is usually reserved for ceremonial occasions.

Indian methods.

The processes are as follows:

1. *Withering* on fine basket-work trays in the sun.

2. *Rolling.* This is done either by the rolling machine or by a line of men on each side of a table, who pass the leaves from one end to the other. When soft and 'mashy,' and giving out juice, the leaves are made into a ball, the juice that has come out being mopped up constantly during the process.

3. *Fermentation.* The balls stand until fermented, and are most carefully watched, as the flavour and quality of the tea depend largely on stopping this process at the right moment, and only skilled tea-makers can judge of this. At the proper time the balls are broken up, and the leaves spread thinly on mats in the sun. When they get rather black they are collected and re-spread, so that all the leaves may be alike, but this does not take long, for

4. *Drying or Firing* should take place as quickly as possible after the fermenting process, to drive off all the moisture. This is generally done in a chest of firing drawers, which consists of a set of trays one above the other, the bottom of each, on which the leaves are spread, being made of fine wire gauze, so that all the trays can be heated at once. Formerly charcoal fires always produced the heat, but now hot air is often used instead. When the tea comes out of this machine it is almost black, and has a very delicate aroma.

5. *Sorting.* In sieves to separate the leaves into the different kinds for commerce.

Chemistry of tea. The analyses of air-dried tea differ according to whether the tea be green or black, where it has been grown, and other circumstances.

The most important constituents of tea are caffeine (theine), tannin, ash, and essential oil. Of these it is generally found that there is rather more caffeine in black tea than in green, and more tannin in green (though this rule is not without exceptions); the amount of ash is fairly constant; the quantity of essential oil is very small in both, but it seems to be larger in green tea than in black. The total matter soluble in hot water is also larger in green tea than in black.

A valuable paper by Y. Kozai (Researches on the Manufacture of Various Kinds of Tea: Bulletin No. 7 of the Imperial College of Agriculture and Dendrology, Japan) gives analyses of the tea-leaves (all of the same kind) from a certain plantation under three different conditions:—

1. Dried at 85° C.
2. Made into green tea.
3. Made into black tea.

The following are the results:—

—	Original leaves dried	Same made into green tea	Same made into black tea
Crude protein . .	37·33	37·43	38·90
Crude fibre . .	10·44	10·06	10·07
Ethereal extract .	6·49	5·52	5·82
Other nitrogen-free ext.	27·86	31·43	35·39
Ash	4·97	4·92	4·93
Caffeine . . .	3·304	3·200	3·300
Tannin (calculated as gallo-tannic acid) .	12·91	10·64	4·89
Soluble in hot water .	50·97	53·74	47·23
Total nitrogen . .	5·973	5·989	6·224
Albuminoid nitrogen .	4·107	3·937	4·106
Caffeine nitrogen .	0·956	0·926	0·955
Amino nitrogen . .	0·910	1·126	1·163

100 parts of dried leaves yielded:—

Green tea	98·64
Black tea	95·47

From the above figures it follows that in the process of manufacture the change in the amounts of the various constituents was such as is shown in the following table, where (+) denotes the gain, (−) the loss in 100 parts of each constituent:

	Green tea	Black tea
Dry matter . . .	− 1·36	− 4·56
Crude protein . . .	− 1·70	− 0·61
Crude fibre . . .	− 4·98	− 7·94
Ethereal extract . .	−16·18	−14·33
Other nitrogen-free extract	+11·31	+21·21
Ash	− 2·42	− 3·01
Caffeine	− 4·49	− 4·92
Tannin	−18·67	−63·82
Soluble in hot water .	+ 5·96	−11·69
Total nitrogen . . .	− 1·08	− 0·61
Albuminoid nitrogen .	− 5·57	− 4·58
Caffeine nitrogen .	− 4·49	− 4·92
Amino nitrogen . .	+22·75	+22·42

The loss in ethereal extract is considerable, because part of the tannin changes during manufacture to a form insoluble in ether. In black tea, however, which undergoes fermentation, acids are formed during the fermentation that are soluble in ether.

The slight loss of ash and of caffeine arises from the mechanical loss of sap during manufacture.

The loss of tannin occurs during the heating processes in the manufacture of both kinds of tea. In black tea there is loss also during fermentation, when the tannin decomposes into substances *insoluble* in hot water. This accounts for the fact that hot water extracts less tannin from black than from green tea, and to this is no doubt largely due the preference given in the United Kingdom to black tea on the assumption that it is more wholesome than the green varieties.

Altogether, the change from the original leaves is greater in black tea, because of the process of fermentation.

The following are general analyses showing the differences between green and black tea :—

GENERAL ANALYSES (Bell).

	Congou (black)	Young Hyson (green)
Moisture	8·20	5·96
Caffeine	3·24	2·33
Albumin insoluble	17·20	16·83
Albumin soluble	0·70	0·80
Extractive by alcohol containing nitrogenous matter	6·79	7·05
Dextrin or gum	—	0·50
Pectin and pectic acid	2·60	3·22
Tannin	16·40	27·14
Chlorophyll and resin	4·60	4·20
Cellulose	34·00	25·90
Ash	6·27	6·07
	100·00	100·00

ANALYSIS OF SIX VARIETIES OF CHINA GREEN TEA (Geissler).

	Max.	Min.	Average
Moisture	7·78	5·39	6·43
Half-hour extract	44·70	30·20	36·74
Total extract	50·00	43·30	46·56
Insoluble leaf	49·61	44·60	47·05
Tannin	19·11	11·87	14·57
Caffeine	2·86	1·52	2·02
Soluble ash	5·02	2·02	3·28
Insoluble ash	6·38	2·11	3·61
Ash insoluble in HCl	0·66	0·21	0·49

ANALYSIS OF ELEVEN CONGOU BLACK TEAS (Geissler).

	Max.	Min.	Average
Moisture	9·15	7·65	8·37
Half-hour extract	32·14	23·48	28·40
Total extract	37·06	27·48	34·35

Tannin	13·89	8·44	11·54
Caffeine	2·87	1·70	2·37
Soluble ash	3·52	2·28	3·06
Insoluble ash	3·86	1·90	2·68
Ash insoluble in HCl	1·31	0·32	0·425

ANALYSIS OF SIX INDIAN TEAS (Geissler).

	Max.	Min.	Average
Moisture	6·19	5·56	5·81
Half-hour extract	39·66	37·80	38·77
Total extract	45·64	41·32	42·94
Insoluble leaf	53·07	48·53	51·24
Tannin	18·86	13·04	14·87
Caffeine	3·30	1·80	2·70
Soluble ash	3·68	3·24	3·52
Insoluble ash	2·22	1·93	2·12
Ash insoluble in HCl	0·296	0·137	0·178

The results of more recent analyses of various teas from India, Ceylon and China (22 samples) are given on p. 428, the percentages being calculated on the tea dried at 100° C. (Tatlock and Thomson, Analyst, 1910, 108).

The following circumstances affect the chemical composition of tea :—

1. *Age of leaves.* From spring to autumn, the percentage of water, crude protein, and nitrogen free extract continually decreases; the caffeine diminishes gradually; the crude fibre increases proportionally as crude protein decreases. The percentage of ethereal extract increases proportionally as nitrogen free extract decreases. The percentage of tannin increases slightly; that of substances soluble in hot water gradually diminishes at first, then increases slowly. The percentage of *total ash* slightly fluctuates, but the constituents change considerably.

Potash and phosphoric acid diminish, whilst the lime, magnesia, iron, soda, manganese, and sulphuric acid increase.

Silica and chlorine remain nearly constant.

Some of the above general statements are shown more exactly by the following figures :

	May p.c.	November p.c.
Water	76	60
Caffeine	2·85	0·84
Total nitrogen	4·91	2·67
Amino nitrogen	0·66	0·08 (September) 0·01 (following May)
Tannin	8	11 or 12
Ash	4·69	5·14

Probably a portion of the amino nitrogen became caffeine nitrogen.

These results were obtained by O. Kellner in conjunction with K. Oku and K. Ogasawara, of Japan (' Landwirthschaftliche Versuchs-Stationen,' 1886, 370).

2. *Effect of light.* On a plantation of uniform conditions and similar plants, Y. Kozai tried what difference of chemical composition there would be between the leaves of plants grown under the usual conditions and those of plants screened from the light by wooden frames during the last three weeks of their growth before picking. He obtained the following results :—

	Screened leaves	Leaves exposed to light
Caffeine	4·532 p.c.	3·784 p.c.
Total nitrogen	7·835	6·945
Caffeine nitrogen	1·311	1·0943
Tannin	no difference.	

The screened leaves were bleached, and had a fine and peculiar aroma.

Kozai states that there is not actually more caffeine in the screened than in the exposed leaves; but that in the latter there is a preponderance of woody fibre which makes the total dry matter larger.

3. *Age of plants.* It has been said that old plants make the best tea. This has not yet been thoroughly proved, but researches by O. Kellner with M. Tanaka and B. Minari on plants aged 4, 7, 16, and 20 years respectively, show that the amount of water decreases regularly with the age of the plant, and that all other changes are extremely irregular. The older the plant, the more manuring and pruning is necessary to get a good crop of leaves.

4. *Manuring* appears to have little effect on the chemical composition of the leaves, although it increases the number on each plant. Bush prunings, weeds, and general rubbish make good manure. Animal manure must be used with great care

Theine or *caffeine* may be considered the active principle of tea, physiologically speaking, since it has been found in nearly all of the various plants whose leaves are used for infusions and take the place of tea.

The published determinations of caffeine in tea vary greatly, but this is partly owing to the different methods used.

Determinations of caffeine made in the Inland Revenue Laboratory (Bell's Foods) gave:

Kind of tea	Price per lb. *s.*	*d.*	Percentage of caffeine
Bohea	1	7	3·31
Congou	2	6	2·93
Young Hyson	3	2	4·29
Gunpowder low	2	6	3·18
,, good	5	0	4·93
Assam, low	2	8	3·03
,, good	4	6	4·83

It will be seen that there is no direct relation between the proportion of caffeine and the commercial value of the tea.

Estimation of caffeine in tea. Waage has examined 37 methods proposed or used for the determination of caffeine, but gives the preference to that of Mülder with certain modifications. This consists in treating the concentrated aqueous infusion by lime or magnesia, evaporating to dryness and extracting the caffeine with chloroform, ether, or benzene. In some cases the aqueous extract is first treated with lead acetate to remove tannin and colouring matters, the excess of lead being removed by sodium phosphate or hydrogen sulphide.

According to Blyth, low results may be obtained through loss in drying the extracted caffeine by prolonged heating at 100°C., owing to the fact that caffeine sublimes below this temperature.

Tannin. The methods for the estimation of tannin are very numerous. That usually employed is Löwenthal's process as modified by Councler and Schröder, and Procter. (*v.* Bull. 13, Chem. Div. of U. S. Dept. of Agric. 890).

A simpler method, giving good results, is that of Tatlock and Thomson, based on the precipitation of the tannin with quinine and weighing as quinine tannate. Cinchonine might be used with advantage instead of quinine as in Chapman's method for the estimation of tannin in hops (*v.* Analyst, 1910, 104).

The recorded percentages of tannin vary greatly, mainly owing to the different methods of analysis employed. In normal teas the tannin should not be less than about 6 p.c., but may exceed 20 p.c. Wigner's analyses gave the following results in exceptionally astringent teas :—

	Tannin p.c.
Mayon Young Hyson tea .	39·0
Very choice Assam . .	33·0
India Young Hyson . .	39·0
Assam (from Dr. McNamara's garden)	27·7
Caper, mixed . . .	42·3

The amount of *ash* is fairly uniform in all teas, and varies from a little below 5 to rather more than 7 p.c. It is always rich in potash and phosphates, and manganese is such a constant constituent as to be almost characteristic. Zöller found the constituents to be as follows (Doc. du Lab. Municip. de Paris, 500) :—

	P.c.
Potash	39·22
Soda	0·65
Magnesia	6·47
Lime	4·24
Oxide of iron	4·38
Manganous oxide	1·03
Phosphoric acid	14·55
Sulphuric acid	trace
Chlorine	0·81
Silica	4·35
Carbonic acid	24·30

The following results were obtained in the Inland Revenue Laboratory (J. Bell) :—

A determination of the amount of ash alone may serve to detect the presence of leaves other than those of the tea plant, for these usually differ largely from tea leaves in the amount of their ash. The soluble ash in genuine tea is relatively high, usually exceeding half the amount of total ash, whilst foreign leaves likely to be used as an adulterant for tea generally contain a much smaller proportion of soluble ash than genuine tea. Paraguay tea, however, contains about the same amount of ash as true tea, but a larger proportion of soluble ash.

Almost the whole of the insoluble portion of the ash dissolves in hydrochloric acid; the insoluble residue is usually less than 1 p.c., any excess being due to sand or silicious matter.

The table, p. 430, gives the amount of ash in various teas dried at 100°, together with the proportion of ash soluble in water and insoluble in dilute mineral acids, and the alkalinity of the ash (Bell).

In tea leaves which have been infused in the ordinary way for domestic use, the amount of ash and other constituents shown in the next table were as follows :—

Description	Percentage of ash	Percentage of Ash			Alkalinity as K_2O
		Soluble in water	Soluble in dilute acids	Insoluble in acids

Very little was known about the *essential oil* of tea prior to the researches of Van Romburgh in 1896, the chief results of which were as follows:—

440 lbs. of fresh leaves of tea distilled with water gave but *traces* of an essential oil, having a strong odour of tea. The water contained methyl alcohol and a very volatile product giving aldehyde reactions (possibly it contains diacetyl).

From *rolled and fermented* fresh leaves, besides the products above mentioned, an essential oil was obtained in larger amount (3 c.c. from 100 lbs. of tea), or about 0·006 p.c.

The oil has a yellowish colour and a penetrating odour of tea; sp.gr. 0·866 at 26°. It rotates polarised light 0° 10′ to the left in a 200 mm. tube. Fractional distillation separated it into two parts, the main portion boiling below 170° and the other above that temperature. The larger fraction consisted of a colourless liquid boiling from 153°–154° (bar. 740 mm.) with a strong odour of tea; sp.gr. 0·855 at 27°. Elementary analysis and the vapour density determinations indicated the formula $C_6H_{12}O$.

Sodium hydroxide and hydroxylamine have no action. With hydrochloric acid and acetic anhydride and with benzoylchloride and sodium hydroxide it gives esters. A solution of bromine in chloroform is decolorised with evolution of heat. It combines with 1 mol. of bromine. Treated with a neutral solution of potassium permanganate it is oxidised. All these reactions make it clear that the main portion of the oil consists of an unsaturated alcohol of the formula $C_6H_{11}OH$.

The higher boiling portions of the oil contained about 1 p.c. of methyl salicylate (Van Romburgh, private communication).

A *non-drying oil*, somewhat resembling olive oil, is obtained from tea-seeds in China and Assam, the former yielding from 30–35 p.c. and the latter from 43–45 p.c. of oil. The first pressings are used as an edible oil, although somewhat objectionable owing to the presence of saponin which is present to the extent of 7 or 8 p.c. in the resulting oil cake. It is therefore unsuitable for feeding purposes, but has been recommended for use as vermicide for dressing lawns. The lower qualities of oil are employed for illuminating, and for soap-making. Fine lubricating oils are also obtained from the seeds of other species of *Thea* in Japan.

The highest amount of *moisture* known in air-dried tea is 16 p.c. According to Wigner, the mean of the amounts yielded by driest Hysons and gunpowders and the moistest Congous is 7·67 p.c. Dragendorff found the average amount of moisture in twenty-three teas of Russian commerce to be 10 p.c. Péligot gives the amount in black tea as 10 p.c.; in green tea as 8 p.c. Bell (see table above) found in 32 samples of tea of different kinds and from various sources that the proportion of moisture varied from 6·6 to 9·7 p.c., the average being 8·3 p.c.

Nitrogen is present in tea both in the form of caffeine and albuminous bodies, and to a greater extent than in most other leaves. Choline and xanthine bases have also been identified in tea.

Péligot (Documents du Laboratoire Municipal de Paris, 501) gives the following percentages of total nitrogen:—

Gunpowder	6·62
Pekoe	6·28
Souchong	6·15
Assam	5·10

Gluten or *legumen* forms a quarter of the weight of the leaves according to Johnstone and Church (Chemistry of Common Life); but as it is hardly soluble in water, it is of no practical dietetic value. More will be dissolved if soda be added to the water. The 'brick tea' used in Thibet is boiled in the alkaline steppe-water which extracts the greater part of the gluten.

Tea infusion. The amount of matter extracted by water from tea is capable of giving useful indications, but truly comparable results can be obtained only by rigid uniformity in the details of the extraction process. The methods are based either on complete extraction and weighing either the extract or the insoluble portion, or partial extraction by infusion and determination of the specific gravity of the infusion.

Peligot (*vide supra*), using the first method, found the following percentages of *total extractive* on the dried leaves:—

Green teas.		*Black teas.*	
Gunpowder .	51·9	Assam . .	45·4
Hyson . .	47·7	Bohea . .	44·4
„ skins .	43·5	Congo . .	40·9
Young Hyson .	51·5	Pekoe . .	34·6
Imperial . .	43·1	„ orange .	48·7
Schoulang . .	45·9	Souchong (fine) .	45·7
Tonkay . .	42·2	„ (ordinary)	41·8

Tatlock and Thomson (Analyst, 1910, 104) adopted the second method, finding the extract by difference; and in order to avoid loss due to the solidifying out of extractive matter on cooling, they greatly increased the proportion of water, boiling 1 grm. of tea with 100 c.c. of water for 1 hour under a reflux condenser, filtering, washing with 80 c.c. of hot water, drying at 100°C. and weighing the insoluble residue on a tared filter. They found the following percentage of water extract:—

	Variations	Average
Indian teas (10) . . .	43·5–49·7	46·4
Ceylon „ (5) . . .	41·3–48·2	44·1
China „ (6) . . .	38·4–46·9	43·1

O. Kellner, in conjunction with S. Ishii and M. Kamoshita, determined the proportions of the constituents of tea in the *infusions ordinarily drunk* in Japan. The methods of making the infusions are, however, different from those employed in this country They are:

1. For Yencha, extra-fine green tea, the leaves are ground to powder, and drunk with the infusion.

2. For superior green tea the leaves are digested for 2 mins. with water at a temperature of 50°–60°C.

3. For medium green tea, boiling water is poured on the leaves, and stands on them for 1 minute.

4. For inferior tea, the leaves are boiled with water.

The object in all these methods is to get out as much caffeine and oil as possible, together with a moderate amount only of tannin.

Kellner digested 90 grms. superior green tea with half a litre of distilled water at 50°C. After 5 mins. the infusion was poured off, and another half-litre of water at 50°C. was added to the leaves. This was repeated three times, and each infusion was analysed separately.

The boiling-water method gives different results. Kellner digested 100 grms. of superior tea with 1 litre boiling distilled water, and the first infusion contained more than the sum of the contents of the three infusions by the warm-water method. The following table shows a summary of his results:—

PERCENTAGE AMOUNT OF EACH CONSTITUENT DISSOLVED.

	Warm water				
	First infusion	Second infusion	Third infusion	Total	Boiling water
Dry matter	5·3	4·7	3·6	13·6	16·1
Caffeine .	14·6	12·0	12·3	38·9	40·1
Tannin .	15·9	14·4	13·9	44·2	36·8
Total nitrogen	5·2	4·7	4·4	14·3	17·1
Ash . .	17·1	14·4	4·9	36·4	36·1
Potash .	15·1	15·1	6·1	36·3	43·3

In the following tables by Tatlock and Thomson (Analyst, 1910, 108) are shown the percentage of the total extractive, caffeine, and tannin obtained in a 3-mins. and a 5-mins. infusion respectively. The columns are numbered to correspond with the teas of which the proximate analyses are given above (p. 428).

RESULTS OF INFUSION PER 100 PARTS OF INGREDIENTS EXTRACTED.

——	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22

A strong decoction of tea frequently becomes turbid on cooling, and is covered with a thin pellicle caused by the separating out of caffeine tannate. The infusion also grows darker as it stands. This is probably due to the increase of tannin in solution and its alteration by oxidation.

With regard to infusions of tea, it should be remembered that different results are obtained from the same tea, according to whether the water used is hard or soft. The larger wholesale dealers have analyses made of the waters used in the different towns and districts which they supply, and blend different teas so as to suit the requirements of different neighbourhoods, the blend depending on the particular water used in each.

In judging the *commercial value* of tea the professional tea-taster makes an infusion by pouring about 100 c.c. of boiling water upon 3 grms. of tea, allowing to infuse for 5 mins. and then decanting the liquor. He is guided mainly by the colour, uniformity, and age of the leaf, and by the bouquet, flavour, and pungency of the infusion. These are usually supposed to depend upon the amount and quality of the volatile oil, but there is good reason to believe that they are intimately associated with the action of certain enzymes in the leaf.

Although considerations other than chemical composition affect the commercial value of tea, as the age, size, and condition of the leaf, whether whole, broken, tea dust, or fannings, yet in teas accepted by expert tea-tasters as of fine quality, a certain uniformity has been observed in the ratio of the caffeine to the tannin. This is as one to three, indicating a *compound* of caffeine and tannin already referred to as caffeine tannate (*see* Lancet, Jan. 1911).

In this form the special characteristics of both caffeine and tannin in the free state are neutralised in the compound, which differs in chemical and physiological properties from, and has none of the objectionable qualities of either of its constituents. In inferior or common teas either caffeine or tannin is present in excess of this ratio, the former imparting a bitter taste to the infusion, and the latter increasing its astringency. The proper balance may be attained by suitable blending.

Adulteration in its old forms is very little practised now, probably not at all in this country. Inferior teas from old stocks are sometimes sold, also teas recovered from wrecked vessels and re-dried, but owing to the examination by the Customs Authorities (acting under the Sale of Food and Drugs Act, 1875) of all tea imported into the United Kingdom, and the general soundness of the tea trade, the importation of adulterated tea is practically a thing of the past.

The modes of adulteration formerly common were :—

1. Adding leaves of different kinds, the principal being ash, beech, birch, bramble, camellia, chestnut, coffee, currant, elder, elm, gooseberry, hawthorn, plum, poplar, raspberry, and willow.
2. Adding 'exhausted' leaves, *i.e.* tea leaves that had already been used.
3. 'Facing' black tea with graphite and adding colouring matters to green tea, notably indigo, Prussian blue, turmeric, mixed with China clay, soapstone, &c. Copper salts are scarcely ever employed, but occasionally a little iron sulphate is used to impart astringency to the tea. The facing material rarely amounts to 1 p.c., and is usually free from deleterious ingredients, being for the most part insoluble in water.
4. Adding catechu and other astringent principles.
5. Adding sand containing ferric oxide to increase the weight of the tea.

Foreign leaves are detected by the microscope. Drawings of leaves principally used as tea adulterants will be found in Bell's Foods, in Bulletin No. 13, U.S. Dept. of Agriculture, and in Villiers and Collin's Traité des Altérations et Falsifications des Substances Alimentaires.

Indications as to the presence of exhausted leaves may be obtained by determinations of the caffeine, tannin, and in particular by the alkalinity of the ash and the proportion of it soluble in water.

The substances used for facing tea can generally be readily removed for examination by shaking up with cold water, pouring off the liquor, and allowing the matter in suspension to subside.

An imitation tea known as 'lie tea' was formerly made in China from the sweepings of the tea-warehouses, foreign leaves, and mineral matter, coloured by one of the facing preparations, cemented together by rice starch and rolled into grains. The percentage of ash in 'lie tea' was always high, often exceeding 50 p.c.

Brick tea. This variety of tea is used largely in Thibet, Western Siberia, and Russia. The cheaper and inferior kinds are very coarse, consisting of both leaves and twigs, frequently mixed with a glutinous rice paste to make them cohere, and compressed by hand into blocks. The curing of the leaf consists simply of a few minutes' heating in iron pans, a slight fermentation by storing in heaps in the 'hongs' or factories, then drying in the sun, sorting into grades, and steaming preparatory to pressure in shallow moulds of the required shape and size in which the blocks are left for 3 or 4 days to harden. Over twenty million pounds of this kind of tea are said to be consumed annually in Thibet.

A superior kind of brick tea is made, chiefly at Hankow, from tea dust which, after sifting and grading, is steamed and compressed in moulds into bricks or cakes by means of an hydraulic press, the blocks being left in the moulds for 2 or 3 weeks until thoroughly dry and hard.

Nearly fifty million pounds of this tea are made annually, chiefly for the Russian Government, in factories under Russian control, and large quantities of Indian tea dust are utilised in the manufacture of this variety of brick tea. The finest grades are made in 'tablet' form, mainly for consumption in European Russia.

Amongst certain Himalayan tribes in Thibet, and in Western Siberia, it is a common practice to *eat* the tea residue, after the infusion has been drunk, mixed with sugar, milk, butter, or other fat. It is very nutritious and forms the food of the natives for weeks at a time.

Different plants are used as tea in different parts of the world. The chief of these is the *Ilex paraguayensis*, or Brazilian holly, the leaves of which make what is known as Paraguay tea or 'maté' (*q.v.*).

Other plants whose leaves are used to make tea are:—

Angræcum fragrans (Thou.) (an orchid) makes the 'Faham tea' of Mauritius.

Catha edulis (Forsk.) makes 'Abyssinian tea,' known as 'Kât' or 'Kaat.'

Coffee-tree (*Coffea arabica* [Linn.]).

Cyclopia subternata (Vog.) ('Boer Tea,' 'Cape tea,' or 'Bush tea').

Glaphyria nitida (Jack) (a species of myrtle), in the Eastern Archipelago.

Ledum palustre (Linn.) and *Ledum latifolium* (Jacq.) make 'Labrador tea.'

Lithospermum officinale (Linn.) ('Gromwell') or 'Bohemian tea.'

Various species of *Melaleuca* and *Leptospermum* (belonging to the myrtle order), various species of *Correa* (belonging to the *Rutaceæ*); *Acæna Sanguisorbae* (Vahl.) (allied to the *Rosaceæ*), and the *bark* of the Australian *Sassafras*, make the 'Abyssinian tea' of Australia and Tasmania.

All the above teas, except Bohemian tea, Bush tea, and Faham tea, contain caffeine, and all have a volatile oil, and an astringent principle allied to tannin. J. C.

TELÆSCIN *v.* HORSE-CHESTNUT.

TELLURITE *v.* TELLURIUM.

TELLURIUM. Sym. Te. At.wt. 127·5; molec.wt. 255·0.

The presence of a new metal was suspected in an auriferous mineral from Transylvania by Müller von Reichenstein in 1782; from this mineral tellurium was isolated by Klaproth (Crell's Ann. 1798, 91). The element was more fully studied by Berzelius (Pogg. Ann. 1826, 8, 411; 1833, 28, 392; 1834, 32, 1, 577).

For researches on tellurium of a general character, *v.* Brauner (Monatsh. 1889, 10, 416), Staudenmaür (Zeitsch. anorg. Chem. 1895, 10, 189), Retgers (*ibid.* 1896, 12, 98), Gutbier (*ibid.* 1902, 32, 51, 54), Metzner (Ann. Chim. Phys. 1898, [vii.] 15, 203).

Occurrence.—Tellurium occurs native in small quantity, associated with silver and gold; but it is usually found combined with metals as tellurides, the most important being *tetradymite* (Bi_2Te_3), *altäite* (PbTe), *coloradolite* (HgTe), *calaverite* ($AuTe_2$), *sylvanite* ($AuAgTe_4$), *petzite* (Ag_3AuTe_2), *nagyagite* ($((AuPb)_2\,(TeSSb)_3)$). The chief localities are *Transylvania* (Petz, Pogg. Ann. 1842, 57, 467; Schönbein, Annalen, 1852, 86, 201; Loczka, Zeitsch. Kryst. 1892, 20, 317, 320; Muthmann and Schröder, *ibid.* 1897, 29, 140); *Colorado* (*v.* Chem. Soc. Abstr. 1896, 70, ii. 612, 613; 1898, 74, ii. 385; Amer. J. Sci. 1897, [iv.] 4, 306; 1898, [iv.] 5, 375, 377, 421, 428; 1900, [iv.] 10, 419, 427; 1904, [iv.] 18, 433; Bull. U.S. Geol. Survey, 1905, No. 262, 55); *West Australia* (*v.* Chem. Soc. Abstr. 1898, 74, ii. 385; Chem. News. 1900, 82, 272; Min. Mag. 1903, 13, 268; Eng. & Min. J. 1903, 75, 814; Ann. Mines, 1901, 19, 530); also *Mexico, Chile, Brazil, Honduras*, and *Asia Minor* (*v.* Bull. Soc. chim. 1873, 20, 481; Bull. Acad. roy. Belg. 1908, 255).

Tellurite (TeO_2) or *tellurium ochre* also occurs, and 17 p.c. of tellurium has been found in the *red sulphur* of Japan (Divers and Shimidzu, Chem. News. 1883, 48, 284).

Preparation.—Tellurium is obtained from the preceding minerals or from the residues obtained in several metallurgical processes. Bismuth telluride, finely powdered, is mixed with sodium carbonate, rubbed up with oil to a thick paste, and calcined in a closed crucible. After lixiviating with cold water, a current of air is drawn through the aqueous solution of sodium telluride, when tellurium separates as a grey powder. Other tellurides are attacked with hydrochloric acid, the insoluble residue heated with concentrated sulphuric acid, and from the diluted sulphate solution, after removing silver as the chloride, the tellurium is precipitated by means of zinc or sulphur dioxide. For details and other methods, *v.* Berzelius, *l.c.*; Löwe, J. pr. Chem. 1853, 60, 163; Oppenheim, *ibid.* 1860, 81, 308; Farbaky, Zeitsch. angew. Chem. 1897, 10, 11.

The alkaline residues from bismuth ores are acidified with hydrochloric acid and treated with sodium sulphide in order to precipitate the tellurium (Matthey, Proc. Roy. Soc. 1901, 68, 161). Tellurium is also extracted from the anode slimes obtained in the course of refining American copper by electrolysis (Whitehead, J. Amer. Chem. Soc. 1895, 17, 849, 855; Lenher, *ibid.* 1899, 21, 347, 351).

Crude tellurium may be purified by boiling it with sodium sulphide solution and sulphur; from the filtered liquid pure tellurium is precipitated by heating with sodium sulphite (Schelle, 7th Inter. Cong. Appl. Chem. 1909, sect. III. A. 80). For its complete purification, the element is dissolved in *aqua regia*, evaporated several times with hydrochloric acid, and precipitated by sulphur dioxide from the diluted and filtered chloride solution. The precipitate is fused with potassium cyanide in a current of coal gas, the mass extracted with water, filtered, and the tellurium precipitated by aspirating air through the solution. The element is converted into telluric acid by Staudenmaier's method (*v. infra*), purified by several recrystallisations, ignited to tellurium dioxide, and the latter dissolved in hydrochloric acid. The pure element, precipitated by sulphur dioxide or hydrazine from the chloride solution, is dried and distilled in a current of hydrogen (Brauner, Monatsh. 1889, 10, 416; Chem. Soc. Trans. 1889, 55, 382; Baker and Bennett, *ibid.* 1907, 91, 1849).

Properties.—Tellurium is a silver-white, lustrous, brittle, metallic-looking substance, of sp.gr. 6·27, which crystallises in hexagonal rhombohedra isomorphous with sulphur and selenium (Muthmann, Zeitsch. physikal. Chem. 1891, 8, 396). It melts at 452°, boils at a red heat, and volatilises readily when heated in a stream of hydrogen. In an almost perfect vacuum it boils at 478° (Krafft, Ber. 1903, 36, 4344). The vapour of tellurium is golden yellow, and consists of diatomic molecules (Deville and Troost, Compt. rend. 1863, 56, 891; Biltz, Zeitsch. physikal. Chem. 1894, 19 415).

Tellurium is precipitated by reducing agents in an amorphous form, sp.gr. 6·015. When heated, it is converted into the crystalline form with evolution of heat (Fabre and Berthelot, Compt. rend. 104, 1405; for a summary of literature on allotropy of tellurium, *v.* Cohen and Kroner, Chem. Weekblad. 1910, 7, 57).

By careful reduction in dilute solution, brown and blue colloidal solutions of tellurium can be prepared (Gutbier, Zeitsch. anorg. Chem. 1902, 32, 51, 91; 1904, 40, 264; 42, 177; Paal and Koch, Ber. 1905, 38, 534; Weimarn and Maljisheff, J. Russ. Phys. Chem. Soc. 1910, 42, 484).

For the emission spectrum of tellurium, *v.* Salet, Compt. rend. 1871, 73, 559, 742; Ann. Chim. Phys. 1873, 28, 49; Ditte, Compt. rend. 1871, 73, 262; Hartley, Chem. Soc. Trans. 1883, 43, 399; de Grammont, Compt. rend. 1898, 127, 866, 868; for spark spectrum, *v.* Watts, Spectrum Analysis, p. 28; and for absorption spectrum, *v.* Gernez, Compt. rend. 1872, 74, 1190.

Tellurium burns in air with a blue flame, forming the dioxide. It is not attacked by hydrochloric acid, but reacts with nitric or sulphuric acid, and also with concentrated potassium hydroxide. It is insoluble in carbon disulphide. Tellurium reduces solutions of gold and silver salts (Hall and Lenher, J. Amer. Chem. Soc. 1902, 24, 918) and reacts with thionyl chloride and similar chlorides (Lenher and Hill, *ibid.* 1908, 30, 737; Horváth, Zeitsch. anorg. Chem. 1911, 70, 408; Prandtl and Borinski, *ibid.* 1909, 62, 237), the tetrachloride being usually obtained. For its behaviour as an electrode, *v.* Le Blanc, Zeitsch. Elektrochem. 1905, 11, 521, 813, 931; 1906, 12, 649. In physical properties tellurium resembles the metals, but chemically it is decidedly non-metallic. It forms one of the oxygen family of elements and closely resembles sulphur and selenium. This is shown by the fact that the three elements are isomorphous, and form mixed crystals when crystallising either from solution in a solvent or from the fused mixture (*v. infra*). The compounds $Te(C_6H_5)_2Br_2$ and $Se(C_6H_5)_2Br_2$ are isomorphous, as also are selenium and tellurium dimethylamine bromides and chlorides; whilst the acid selenates and tellurates of rubidium have been shown to form mixed crystals (Muthmann, Zeitsch. physikal. Chem. 1891, 8, 396; Norris and Mummers, Amer. Chem. J. 1900, 23, 486; Pellini, Atti. R. Accad. Lincei, 1906, 15, i. 629, 711; 15, ii. 46; 1909, 18, i. 701; 18, ii. 19, 279).

Atomic weight. This is of particular interest, since, judging by the well-defined chemical similarities exhibited by sulphur, selenium, and tellurium, the atomic weight of tellurium would be expected to be less than that of iodine, in order that tellurium and iodine might fit into the Periodic Classification in the places that would be assigned to them from a consideration of their chemical properties. The atomic weight of tellurium is, however, found to be 127·5, distinctly higher than that of iodine (126·9). Numerous attempts to show that tellurium is not homogeneous (Brauner, Monatsh. 1889, 10, 411; Chem. Soc. Trans. 1889, 55, 382; Baker and Bennett, *ibid.* 1907, 91, 1849; Baker, Chem. News. 1908, 97, 209; Staudenmaier, Zeitsch. anorg. Chem. 1895, 10, 189; Pellini, Gazz. chim. ital. 1902, 32, 131; Gutbier, Sitzungsb. phys.-med. Soc. Erlangen, 1906, 37, 270; Norris. J. Amer. Chem. Soc. 1906, 28, 1675; Lenher, *ibid.* 1908, 30, 741; 1909, 31, 20; Marckwald. Ber. 1907, 40, 4730; 1910, 43, 1710) have failed; the positive results of Browning and Flint (Amer. J. Sci. 1909, 28, 347; 1910, 30. 209) have not been confirmed by Harcourt and Baker (Chem. Soc. Trans. 1911, 99, 1311; Dudley and Bowers, J. Amer. Chem. Soc. 1913, 875). The atomic weight has been determined on material prepared from widely different sources, by the syntheses and analyses of the dioxide and tetrabromide, by the analyses of telluric acid, the double bromide of tellurium and potassium, the basic nitrate, and other compounds, and by the measurement of its electro-chemical equivalent; the results point definitely to the value 127·5 as correct (*v.* the investigations cited above, and also Wills, Chem. Soc. Trans. 1879, 35, 704; Chikashigé, *ibid.* 1896, 69, 881; Gooch and Howland, Amer. J. Sci. 1894, 58, 375; Metzner, Compt. rend. 1898, 126, 1716; Koethner, Annalen, 1901, 319, 1; Scott, Chem. Soc. Proc. 1902, 18, 112; Gallo, Atti. R. Accad. Lincei. 1905, [v.] 14, i. 23, 104). The lower value obtained by Steiner (Ber. 1901, 34, 570) by the combustion of tellurium diphenyl has not been confirmed; and it still remains to be discovered why the positions of tellurium and iodine in the Periodic Classification, determined by their atomic weights, should be the reverse of those which their chemical properties indicate.

Tellurides. A number of these compounds occur as minerals (*v. supra*). The following have been shown to exist by the methods of thermal and microscopic analysis, the mercury compound alone having no melting-point: $AuTe_2$, Cu_4Te_3, Cu_2Te, HgTe, CdTe, Tl_2Te, Tl_5Te_3, Tl_2Te_5 PbTe, SnTe, Sb_2Te_3, As_2Te_3, Bi_2Te_3 (Pélabon, Compt. rend. 1906, 142, 207; 1907, 145, 118; 1909, 148, 1176; Fay and Ashley, Amer. Chem. J. 1902, 27, 95; Fay and Gillson, *ibid.* 27, 81; Fay, J. Amer. Chem. Soc. 1907, 29, 1265; Pellini and Aureggi. Atti. R. Accad. Lincei, 1909, 18, ii. 211; Pellini and Quercigh, *ibid.* 1910, 19, ii. 445; Chikashigé, Zeitsch. anorg. Chem. 1907, 54, 50; Biltz and Meklenburg, *ibid.* 1909, 64, 226; Kobayashi, *ibid.* 1910, 69, 1). By direct union of the elements K_2Te and Na_2Te can be obtained; numerous metallic tellurides have been prepared from aqueous solutions of these compounds by double decomposition; they are usually readily oxidised by air when moist (Tibbals, J. Amer. Chem. Soc. 1909, 31, 902). Carbon telluride CTe_2 is also known (Stock and Blumenthal, Ber. 1911, 44, 1832).

Hydrogen telluride TeH_2, discovered by Davy (1810), is formed by the direct union of its elements, or by the action of dilute acids on the tellurides of zinc, aluminium, and magnesium. It is prepared by electrolysing 50 p.c. sulphuric acid at −15°C., using a piece of tellurium as cathode; the gas evolved at the cathode, when quickly dried, is nearly pure hydrogen telluride. The substance is a fœtid-smelling, inflammable, extremely unstable gas, which condenses to a liquid boiling at 0°C. It has a vapour density of 65(H=1) and contains its own volume of hydrogen. It resembles hydrogen sulphide in chemical properties (Ernyei, Zeitsch. anorg. Chem. 1900, 25, 313).

COMPOUNDS WITH HALOGENS.

Tellurium tetrafluoride TeF_4 is formed when the dioxide is heated with hydrofluoric acid in a platinum retort; it distils over and forms a colourless, very deliquescent mass. The hydrate $TeF_4,4H_2O$ separates from solutions in hydrofluoric acid. Numerous double fluorides, *e.g.* $KF \cdot TeF_4$, $BaF_2 \cdot 2TeF_4,H_2O$ are known (Metzner, Compt. rend. 1897, 125, 23; Hogborn, Bull. Soc. chim. 1881, 35, 61; Wells and Willis, Amer. J. Sci. 1901, 12, 190).

Tellurium hexafluoride TeF_6, formed by the direct union of its elements, is a gas, slowly decomposed by water. Its molecular weight, determined from its vapour density, is 239, corresponding to the simple formula (Prideaux, Chem. Soc. Trans. 1906, 89, 320; *cf.* Moissan, Ann. Chim. Phys. 1891, [vi.] 24, 239).

Tellurium dichloride $TeCl_2$, formed by the direct union of its elements, is an almost black substance, which melts at 175°, and boils at 327°, yielding a deep red vapour having the normal density (Michaelis, Ber. 1887, 20, 2488, 2491); for the absorption spectrum of the vapour, *v.* Friederichs, Chem. Zentr. 1905, ii. 1073. The dichloride is decomposed by water into tellurium, tellurous and hydrochloric acids.

Tellurium tetrachloride $TeCl_4$ is formed when excess of either chlorine or sulphur chloride (Lenher, J. Amer. Chem. Soc. 1902, 24, 188) acts on tellurium. It is a white crystalline substance, which melts at 224° to a yellow liquid, and boils at 380°, giving a red vapour of normal density (Michaelis, *l.c.*). It is very hygroscopic, and is readily hydrolysed by water to tellurous and hydrochloric acids. It forms a large number of additive compounds with metallic chlorides, and also unites with hydrochloric acid (Wheeler, Amer. J. Sci. 1893, [iii.] 45, 267; Weber, Pogg. Ann. 1858, 104, 422; Metzner, Compt. rend. 1897, 125, 23; *cf.* Lenher and Titus, J. Amer. Chem. Soc. 1903, 25, 730; Lenher, *ibid.* 1900, 22, 136).

Tellurium dibromide $TeBr_2$, obtained by heating the tetrabromide with tellurium, is a black crystalline substance, melting at 280°, and boiling at 339°; the vapour is violet. It resembles the corresponding chloride (Brauner, Chem. Soc. Trans. 1889, 55, 410).

Tellurium tetrabromide $TeBr_4$, formed by the direct union of the two elements, can be sublimed *in vacuô*. It forms fiery red crystalline crusts when hot, orange yellow when cold; the density is 4·31. It melts at about 380°, and boils at about 420°, but the vapour undergoes dissociation into the dibromide and bromine. Tellurium tetrabromide dissolves in a small quantity of water, but is readily hydrolysed by an excess. It forms numerous double bromides, *e.g.* K_2TeBr_6 which crystallise beautifully and are easy to prepare (Wills, Chem. Soc. Trans. 1879, 35, 711; Wheeler, Amer. J. Sci. 1893, iii. 45, 267).

Tellurium diiodide TeI_2 does not appear to exist, the substance described by Berzelius being a mixture (Gutbier and Flury, Zeitsch. anorg. Chem. 1902, 32, 108).

Tellurium tetraiodide TeI_4, obtained by the action of hydriodic acid on tellurous acid (*cf.* Gooch and Morgan, Amer. J. Sci. 1896, 2, 271), is an iron-grey crystalline substance, which when heated melts and then decomposes. It forms double salts with metallic iodides (Wheeler, *l.c.*).

Tellurium dicyanide $Te(CN)_2$ can be obtained by the interaction of the tetrabromide with silver cyanide in benzene solution (Cocksedge, Chem. Soc. Trans. 1908, 93, 2176). It is decomposed by water.

OXIDES AND OXYACIDS OF TELLURIUM.

Tellurium monoxide TeO is a black powder, obtained by heating $TeSO_3$ to 230° *in vacuô* (Divers and Shimosé, Chem. Soc. Trans. 1883, 43, 319). It dissolves in concentrated sulphuric acid, forming a red solution from which *tellurium sulphate* is said to separate.

Tellurium dioxide TeO_2 is formed by burning tellurium in air, or by igniting tellurous or telluric acid, and is prepared by oxidising tellurium with warm nitric acid of sp.gr. 1·25 (Klein and Morel, Bull. Soc. chim. 1885, [ii.] 43, 198). It is a white, crystalline, dimorphous solid, which melts at a red heat and may be slowly sublimed. It is easily reduced to tellurium by hydrogen or carbon. It is practically insoluble in water, but dissolves in alkali hydroxides forming tellurites. The oxide is slightly basic, since it forms a basic sulphate $2TeO_2 \cdot SO_3$ and a basic nitrate $2TeO_2 \cdot HNO_3$ (Klein, Compt. rend. 1884, 99, 326; Ann. Chim. Phys. 1887, 10, 108; Norris, Fay and Edgerly, Amer. Chem. J. 1900, 23, 105).

Tellurous acid H_2TeO_3 is a light white powder obtained by pouring a solution of tellurium in dilute nitric acid into an excess of water, washing the precipitate and drying it over sulphuric acid. It is slightly soluble in water, and behaves as a weak, dibasic acid; the alkali salts only are soluble in water (Berzelius, Pogg. Ann. 1834, 32, 577; Oppenheim, J. pr. Chem. 1857, 71, 267).

Tellurous acid may be oxidised to telluric acid in either acid or alkaline solution; these reactions are used in its volumetric estimation (Brauner, Chem. Soc. Trans. 1890, 59, 238). It is reduced to tellurium by sulphur dioxide and other reducing agents.

Tellurium trioxide TeO_3 is an orange-yellow, crystalline mass of sp.gr. 5·07, obtained by heating telluric acid nearly to redness, and dissolving out any admixed dioxide from the residue by cold hydrochloric acid. It is insoluble in water, dissolves in concentrated potassium hydroxide, and slowly reacts with concentrated hydrochloric acid, being reduced to tellurous acid.

Telluric acid H_2TeO_4 may be obtained by decomposing its barium salt with sulphuric acid. It is best prepared by dissolving tellurium in nitric acid and boiling the strongly acid solution with chromic acid; on cooling the solution the dihydrate $H_2TeO_4,2H_2O$ crystallises out (Staudenmaier, Zeitsch. anorg. Chem. 1895, 10, 189). This hydrate is dimorphous, crystallising in both the monoclinic and the cubic systems (Gossner, Zeitsch. Kryst. 1904, 38, 498); its density is 3·05. The anhydrous acid is obtained by gently heating the dihydrate.

Telluric acid dihydrate dissolves in cold water very slightly, but is easily soluble in hot water. Sulphur dioxide and other reducing agents easily reduce it to tellurium. It behaves as a very feeble acid.

Another modification of the acid, allo*telluric acid*, is obtained by heating the dihydrate to

160° for some time; it dissolves very slowly in cold water and is a much stronger acid than the ordinary form (Mylius, Ber. 1901, 34, 2208; *cf.* Brauner, Chem. Soc. Trans. 1895, 67, 549; Gutbier, Zeitsch. anorg. Chem. 1902, 32, 96).

The alkali tellurates are soluble in water; those of the other metals are difficultly soluble in water, but readily soluble in hydrochloric acid (Gutbier and Wagenknecht, *ibid.* 1904, 40, 260; Hutchins, J. Amer. Chem. Soc. 1905, 27, 1157). Besides normal and acid tellurates, more complex salts, *e.g.*

$K_2TeO_4{\cdot}TeO_3,4H_2O$; $K_2TeO_4{\cdot}3TeO_3,4H_2O$ and $K_4TeO_5,8H_2O$ are known. A number of tellurates exist in two forms, one being white and soluble in water or acids, and the other being yellow and insoluble in these liquids (Berzelius). Complex compounds of telluric acid with iodates, phosphates, &c., are known (Weinland and Prause, Ber. 1890, 23, 1015; Zeitsch. anorg. Chem. 1899, 21, 43; 1901, 28, 45).

The molecular weight of telluric acid in aqueous solution corresponds to the formula $H_2TeO_4,2H_2O$, and it is therefore regarded as having the constitution $Te(OH)_6$.

Tellurates are reduced to tellurites either by ignition or by boiling with concentrated hydrochloric acid.

Tellurium sulphoxide $TeSO_3$, obtained by dissolving tellurium in pure sulphur trioxide, is a red amorphous solid, melting at 30°, which is decomposed by water (Weber, J. pr. Chem. 1882, [ii.] 25, 218; Divers and Shimosé, *l.c.*).

Tellurium sulphides. The precipitates obtained by passing hydrogen sulphide into solutions of tellurites and tellurates, and which were described by Berzelius as sulphides, are simply mixtures of sulphur and tellurium (Becker, Annalen, 1876, 180, 257; Brauner, Chem. Soc. Trans. 1895, 67, 545; Gutbier and Flury, Zeitsch. anorg. Chem. 1902, 32, 272). The substance initially precipitated from a cold solution of a tellurite appears to be a mixture of TeS and S, the former decomposing on standing (Snelling, J. Amer. Chem. Soc. 1912, 34, 802). No compound has been isolated from fused mixtures of the two elements, which form two series of mixed crystals, and are therefore isodimorphous (Pellini, Atti R. Accad. Lincei, 1909, [v.] 18, i. 701; ii. 19; Jaeger, Proc. K. Akad. Wetensch. Amst. 1910, 12, 602; Chikashigé, Zeitsch. anorg. Chem. 1911, 72, 109). The sulphides appear to exist, however, in colloidal solution (Gutbier, Zeitsch. anorg. Chem. 1902, 32, 272, 292) and thiotellurites and thiotellurates have been isolated (Berzelius, Pogg. Ann. 1826, 8, 411; Oppenheim, J. pr. Chem. 1857, 71, 267).

Organic Derivatives.

Diethyl telluride $Te(C_2H_5)_2$ *v.* Ethyl.

Dimethyl telluride $Te(CH_3)_2$, obtained from methyl barium sulphate and potassium telluride, is a pale-yellow oil, with a garlic odour. The diiodide is obtained by heating tellurium with methyl iodide; and from this *trimethyl tellurium iodide* $Te(CH_3)_3I$ is prepared by the action of methyl iodide, sodium sulphite, and sodium carbonate (Wöhler and Dean, Annalen, 1855, 93, 233; Heeren, *l.c.*; Demarçay, Bull. Soc. chim. 1883, [ii.] 40, 100; Scott, Chem. Soc. Proc. 1904, 20, 157).

Diphenyl telluride $(C_6H_5)_2Te$ is obtained by heating mercury diphenyl with tellurium (in CO_2). It is a liquid, boiling at 312°–320°. The *dibromide* forms small yellow prisms, melting at 203·5°; it is converted into the *oxide* by warming with sodium hydroxide (Krafft and Lyons, Ber. 1894, 27, 1769; Pellini and Menin, Gazz. chim. ital. 1900, 30, ii. 472).

Di-α-naphthyl telluride $Te(C_{10}H_7)_2$ melts at 126·5°; the dichloride and dibromide of this compound melt at 265° and 244° respectively (Lyons and Bush, J. Amer. Chem. Soc. 1908, 30, 831).

For the *chloride, bromide,* and *iodide* of *tellurium triphenyl,* and their derivatives, *v.* Lederer, Compt. rend. 1910, 151, 611; *see* also Rust, Ber. 1897, 30, 2828; Rohrbaech, Annalen, 1901, 315, 9.

Detection and estimation of tellurium.—Tellurium is precipitated (by reducing agents or by electrolysis) as the element and weighed as such, or else precipitated and weighed as dioxide; numerous volumetric methods have been devised, *v.* Analysis, and Divers and Shimosé, Chem. Soc. Trans. 1883, 43, 329; McIvor, Chem. News, 1902, 86, 308; 1903, 87, 17; Gutbier, Zeitsch. anorg. Chem. 1904, 41, 448; 1902, 32, 260, 295; Pellini, Atti. R. Accad. Lincei, 1903 12, ii. 312; 1904, 13, ii. 275; Gallo, *ibid.* 1904, 13, i. 713; Pellini, Gazz. chim. ital. 1903, 33, i. 515; Brauner and Kuzma, Ber. 1907, 40, 3362; Lenher and Homberger, J. Amer. Chem. Soc. 1908, 30, 387; Perkins, Amer. J. Sci. 1910, 29, 540.

TELLURIUM OCHRE *v.* Tellurium.

TEMPER. An alloy of arsenic and lead sometimes used for hardening shot, *v.* Arsenic, alloys of; also, Tin.

TEMPER-CARBON is the name given to the carbon liberated during the tempering of steel. The change consists in the formation of a conglomerate of temper-carbon, ferrite and pearlite from a mixture of pearlite and cementite. It is identical with ordinary graphite (Charpy, Compt. rend. 1907, 145, 1173).

TENNANTITE *v.* Fahl-ore.

TERBIUM. Sym. Tb. At.wt. 159·2. This extremely rare element is present as oxide in the terbia earths which form a connecting link between the more basic cerite earths and the less basic ytterbite earths. The crude 'terbia' consists mainly of gadolinia, but it owes its characteristic yellow colour to the presence of small quantities of terbium peroxide. The existence of this elusive element, terbium, was first indicated by Mosander in 1843, but more than 60 years elapsed before its oxide and salts were isolated in a highly purified condition.

Occurrence.—In small quantities in monazite, cerite, ytterbite (gadolinite), samarskite, äschynite, and other minerals containing the rare earths (*v.* Cerite earths).

Separation and purification. The most soluble portions of the double ammonium or magnesium nitrate fractionation (*v.* Neodymium) form a convenient starting-point for the separation of the three metals of the terbium group, namely, europium, gadolinium, and terbium. A preliminary separation of the cerite metals with potassium sulphate is not to be recommended, since appreciable amounts of the terbium metals are co-precipitated with the sparingly soluble double sulphates.

Methods of separation based on (1) fractional precipitation with ammonia, (2) fractional crystallisation of double sulphates, ethyl sulphates, oxalates or formates lead rather to a concentration of the terbium group than to a separation of its components, the chief constituent gadolinium being the only one isolated in a moderately pure state by any of these processes (*cf.* EUROPIUM and GADOLINIUM).

The separation of terbium from gadolinium was first accomplished by crystallising repeatedly the double nickel nitrates and then precipitating the bases fractionally with ammonia. In this way 7 grms. of pure terbia were obtained (Urbain, Compt. rend. 1904, 139, 736; 1905, 141, 521).

Fractionation of the double magnesium nitrates of the terbia-yttria group from monazite, followed by an application of the basic salt method (*v.* SCANDIUM), and final repeated crystallisation of the oxalates lead to a separation of terbium (Feit, Zeitsch. anorg. Chem. 1905, 43, 267).

The nitrates of gadolinium and terbium, unlike the other salts of these metals, differ somewhat widely in solubility. Bismuth nitrate, which is more soluble in nitric acid than gadolinium nitrate, and slightly less soluble than terbium nitrate, is added in excess to an acid solution of the two salts. A complete separation of gadolinium and terbium is effected by fractional crystallisation of the mixture. The terbia thus isolated is identical with the products obtained in the foregoing separations, and its metal is identical with the elements provisionally indicated by the symbols Z_δ, Z_β (Lecoq de Boisbaudran), Γ (Demarçay), and G_β (Crookes).

Terbium oxide (*terbia*) Tb_2O_3 is white and the terbium salts with colourless acid radicles are themselves colourless.

Terbium peroxide Tb_4O_7, dark-brown or black mass produced by igniting terbium oxalate or sulphate respectively; it dissolves in mineral acids to form the following salts which are neutral to litmus: **terbium nitrate**

$$Tb(NO_3)_3,6H_2O,$$

m.p. 89°, monoclinic crystals; **terbium sulphate** $Tb_2(SO_4)_3,8H_2O$, micaceous lamellæ; **terbium chloride** $TbCl_3,6H_2O$, very hygroscopic, transparent, prismatic crystals.

Spectra.—Absorption spectrum, 1 band (λ488) in blue, and 9 in ultra-violet (Compt. rend. 1904, 139, 1015). Spark spectrum, very complex (*ibid.* 1906, 142, 957; Sitzungsber, Akad. Berlin, 1906, 384)

Pure terbia gives no cathode luminescence, but traces of this oxide mixed with gadolinia and aluminia produce respectively a green and white luminescence, the latter effect being remarkably striking. G. T. M.

TEREBENE *v.* OILS, ESSENTIAL; and TERPENES.

TEREBIC ACID *v.* LACTONES.

TEREPHTHALIC ACID *v.* PHTHALIC ACID.

TERPENES. The name 'terpene' has been, until recently, applied to unsaturated hydrocarbons having the empirical formula $C_{10}H_{16}$, which exist widely diffused in the vegetable kingdom as constituents of various essential or volatile oils. Of these, essence, oil, or spirit of turpentine is one of the most characteristic and best known. Of late years the term has been extended somewhat so as to include such compounds as menthene $C_{10}H_{18}$, and certain homologues of the terpenes $C_{10}H_{16}$, produced by artificial synthetical processes.

The terpenes in nature are associated with products which have probably been formed from them, or simultaneously with them by polymerisation, oxidation, or the action of water and acids. These products are often of greater importance as perfumes or medicinal agents than the terpenes with which they are diluted, as, for example, in such cases as the essential oils of lemon, bergamot and other fruits of the natural order *Aurantiaceæ*, the essences extracted from the mints and other plants of the *Labiatæ*, those of caraway and other fruits of the *Umbelliferæ*. On the other hand, the varieties of spirit of turpentine obtained from the wood, leaves, or fruits of various *Coniferæ* are of great practical importance as solvents, and in the production of paints and varnishes (*v.* OILS, ESSENTIAL).

For the purposes of this article it will be convenient to restrict the name *terpene* to the hydrocarbons $C_{10}H_{16}$, except in a few cases specifically indicated. The name *hemiterpene* may be applied to compounds of half this molecular weight, C_5H_8; the name *sesquiterpene* to those of the formula $C_{15}H_{24}$, and the name *polyterpene* to the more complex polymerides $C_{20}H_{48}$, &c.

Compounds containing more than 16 atoms of hydrogen to 10 atoms of carbon may be called *hydroterpenes*.

The terpenes are generally liquids having a characteristic odour, not sensibly soluble in water, and of lower density than water, to which they communicate their peculiar taste and odour (Distilled Waters of Pharmacy). They are miscible to a large though limited extent with alcohol and miscible in all proportions with glacial acetic acid. The natural terpenes are all optically active, some being dextro- and others lævorotatory.

Spirit of turpentine has been known for ages as obtainable by distillation with water of the natural exudation from various pine and fir trees. One of the first recorded facts relating to the chemistry of the terpenes is the production of the solid hydrochloride by passing hydrogen chloride into turpentine oil (Kind, Tromsdorff's Journ. d. Pharmacie, xi. pt. ii. 132, 1803). This was for a long time confused with common camphor, and is still sometimes referred to as 'artificial camphor.'

It was not until Liebig's process for the analysis of organic compounds had been perfected that the composition of spirit of turpentine was known, and it was shown that essence of lemon has the same formula (Dumas, Annalen, 1833, 6, 245; also Blanchet a. Sell, and *ibid.* 262).

It was known that the terpene from essence of lemon boils at a temperature about 20° higher than the b.p. of spirit of turpentine, but down to about 1876 it was supposed that there was an indefinitely large number of hydrocarbons of same formula $C_{10}H_{16}$, and no classification had been attempted. Tilden and Shenstone then obtained the nitrosochlorides (Chem. Soc.

Trans. 1877), and from a study of these compounds Tilden divided the then known terpenes into three classes (Chem. Soc. Trans. 1878) as follows: (1) turpentines or terpenes proper, (2) citrenes or limonenes, (3) sylvestrene, discovered by Atterberg (Ber. 10, 1202). Disregarding for the present the polyterpenes, the following additional groups must now be recognised: terpinene, terpinolene, *iso*pinene, pinolene, phellandrene, fenchene, camphene, carvestrene, *iso*carvestrene, and other menthadienes, thujene, sabinene. *cyclo*-Pentanes C_9H_{14} and various open-chain hydrocarbons resembling *cyclo*-terpenes, as closely allied compounds, must also be taken into account. Since 1885 the terpenes and their derivatives have been studied by many chemists. The most important systematic researches are those of O. Wallach (Annalen, 225, &c.), A. von Baeyer (Ber. 26, &c.) and W. H. Perkin, junr. (Chem. Soc. Trans. 1904, &c.).

The several hydrocarbons will now be described under the names which have been, for the most part, introduced by Wallach.

Cyclic Terpenes.

1. **Pinene group** (=turpentines or terpenes proper).

Australene, or dextro-pinene, of which rectified American turpentine, from *Pinus palustris* (Mill.) and *P. Tæda* (Linn.), and especially the Burmese turpentine from *P. Khasya* (Griff.), almost wholly consists, is obtained by agitating the commercial oil with an alkaline solution, drying completely, and carefully fractionating (156°). Dextrorotatory $[\alpha]_D=+40\cdot5$. Sp.gr. 0·8765 at 0°/4°, 0·8586 at 25°/25°, 0·8278 at 100°/100° (Tilden, unpublished experiments). This compound is also a constituent of many volatile oils, *e.g.* Russian and Swedish turpentine oils, from *Pinus sylvestris* (Linn.), and *P. Ledebourii* (Endl.) (Tilden, Chem. Soc. Trans. 33, 80); wormwood and spearmint (Brühl, Ber. 21, 156), and many others.

Terebenthene or lævopinene. French turpentine oil, from *P. Pinaster* (Soland.), consists chiefly of this hydrocarbon. B.p. 156°. $[\alpha]_D=-40\cdot32$. Sp.gr. 0·8767 at 0°/0°, 0·8619 at 17·88°/17·88° (Riban, Compt. rend. 78, 788; 79, 314). Present also in oil of rosemary (Bruylants, J. 1879, 944), oil of lemon (Tilden, Pharm. J. [3] 9, 654), sage and juniper (Chem. Soc. Trans. 31, 554), thyme and anise (Brühl, Ber. 21, iii. 156), and others.

For production and properties of turpentine oils *v.* Oils, essential.

Both dextro- and lævo- rotatory pinenes from different sources differ considerably in rotatory power, owing to the presence in varying quantities of hydrocarbons of opposite rotatory power. Pure pinene, optically inactive (b.p. 155°–156°, sp.gr. 0·858 at 20°, ref. power $n_D=1\cdot46553$ at 21°), is obtained by the decomposition of the nitrosochloride by aniline (Wallach, Annalen, 258, 243), or better by methylaniline or dimethylaniline (Tilden, Chem. Soc. Trans. 1904, 763). All varieties of pinene agree in the following chemical characters.

Dry hydrogen chloride unites with the hydrocarbon, forming a monohydrochloride $C_{10}H_{16}HCl$, m.p. 125°. If the pinene used is not quite free from moisture a certain amount of dipentene dihydrochloride is formed, and this, with the monohydrochloride, forms a liquid from which the latter can be only partially recovered by fractional distillation or cooling. Pinene obtained by fractional distillation from ordinary turpentine oil contains small quantities of isomeric hydrocarbons (pinolene, β-pinene), which yield liquid hydrochlorides. From such pinene, therefore, the theoretical yield of monohydrochloride is never obtained.

The hydrochloride obtained from dextropinene is dextrorotatory, that from lævopinene is lævorotatory.

In the presence of water, alcohol, ether, or acetic acid, hydrogen chloride forms a dihydrochloride $C_{10}H_{16}2HCl$, m.p. 50° (*v. Dipentene, infra*).

Nitrosyl chloride gas passed into a solution of the terpene in chloroform at −10° forms a nitrosochloride $C_{10}H_{16}NOCl$ (Tilden, Chem. Soc. Trans. 1875, 514, and 1877, i. 554), the same compound being formed by the action of hydrochloric acid on a cooled mixture of the terpene with amyl or ethyl nitrite and glacial acetic acid (Wallach, Annalen, 245, 245). The best yield of nitrosochloride is obtained when a mixture of dextro- and lævo- pinenes is employed in proportion to provide an optically inactive liquid. When strongly active pinene, dextro- or lævo-, is used the product is small. This appears to be due to the fact that the nitrosochloride is bimolecular $[C_{10}H_{16}NOCl]_2$ (Baeyer, Ber. 1895, 28, 648), and is optically inactive by internal compensation, and when an active variety is used one half of the hydrocarbon or the nitrosochloride undergoes inversion, the change being attended by evolution of heat. The melting-point of the nitrosochloride is usually from 103° to 105°, but after careful recrystallisation from chloroform it is 115° (Tilden, Chem. Soc. Trans. 1904, 85, 759).

The nitrosochloride heated with alcoholic potash yields an *iso*nitroso compound $C_{10}H_{15}NO$, m.p. 132°. (For crystallography *see* Story-Maskelyne, Chem. Soc. Trans. 1875, 518; and Phil. Mag. 1879, 129.)

Primary and secondary fatty amines react with the nitrosochloride producing nitrolamines which possess characteristic properties. The nitrolbenzylamine $C_{10}H_{16}NO\cdot NH\cdot CH_2\cdot C_6H_5$ melts at 122°, and the piperidide

$$C_{10}H_{16}\cdot NO\cdot N : C_5H_{10}$$

melts at 118°–119° (Wallach). Alcoholic ammonia converts the nitrosochloride into the nitrolamine $C_{10}H_{16}NO\cdot NH_2$, m.p. 123°–125° (Leach, Chem. Soc. Trans. 1907, 91, 1).

Pinene nitrosochloride interacts in a different way with aniline and aromatic bases generally. Primary bases give a diazo compound, while secondary bases yield a nitroso- compound, the hydrocarbon being in both cases regenerated in an optically inactive form.

The nitrosochloride interacts with potassium cyanide in the presence of alcohol, yielding the monomolecular cyanide or nitrile

$$C_{10}H_{15}(N\cdot OH)CN$$

m.p. 71° (Tilden and Burrows, Chem. Soc. Trans. 1905, 87, 344).

Pinene nitrosochloride also interacts with sodium azide in the presence of alcohol, producing a pinenenitrosoazide $C_{10}H_{15}(N\cdot OH)N_3$ which melts at 120°. When this compound is boiled with water it is converted partly into an isomeride, melting at 126°, and partly into the oxime of hydroxydihydrocarvone (m.p. 133°·5) already described by Wallach (Forster and Newman, Chem. Soc. Trans. 1911, 99, 244).

Pinene appears to combine with four atoms of bromine, but the product is unstable and quickly evolves hydrogen bromide. If two atomic proportions of bromine are added to a mixture of pinene and carbon tetrachloride a dark liquid is obtained, from which a small quantity of a crystalline dibromide $C_{10}H_{16}Br_2$, m.p. 169°–170°, can be extracted. When heated with aniline this compound yields ordinary cymene (Wallach, Annalen, 264, 1).

Pinene, mixed with alcohol and nitric acid, yields crystallised terpin hydrate, a compound which has long been known as a product of the prolonged contact of turpentine with various aqueous liquids (Wiggers, Annalen, 33, 358; 57, 247; Tilden, Chem. Soc. Trans. 33, 247; Hempel, Annalen, 180, 71; *see* also *Terpineol, infra*).

When exposed to air or oxygen in the presence of sunlight pinene yields a crystalline compound $C_{10}H_{18}O_2$, discovered by Sobrero (Compt. rend. 33, 66). This is also readily formed by oxidising pinene by means of an aqueous solution of mercuric acetate (Henderson and Agnew, Chem. Soc. Trans. 1909, 95, 289). This compound, sometimes known as *sobrerol*, possesses the properties of a tertiary alcohol. When distilled with dilute acid it loses the elements of water, and yields a compound $C_{10}H_{16}O$, which is identical with one of the products of the action of nitrous acid on pinene, isolated by Wallach and Otto, and called by them *pinole* (Annalen, 253, 249). The alcohol is dextro- or lævo- rotatory according to the character of the terpene from which it is formed. The pure substance melts at 150°, but when equal weights of the two varieties are mixed an inactive compound is obtained, which melts at 131° (Armstrong and Pope, Chem. Soc. Trans. 59, 311). Pinole is an unsaturated compound and yields a crystalline dibromide, m.p. 94°, a hydrochloride and hydrobromide, and a nitrosochloride, m.p. 103°. From the last-named compound a series of nitrolamines have been obtained. By oxidation with permanganate pinole readily yields terpenylic acid $C_8H_{12}O_4$, together with small quantities of other products.

When pinene is oxidised by nitric acid two main products are obtained, namely terebic acid $C_7H_{10}O_4$ and terpenylic acid $C_8H_{12}O_4$. If permanganate is used the chief product is α-pinonic acid $C_{10}H_{16}O_3$ (Baeyer, Ber. 1896, 29, 3).

Pinene distilled with bleaching powder and water yields a large quantity of chloroform. Picric acid has no action on the pinenes at ordinary temperatures, but at the boiling-point of the hydrocarbon a brisk reaction sets in, and after cooling a pale yellow crystalline compound is deposited, which on boiling with alkali yields borneol (Lextreit, Compt. rend. 102, 555; Tilden and Forster, Chem. Soc. Trans. 1893, 63, 1388).

2. **β-Pinene** (tropinene) is supposed to occur in turpentine oil in small quantity. It has been obtained, together with fenchene, from nopinone, a ketone obtained by Baeyer among the products of oxidation of turpentine oil. Nopinone was prepared and further studied by Wallach and Blumann (Annalen, 1907, 356, 227; Wallach, 1908, 363, 1). The synthetical β-pinene unites with hydrogen chloride to form bornyl chloride [117°–120°] and dipentene dihydrochloride [49°–50°].

3. **Limonene group** (=citrenes).

Dextro-limonene, b.p. 175°–176°, sp.gr. 0·846 at 20°. When obtained from oil of orange $[\alpha]_D = +106°{\cdot}8$ *ca.* (Wallach, Annalen, 252, 145). This hydrocarbon constitutes the chief ingredient in oils of orange, bergamot, lemon, and limes; it is also present in oils of carraway, pine needles (*P. sylvestris* ?), dill, erigeron, &c.

Lævo-limonene is contained in the oil of Scotch fir leaves (*P. sylvestris* [Linn.]), sometimes called 'Firwool oil' (Tilden, Chem. Soc. Trans. 33, 83; Wallach, Annalen, 227, 287). A specimen, believed to have been obtained from leaves of *P. picea*, gave b.p. 175°–176°, sp.gr. 0·846 at 20°/20°, $\alpha]_D = -105°$ (Wallach, *ibid.* 246, 221).

The limonenes are distinguished by giving with hydrogen chloride a liquid monochloride, and a dihydrochloride, m.p. 50°, identical with that obtained from the pinenes; also a nitrosochloride $C_{10}H_{16}NOCl$, either by the direct addition of nitrosyl chloride (Tilden and Shenstone) or by action of amyl or ethyl nitrite and hydrochloric acid (Wallach). From the nitrosochloride is obtained a nitroso compound, m.p. 72°, which, when prepared from *lævo*-limonene, is identical in every respect with carvoxime $C_{10}H_{14}N{\cdot}OH$ from carvone. (For Crystallography *v.* N. Story-Maskelyne, Phil. Mag. 1879, 132; for a comparison of the rotatory powers of the two limonenes and their derivatives *v.* Wallach, Annalen, 252, 141). The limonenes are further characterised by the formation of a crystalline tetrabromide $C_{10}H_{16}Br_4$, m.p. 104°–105°, by direct addition of bromine (Wallach, *ibid.* 227, 277).

The nitrosochloride obtained as described above either from dextro- or lævo- limonene is always a mixture of two compounds, which are separable from each other by means of cold chloroform in which the α- compound is more soluble than the β-. The former crystallises from ether in large clear crystals, the latter in needles. There is a slight difference of melting-point, and the α- compound has in each case a greater rotatory power than the β-. α-Nitrosochloride, m.p. 103°–104°, $[\alpha]_D = +$ or $-314°$ (Conrady, Annalen, 252, 145). β-nitrosochloride, m.p 105°–106°, has $[\alpha]_D = +$ or $-241°$*ca.* Wallach has traced the characters of some of the nitrolamines derived from the two nitrosochlorides, and finds that those derived from the α- compound are identical with those from the β- compound (Annalen, 252, 113). The corresponding nitrosocyanides, however, do not appear to be the same, neither do the products formed by the action of magnesium methyl iodide on the α- and β-nitrosochlorides respectively (Tilden and Shepheard, Chem. Soc. Trans. 89, 920; also Tilden and Leach, *ibid.* 85, 931).

Dipentene (*limonene*) is the racemic compound formed by mixing together equal quantities of dextro- and lævo-limonenes. Just as racemic acid and its salts differ in some physical characters from tartaric acid and the tartrates, so dipentene differs in some respects from the limonenes. Although the boiling-point of the inactive mixture is nearly the same as that of the limonenes, such differences as the following are observed in the melting-points of derivatives:—

	Limonene	Dipentene
Tetrabromide $C_{10}H_{16}Br_4$.	105°	124°
d or *l*-Carvoxime $C_{10}H_{14}NOH$	72°	93°

&c. (Wallach, Ber. 1891, 24, 1559).

The name 'dipentene' includes diisoprene, *iso*terebenthene, formed by the action of heat on terebenthene, cinene, cajeputene, and also caoutchene, one of the products of the destructive distillation of caoutchouc (*q.v.*). Dipentene is produced, together with terpinene terpinolene, and terpineol by the action of sulphuric or phosphoric acid on terpin, or by the action of sulphuric acid on the pinenes under certain conditions. The product thus obtained was formerly called 'terpilene.' Dipentene may be prepared from the dihydrochloride, m.p. 50°, obtained from either limonene or moist pinene, by the action of heat on the chloride (Tilden, Ber. 12, 1133), or by boiling it with a mixture of sodium acetate and acetic acid, or with alcohol and aniline (Wallach). Dipentene thus obtained is, however, accompanied by considerable quantities of cymene, terpinene, terpinolene, together with a small amount of a saturated hydrocarbon of boiling-point 155° (Tilden, Chem. Soc. Trans. 1893). The foregoing methods are all artificial; among the natural products in which dipentene is known to exist are the volatile oils of the camphor tree (Wallach, Annalen, 227, 296), also oil of elemi, and in Russian and Swedish turpentine (Wallach), and many other essential oils.

When prepared from the dihydrochloride with the utmost care by the action of aniline, dipentene appears to be accompanied with another hydrocarbon, perhaps ψ-limonene, which raises the boiling-point to 177°–178° (Wallach, Ber. 1907, 40, 600).

Dipentene, like the limonenes, unites with only one molecule of hydrogen chloride when presented in the form of the dry gas; in the presence of moisture all unite with 2HCl to produce the optically inactive saturated compound $C_{10}H_{16}2HCl$, m.p. 50°, which is identical with the dihydrochloride, formed under the same circumstances from pinene.

Dipentene yields a nitrosochloride, m.p. 101°–102°, which, like the corresponding compounds from the limonenes and from pinene, is bimolecular. It yields an inactive carvoxime, m.p. 93°, which may be formed by mixing together equal weights of lævocarvoxime, m.p. 72°, from dextrolimonene and dextrocarvoxime, m.p. 72°, from lævolimonene. This compound, notwithstanding the difference of melting-point, gives by Raoult's method a molecular weight corresponding to the simple formula $C_{10}H_{15}NO$ (Wallach, Annalen, 246, 230).

When α- limonene nitrosochloride (*v. Limonene*), prepared from either dextro- or lævolimonene, is warmed with an alcoholic solution of piperidine, a mixture of two crystallisable nitrolamines results in each case, as follows:

Nitrolpiperidines $C_{10}H_{16}\cdot NO\cdot NC_5H_{10}$.

From lævolimonene.

α-compound, m.p. 93°–94°. Rhombic (from alcohol). $[\alpha]_D=-67\cdot60^\circ$. Hydrochloride *dextro*-rotatory.

β-compound, m.p. 110°–111°. Monosymmetric. $[\alpha]_D=+60\cdot18^\circ$. Hydrochloride almost inactive.

From dextrolimonene.

α-compound, m.p. 93°–94°. Rhombic. $[\alpha]_D=+67\cdot75^\circ$. Hydrochloride *lævo*- rotatory.

β-compound, m.p. 110°–111°. Monosymmetric. $[\alpha]_D=-60\cdot48^\circ$. Hydrochloride ?

Similar results have been obtained by the employment of aniline and benzylamine. The salts of the bases thus produced possess in every case a rotatory power opposite in direction to that of the base from which each is derived.

From the foregoing statement it is clear that from each of the two active modifications of limonene two distinct series of bases are derived. Two other series may be formed from the inactive hydrocarbon. Thus when the two α-piperidine bases, m.p. 93°–94°, above described are dissolved in petroleum spirit, and the solutions mixed, an inactive nitrolamine, m.p. 154°, is at once precipitated. A second inactive compound, m.p. 152°, is formed in like manner by mixing the β- limonene bases (Wallach, Annalen, 252, 123).

Limonene oxidised with a weak solution of permanganate gives first a tetrahydric alcohol $C_{10}H_{16}(OH)_4$, m.p. 191·5°–192°, which crystallises in needles and has a faintly sweet taste (G. Wagner, Ber. 23, 2307). By oxidation with nitric or chromic acids limonene yields terpenylic acid (Krafft and Sauer, *ibid.* 1877, 10, 522).

Pure dextrolimonene and lævolimonene give when oxidised no toluic or other benzenoid acid, and pure dipentene, which may be obtained from the products of destructive distillation of india-rubber (*v. Caoutchouc*), when oxidised yields the same products as limonene (Chem. Soc. Trans. 53, 879, and 63, 292).

Cis-trans isomerism has been found by Baeyer to exist among the derivatives of dipentene. When the dihydrochloride is produced by the action of hydrogen chloride on eucalyptol at 0°, it forms a camphor-like mass, which melts at 25°. This is assumed to be the *cis*- form, the already known hydrochloride, m.p. 50°, being the *trans*- form. The corresponding hydrobromides have the melting-points 39° and 64° respectively. Both forms yield the same dipentene, but different terpins (*see Terpin*) (Ber. 1894, 26, 2861).

4. **Sylvestrene group.** Dextrosylvestrene was discovered by Atterberg in Swedish turpentine obtained among the products of destructive distillation of fir-wood (Ber. 10, 1206), also in Russian turpentine oil (Tilden, Chem. Soc. Trans. 33, 80; Wallach, Annalen, 230, 245) in company with *d*-pinene. This variety is dextrorotatory; $[\alpha]_D=66\cdot32^\circ$. *l*-Sylvestrene has since been found in the oleo-resin of *Dacryodes hexandra* (Griseb.) (More, Chem. Soc. Trans. 1899, 75, 718). Sylvestrene has an odour which is different from that of common turpentine, and resembles that of fresh fir-wood. It has a density at 16°=0·8510, at 20°=0·8470. It forms a liquid monohydrochloride and a crystalline dihydrochloride, m.p. 72°, of which $[\alpha]_D=18\cdot99^\circ$, and from which the hydrocarbon may be recovered unchanged by heating with aniline and alcohol. Sylvestrene yields a nitrosochloride $C_{10}H_{16}NOCl$, b.p. 106°–107°, which is strongly dextrorotatory, and from which various

nitrolamines may be formed. Benzylnitrolamine has $[\alpha]_D=185\cdot6°$; m.p. 71°. Sylvestrene tetrabromide [135°] crystallises in monosymmetric tables (Wallach, Annalen, 239, 29).

Sylvestrene is characterised by the production of a blue colour when a solution of it in acetic anhydride is mixed with a drop of concentrated sulphuric acid, other terpenes giving a red or yellow colour.

Carvestrenes. Dihydrocarvone unites with hydrogen bromide forming an additive compound from which, by the action of alkalis, hydrogen bromide is removed and an isomeride of dihydrocarvone $C_{10}H_{16}O$ is produced to which the name *carone* has been given. This is an oil, b.p. about 210°, and yields a liquid oxime. By reduction of the oxime $C_{10}H_{16}:NOH$ a base *carylamine* $C_{10}H_{19}N$ is produced, and from this by heating the hydrochloride in dilute aqueous or alcoholic solution an isomeric base *vestrylamine* is formed. Vestrylamine hydrochloride yields a hydrocarbon when distilled in a current of hydrogen chloride. The crude hydrocarbon yields together with other products a crystalline hydrobromide $C_{10}H_{16}2HBr$, m.p. 48°–50°. This is *carvestrene hydrobromide*, and by the action of quinoline it yields the hydrocarbon which boils at 178° (corr.). It smells like dipentene, becomes resinous on exposure to the air, decolorises potassium permanganate solution instantaneously, and is oxidised by chromic acid at ordinary temperatures. It is optically inactive, and when mixed with acetic anhydride it gives, on adding sulphuric acid, a blue colouration characteristic of sylvestrene. It bears the same relation to sylvestrene as dipentene to limonene (Baeyer, Ber. 1894, 27, 3485).

Carvestrene has more recently been synthesised completely by Perkin and Tattersall (Chem. Soc. Trans. 1907, 91, 480).

iso-*Carvestrene* is also a purely synthetic product (Fisher and Perkin, 1908, 93, 1876). This terpene boils at 176°–177°, it has a pungent odour of lemons, and is oxidised but slowly in the air. A drop of sulphuric acid added to its solution in acetic anhydride produces a violet coloration which rapidly fades. No crystalline hydrochloride or hydrobromide or bromide has been obtained.

With the exception of sylvestrene, the constitution of which still remains to be proved, the terpenes of the *meta*menthadiene series (*see* below) are not known to occur in essential oils.

5. **Terpinolene.** When pinene is mixed with a small quantity of sulphuric or phosphoric acid a considerable evolution of heat is observed, the liquid ultimately becomes optically inactive, and a mixture of hydrocarbons $C_{10}H_{16}$, together with products of polymerisation $(C_{10}H_{16})_n$, results. From the portion which on distillation comes over below 200° may be separated dipentene, terpinolene, and terpinene, together with more or less cymene and small quantities of other compounds. The distillate at about 176°, which was formerly supposed to consist of a single hydrocarbon called 'terpilene,' consists chiefly of dipentene. From the fractions at 180°–190° terpinene and terpinolene may be obtained, though not in a state of purity.

To obtain pure terpinolene γ-terpineol, m.p. 69°–70°, acetate is boiled with quinoline (Baeyer, Ber. 27, 436). Wallach prefers to dissolve terpineol in anhydrous formic acid, whence on the application of gentle heat terpinolene rapidly separates (Annalen, 1909, 368, 1).

Terpinolene boils at about 185°. By uniting with hydrogen chloride and hydrogen bromide it forms the dipentene compounds, m.p. 50° and m.p. 64°. The nitrosochloride is unknown. It forms an optically inactive tetrabromide, which crystallises in monosymmetric tables, m.p. 116°, and is quite distinct from the tetrabromides of dipentene and limonene, especially in its instability, the crystals becoming gradually converted into an opaque mass, with lower melting-points 112° *ca.*

6. **Terpinene.** The product obtained by boiling terpin hydrate with diluted sulphuric acid (Tilden, Chem. Soc. Trans. 33, 250), that formed by the action of slightly diluted sulphuric acid on turpentine (Armstrong and Tilden, *ibid.* 35, 747), also the product of heating the dihydrochloride $C_{10}H_{18}Cl_2$, m.p. 50°, were formerly believed to be identical, and received the name terpinylene or terpilene (Berthelot).

The action of sulphuric or phosphoric acid on terpenes and on terpin is now known to yield, in addition to products of polymerisation (colophene), three distinct hydrocarbons—namely, dipentene, b.p. 175°–176°, terpinolene already described, b.p. 185°, and terpinene (Wallach).

Later researches (Wallach, Annalen, 1908, 362, 285; also 1910, 374, 217) show that the terpinene hitherto obtained is a mixture of two or more isomerides. Ordinary terpinene is believed to contain α-terpinene, boiling at about 179°, β-terpinene, b.p. 173°–174°, and a γ-terpinene or terpinolene. Ordinary terpinene is characterised by the action of nitrous acid which forms a crystalline nitrosonitrite

$$C_{10}H_{16}N_2O_3$$

m.p. 155° (Wallach, Annalen, 239, 33).

β-Terpinene forms a sparingly soluble crystalline tetrabromide $C_{10}H_{16}Br_4$ [154°–155°] and a dihydrochloride, m.p. 52°.

Terpinene-nitrosonitrite · by the action of bases is converted into nitrolamines, for example:

$$C_{10}H_{15}{<}\begin{matrix}NOH\\NH_2\end{matrix}{>}\ \text{m.p. } 116°\text{–}118°,$$

$$C_{10}H_{15}{<}\begin{matrix}NOH\\NHC_2H_5\end{matrix}{>}\ \text{m.p. } 130°\text{–}131°$$

(Wallach, Annalen, 241, 315).

7. **Phellandrene** (Pesci, Gazz. chim. ital. 16, 225). The seeds of *Oenanthe phellandrium* (Linn.), contain about 2·5 p.c. of a volatile oil, of which about 80 p.c. consists of a dextrorotatory terpene, b.p. 171°–172°. The same hydrocarbon is contained, together with anethol, in the oil of bitter fennel, *Fœniculum vulgare* (Mill.) (Wallach, Annalen, 239, 40). It also forms a constituent of oil of elemi, and in small quantity is said to exist in the oils of cassia, cinnamon (Duyk), and sassafras (Power and Kleber).

In the oil of *Eucalyptus amygdalina* (Labill.) Wallach found the isomeric *l*-phellandrene (Annalen, 246, 232).

Phellandrene in either form is easily alterable by the action of acids into dipentene and terpinene; also into a solid polymeride $C_{20}H_{32}$, m.p. 86°.

Phellandrene is specially characterised by the formation of a nitrosonitrite $C_{10}H_{16}\cdot N_2O_3$, first observed by Cahours, afterwards (Zeits.

Chem. 1869, 579) examined by Bunge. Pesci obtained it by the action of a nitrite and dilute sulphuric acid upon the hydrocarbon.

Crude *l*-phellandrene from eucalyptus oil contains two isomeric phellandrenes $C_{10}H_{16}$, together with small quantities of cymene $C_{10}H_{14}$ and cineole $C_{10}H_{18}O$ (Semmler, Ber. 1903, 36, 1749).

d-Phellandrene from elemi oil is identical with *d*-phellandrene from bitter fennel oil but not with *d*-phellandrene from water fennel oil. The former is to be called *d*α-, the latter *d*β-phellandrene. *l*-Phellandrene from eucalyptus is *l*α-phellandrene.

Both *d*α- and *l*α-phellandrene form two nitrites which are separable by crystallisation from acetone and alcohol. The α-nitrite from both melts at 112°–113°, and has approximately the same rotatory power though in opposite directions and opposite in direction to the rotation of the parent hydrocarbon ; thus *d*-phellandrene yields a *l*-nitrite. The β-nitrite from both the phellandrenes melts at 105°, and the rotatory powers of these compounds exhibit similar relations to each other and to the parent.

*d*β-Phellandrene yields similar derivatives (Wallach, Annalen, 1904, 336, 9).

By reduction of phellandrene nitrite, prepared from water-fennel oil by Pesci's method with zinc and glacial acetic acid, a lævorotatory diamine is obtained which boils at 250°–253°. When phellandrene nitrite from eucalyptus is reduced a lævorotatory diamine $C_{10}H_{16}(NH_2)_2$, which is not identical with Pesci's, is formed also boiling at 250°–253°. The hydrochloride of this base melts at 209°–210°. By dry distillation it yields cymene, ammonia and ammonium chloride. Phellandrene nitrite treated with ammonia (Pesci) or with sodium ethoxide (Wallach and Herbig) yields a liquid which boils at 134°–138°, and is identical with the 'nitrophellandrene' described by Pesci (Gazz. chim. ital. 16, 225). Further reduction of the nitrite or of the nitro compound by means of alcohol and sodium leads to the production of tetrahydrocarvone, tetrahydrocarveol, and tetrahydrocarvylamine (Wallach and Herbig, Annalen, 1895, 287, 371).

8. **Fenchene.** Dextrofenchone, $C_{10}H_{16}O$, an isomeride of camphor, is present in fennel oil, and the fraction boiling between 190° and 195° consists chiefly of this compound. Lævofenchone occurs in thuja oil, and is left when the crude ketone is treated with strong nitric acid. By the reduction of *d*-fenchone a lævorotatory fenchylic alcohol is obtained. When this is treated with phosphorus pentachloride, and hydrogen chloride is removed from the product by the action of bases, the hydrocarbon fenchene is obtained. It was originally supposed that this terpene was an individual substance. It appears, however, that fenchylic alcohol gives two fenchylic chlorides and these furnish two fenchenes, one dextro-, the other lævorotatory. As both are derived from dextrofenchone Wallach distinguishes them as D*d*-fenchene and D*l*-fenchene respectively.

From lævofenchone corresponding L*d*- and L*l*-fenchenes have been prepared.

The fenchenes yield an unstable liquid dibromide and are distinguished from other terpenes by comparative indifference toward nitric acid. D*d*-Fenchene is quickly oxidised by a 3 p.c. solution of permanganate, while D*l*-fenchene is slowly oxidised by the same agent. The product is hydroxyfenchenic acid

$$OH{\cdot}C_9H_{14}{\cdot}CO_2H,$$

of which the m.p. and rotation differ according to the origin of the acid.

D*l*-Hydroxy fenchenic acid, m.p. 152°–153° $[\alpha]_D = -56{\cdot}8°$

D*d*- „ „ „ m.p. 138°–139° $[\alpha]_D = +7{\cdot}69°$

L*d*- „ „ „ m.p. 152°–153° $[\alpha]_D = +57{\cdot}3$

r „ „ „ m.p. 142°–143°

(Wallach and Hertz, Annalen, 1898, 302, 371).

A large amount of work has been done on the derivatives of the fenchones, but the formula of fenchone, and consequently of fenchene, is still unsettled (Wallach, *ibid.* 1909, 369, 63). *V.* FENCHONE.

9. **Pinolene.** The mixture of liquid hydrochlorides obtained on saturating crude American pinene with hydrogen chloride when decomposed by bases yields a fraction, b.p. 145°–148°, of constant rotatory power. This is found by Aschan to be a mixture of two isomeric terpenes $C_{10}H_{16}$, of which one is removed by treatment with permanganate, whilst the other remains unattacked. To the former he gives the name α-pinolene, the latter β-pinolene. β-Pinolene is a colourless liquid, b.p. 142°–144°. The hydrochloride, m.p. 25°–26°, is apparently different from the hydrochloride, m.p. 38°, obtained from crude pinolene. Both when heated with aniline and alcohol yield *iso*pinene, b.p. 154°–156°, which forms a crystalline hydrochloride, m.p. 36°–37°. Another hydrocarbon obtained by the action of hydrogen on α-pinene in presence of palladium is described by Zelinsky under the name *iso*pinene (Ber. 1911, 44, 2782). This yields neither hydrochloride nor nitrosochloride. The acid formed by oxidation of α-pinolene by potassium permanganate has been identified as *r*-camphoric acid (Aschan, Chem. Soc. Abstr. 1909, i. 659).

10. **Camphene group.** The monohydrochloride, m.p. 128° (b.p. 210°), of pinene has been long known and was formerly described as 'artificial camphor.' This compound is remarkably stable, but it may be decomposed by heating with sodium stearate or benzoate, with potassium acetate, with alcoholic potash or ammonia, or by a mixture of sodium acetate and caustic soda with alcohol. The resulting hydrocarbon is a camphene, m.p. 51°–52°, b.p. 160°, dextro- or lævo- rotatory, or inactive, according to the nature of the hydrochloride used and the reagent employed (Berthelot, Compt. rend. 47, 266, and 55, 496, 544). The inactive compound seems to be produced when a high temperature is used. A camphene is also formed from bornyl chloride (art. CAMPHORS, vol. i. p. 616) by the action of alcoholic potash (Riban), by the action of water and magnesia (Kachler, Annalen, 197, 86), or by heating with aniline to the boiling-point of the latter (Wallach, *ibid.* 230, 234). Camphene is also formed from camphor chloride (vol. i. p. 618) and from pinene hydrochloride by the action of sodium (Montgolfier, Compt. rend. 87, 84).

In this last case it is accompanied by a hydrocarbon $C_{10}H_{18}$ resembling a paraffin, m.p. 120°, which presents an appearance and odour similar to camphene, but is not attacked by sulphuric or fuming nitric acid.

Camphene is also formed, together with other products, by the action of strong sulphuric acid on turpentine, and constitutes the chief ingredient in the liquid formerly known as 'terebene' (Armstrong and Tilden, Chem. Soc. Trans. 1879, 745).

Camphene occurs in many essential oils, such as oil of rosemary, spike (*Lavandula Spica* [Cav.]), valerian, Siberian fir (*Abies sibirica*), citronella, &c. The melting-point of natural camphene is, however, generally lower than that of the artificial, and Wallach appears to have proved that the derivatives of the camphenes are isomeric, not identical (Annalen, 1907, 367, 72).

Ordinary camphene, active or inactive, possesses a characteristic camphoraceous smell, is soluble in alcohol, and crystallises therefrom in leaflets. It combines with hydrogen chloride to form a chloride $C_{10}H_{17}Cl$, m.p. 157°, which is distinguished from pinene hydrochloride by its inferior stability (Riban, Compt. rend. 80, 1330; Ehrhardt, Chem. News, 54, 239).

Camphene hydrochloride was formerly regarded as identical with bornyl chloride (Kachler and Spitzer, Annalen, 200, 340), but according to Reychler (Bull. Soc. chim. 1896, [iii.] 15, 366), and later Wagner and Brickner (Ber. 1899, 32, 2302), camphene hydrochloride is identical with *iso*bornyl chloride. They regard pinene hydrochloride as the true chloride of borneol. This conclusion is confirmed by Hesse (*ibid.* 1906, 39, 1127).

Camphene does not combine with bromine, and is attacked by it only slowly, with formation of an oily monobromo derivative (230°–240°). Camphene does not combine with nitrosyl chloride. It is converted at about 300° into liquid products which have not been investigated.

When oxidised by chromic acid, ordinary camphene yields camphor, but, according to Marsh and Gardner (Chem. Soc. Trans. 59, 649), when dilute nitric acid is employed as the oxidant a tribasic acid $C_{10}H_{14}O_6$, called by them *camphoic acid*, is produced. Camphoic acid is not produced by the oxidation of camphor or camphoric acid; it has been identified as carboxyl*apo*camphoric acid by Bredt and Jagelki (Chem. Zeit. 1896, 20, 842).

When ordinary camphene is oxidised by neutral permanganate one of the first products formed is camphene glycol $C_{10}H_{16}(OH)_2$, m.p. 200°, together with a ketone, camphenylone $C_9H_{14}O$, m.p. 36°–38°, and a compound $C_{10}H_{16}O_2$, m.p. 169°–170°. When acidified the products of oxidation included camphene camphoric acid $C_{10}H_{16}O_4$, and camphenylic acid $C_{10}H_{16}O_3$. The origin of some of these products is, however, uncertain (*see* Wagner, Moycho and Zienkowski, Ber. 1904, 37, 1032, and Moycho and Zienkowski, Annalen, 1905, 340, 17).

A camphene, m.p. 97·5°–98°, b.p. 150°, together with ordinary camphene, was obtained by Wagner and Brickner (Ber. 1900, 33, 2121) from pinene hydriodide, and is called by them *bornylene* owing to the belief that it is the true relative of camphor and borneol. For the other camphene, m.p. 51°–52°, the name *iso*bornylene is proposed.

It appears, therefore, that at least three camphenes exist which are indistinguishable by appearance and odour, but differ in melting-point and in products of oxidation.

11. **Thujene group.** Several essential oils, such as those of thuja, tansy, wormwood, and sage, contain a ketone $C_{10}H_{16}O$ called thujone or tanacetone. Thujoneoxime, m.p. 54°–55°, is converted into an isomeride, m.p. 90°, by the action of phosphorus pentachloride, and into another optically inactive modification, m.p. 119°–120°, by contact with warm concentrated sulphuric acid. Each of these oximes is reducible to a corresponding base, and the hydrochloride of the base splits under the influence of heat into ammonium chloride and a terpene $C_{10}H_{16}$. The individuality of the hydrocarbons thus formed is still uncertain; by combination with 2 molecules of the hydrohaloids they yield liquid and solid compounds which are now considered to be derivatives of terpinene. Probably isomerisation occurs in most of these transformations (Kondakoff, J. pr. Chem. 1908, [ii.] 77, 135).

12. **Sabinene.** Oil of savin distilled yields about 30 p.c. of a fraction, boiling between 162° and 170°, which consists principally of the hydrocarbon *sabinene* $C_{10}H_{16}$, b.p. 165°–167° (sp.gr. 0·84, mol. refr. 44·9). This yields an oily dibromide, and when oxidised by cold solution of permanganate it yields a glycol $C_{10}H_{18}O_2$, m.p. 54°. An acid sabinenic acid $C_{10}H_{16}O_3$, m.p. 57°, is formed at the same time: it yields a sparingly soluble sodium salt (Semmler, Ber. 1900, 33, 1455). This is an α-hydroxy acid, losing carbon dioxide when oxidised by lead peroxide, to form sabinene ketone $C_9H_{14}O$, b.p. 213°, which is lævorotatory, although sabinene, sabinene glycol and sabinenic acid are all dextrorotatory. Sabinene occurs in the essential oil of Ceylon cardamom and in Majorana oil. When shaken with sulphuric acid sabinene yields a terpin $C_{10}H_{18}(OH)_2$, m.p. 137°, and a terpineol $C_{10}H_{17}{\cdot}OH$, b.p. 209°–212°, which forms a dihydrochloride $C_{10}H_{18}Cl_2$, m.p. 52°. The same *trans*terpinene compound is produced from sabinene by the action of hydrogen chloride in glacial acetic acid. The hydrocarbon is converted into terpinene by boiling dilute sulphuric acid (Wallach, Annalen, 1906, 350, 141).

13. **Dacrydene,** from leaves of *Dacrydium Franklini* (Hook.) (Huon Pine of Tasmania) (b.p. 165°–166°, sp.gr. 0·8524 at 22°, $[\alpha]_D = +14{\cdot}48°$) forms a nitrosochloride, m.p. 120°–121°, but the bromide is liquid and no solid compound with hydrogen chloride has been obtained (H. G. Smith, The Pines of Australia, Sydney, N.S.W., 1910).

14. **Origanene** from *Origanum spp.* grown in Cyprus. A liquid which boils at 160°–164° at 750 mm., with sp.gr. 0·847 at 16°, a rotation of +1·50° in a 1 dcm. tube and ref. index $n_D = 1{\cdot}480$. It forms a nitrosochloride, m.p. 91°–94°, and from this a nitrolbenzylamine, m.p. 104°–105, and nitrolpiperidide, m.p. 198°, are obtained. The dibromide and hydrobromide are liquid, and a nitrosite has not been obtained. By agitation with dilute sulphuric acid origanene yields ordinary terpin hydrate and the dibromide treated with alcoholic potash yields p-cymene. Oxidation by means of hydrogen peroxide yields succinic acid (Pickles, Chem. Soc. Trans. 1908, 93, 862).

OPEN CHAIN TERPENES $C_{10}H_{16}$.

Myrcene is obtained from oil of bay or sassafras by agitating with soda solution and distilling off the undissolved hydrocarbon under reduced pressure. The following constitution is attributed to it by Barbier (Compt. rend. 1901, 132, 1048) $C_{10}H_{16}$ or

$$CMe_2 : CH{\cdot}CH_2{\cdot}CH : CMe{\cdot}CH : CH_2.$$

Reduced by sodium and alcohol it yields dihydromyrcene $C_{10}H_{18}$, b.p. 171·5°–173·5°, and this when treated with a mixture of acetic and sulphuric acids yields *cyclo*dihydromyrcene

$$CMe\begin{cases} \!\!\!= CH\text{———}CH_2 \\ \!\!\!- CHMe\text{—}CMe_2 \end{cases}\!\!>CH_2$$

, b.p. 169°–172° (Semmler, Ber. 1901, 34, 3122).

Ocimene is the name given by van Romburgh to a hydrocarbon obtained from the leaves of *Ocimum basticum*, and subsequently examined by Enklaar (Proc. K. Akad. Webensch. Amsterdam, 1906, 8, 714). It is said to boil under atmospheric pressure at 172·5°, but is thereby changed into allo-*ocimene*. By reduction with sodium and alcohol ocimene and *allo*ocimene yield the same compound as myrcene. These hydrocarbons are rapidly oxidised in contact with free oxygen.

SESQUITERPENES $C_{15}H_{24}$.

According to Gladstone (Chem. Soc. Trans. 1872, 1), the oils of clove, calamus, cascarilla, patchouli, and cubebs contain a hydrocarbon of this composition. A sesquiterpene has also been found by Wallach (Annalen, 238, 81) in oils of galbanum and savin and in 'huile de cade,' a kind of tar made by distillation of the wood of *Juniperus Oxycedrus* (Linn.). According to the latter chemist, the hydrocarbon *cadinene* obtained from cade or cubebs possesses the following properties. It unites with 2HCl, forming a compound which crystallises from ether in large hemihedral rhombic prisms, m.p. 117°–118°, the solution of which is lævorotatory. Heated with aniline or with sodium acetate the hydrocarbon is set free in a pure state, b.p. 274°–275°; sp.gr. 0·921 at 16°/16°. The hydrobromide $C_{15}H_{24}{\cdot}2HBr$ melts at 124°–125°; the hydriodide $C_{15}H_{24}{\cdot}2HI$ at 105°–106°, with partial decomposition. The hydrocarbon, especially when partially resinified by exposure to the air, gives the following characteristic colour reaction: Dissolved in chloroform or glacial acetic acid, and then shaken up with a few drops of strong sulphuric acid, the liquid assumes an intense green and then blue colour, which when heated passes into red.

Cadinene (lævorotatory) also occurs in the oils of betel, camphor, juniper, asafœtida, coto, and olibanum.

Carophyllene occurs in oils of cloves and copaiba, but has not been obtained pure by fractional distillation. It boils at about 258°–260°. When dissolved in a mixture of glacial acetic and sulphuric acid and the mixture subseq ently steam distilled, a volatile but crystalline alcohol, $C_{15}H_{25}OH$, is formed. The alcohol melts at 96° and boils at 287°–289°. When treated with dehydrating agents the original hydrocarbon is not reproduced, but an isomeride to which the name *clovene* has been given (Wallach and Walker, Annalen, 271, 285).

Caryophyllene produces liquid addition products with the halogen acids, but it forms a solid nitrosochloride, m.p. 158°–160°, and nitrosate, m.p. 147°–150°. The nitrosite forms blue needles, m.p. 107°.

According to Deussen and Lewinsohn (Annalen, 1907, 356, 1) this nitrosochloride is a mixture from which alcoholic ethyl acetate extracts β-caryophyllene nitrosochloride, m.p. 159°, $[\alpha]_D = -98{\cdot}07°$, together with another substance $C_{15}H_{23}O_2N$, m.p. 162·5°–163·5°, $[\alpha]_D = +217{\cdot}2°$. The residue is the α-nitrosochloride, m.p. 177°–179°, which is optically inactive and reacts with benzylamine forming the nitrolamine, m.p. 126°–128°.

Later researches lead to the conclusion that Wallach's caryophyllene is a mixture of two or more isomerides (Deussen, Ber. 1909, 42, 376; Annalen, 1909, 369, 41).

Humulene from oil of hops has been studied by Chapman (Chem. Soc. Trans. 1895, 67, 54, and 780). The sesquiterpene is optically inactive, it boils at 263°–266° and has a vapour density corresponding to $C_{15}H_{24}$. It forms an oily tetrabromide and yields no alcohol when treated in the same manner as caryophyllene. Humulene forms a liquid dihydrochloride, a white crystalline nitrosochloride, m.p. 164°–165°, a nitrosate [162°–163°], and a blue crystalline nitrosite $C_{15}H_{24}N_2O_3$ [*ca.* 121°]. From the nitrosochloride a nitrolpiperidide, m.p. 153°, and nitrolbenzylamine, m.p. 136°, were obtained.

A comparison of caryophyllene and humulene shows that these hydrocarbons are distinct substances (Kremers, Schreiner and James, Pharm. Archives, 1898, i. 209).

Cedrene obtained from oil of cedar is said to boil at 260° (Chapoteaut, Bull. Soc. chim. [ii.] 37, 303). It is lævorotatory $a_D = -17°\ 54'$. It produces unstable compounds with bromine and halogen acids, and when oxidised yields with chromic acid a ketone $C_{15}H_{24}O$ (Rousset, *ibid.* 1897, [iii.] 17, 485). According to Semmler and Hofmann the composition of cedrone is $C_{15}H_{22}O$, b.p. 147°–150°. Cedrene oxidised with permanganate yields cedrene glycol $C_{15}H_{26}O_2$ which crystallises in large prisms, m.p. 160° (Ber. 1907, 40, 3521).

An attempt to prepare from isoprene a polymeride of the composition $C_{15}H_{24}$ proved unsuccessful (Wallach).

Conimene, a hydrocarbon $C_{15}H_{24}$, b.p. 264°, with a pleasant odour, is obtained from the incense-resin (*Protium heptaphyllum* [March]) of British Guiana (Stenhouse and Groves, Chem. Soc. Trans. 1876, i. 175).

POLYTERPENES $C_{20}H_{32}$, &c.

The members of this group may be divided into three classes, viz. (1) Fluid constituents of certain essential oils; (2) products of the polymerisation of terpenes; and (3) caoutchouc and gutta percha.

1. The least volatile portions of many essential oils contain a hydrocarbon probably having the composition $(C_{10}H_{16})_n$, but very little is known concerning these substances. Some of the oils to which the formula $C_{20}H_{32}$ was formerly attributed appear to be sesquiterpenes, the hydrocarbon from balsam of copaiba for example. *See Caryophyllene.*

2. *Colophene* is a viscid yellow fluid, often strongly fluorescent, which begins to boil at

about 300°. It is produced by exposing oil of turpentine or other terpenes to a temperature of about 300° for some hours, or by the action upon them of concentrated sulphuric or phosphoric acid, phosphorus pentoxide, or boron fluoride, &c. The name colophene was given by Deville to the less volatile portion of the product of the action of sulphuric acid on French turpentine, apparently under the impression that it was identical with the oil obtained by distillation of resin. The latter, however, contains oxygen, and exhibits totally different properties.

Colophene obtained by the action of strong sulphuric acid on turpentine oil cannot be distilled without decomposition, even under reduced pressure. The first portions of the distillate contain camphene and dipentene; the boiling-point then rises higher and higher, and even when the temperature approaches that of dull redness a residue is left, which on cooling becomes nearly solid (Armstrong and Tilden, Chem. Soc. Trans. 1879, 748). The portions passing over at 300° and upwards appear to consist of saturated compounds, for they absorb mere traces of hydrogen chloride. Riban has obtained from terebenthene, by the action of antimony trichloride, a solid to which he assigns the formula $C_{40}H_{64}$. This is decomposed by heat, and combines with hydrogen chloride to form two compounds

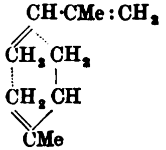
$$C_{40}H_{64},HCl \text{ and } C_{40}H_{64},2HCl$$

(Compt. rend. 79, 389).

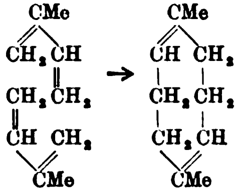
3. *Caoutchouc*. *V*. Rubber.

True rubber is a product which results from the coagulation of the milky juice of trees belonging to several distinct natural orders, as explained in the article referred to. It consists, when pure, of a white, exceeding tough and elastic solid. As usually found in commerce it presents various shades of brown or black colour which are produced by the action of smoke or of atmospheric air on the product of coagulation. Pure india-rubber consists of a hydrocarbon $(C_5H_8)_n$ of high molecular weight, and completely colloidal character. It is insoluble in water and alcohol, but appears to dissolve to a small extent in benzene and its homologues, carbon disulphide, chloroform, and some other liquids forming viscous liquids. The apparent solubility of rubber depends, however, on the treatment to which it has been previously subjected. Rubber unites chemically with many substances, including sulphur and bromine. It combines with the halogen in the proportion of four atoms for every ten atoms of carbon, and therefore seems to have the same capacity of saturation as the limonenes. When destructively distilled it yields a mixture of hydrocarbons consisting of isoprene (b.p. 36°–37°), caoutchene which is identical with dipentene (b.p. 176°), and heveene, which appears to be a variety of colophene (b.p. *ca.* 315°). Rubber, therefore, has the same ultimate composition as the terpenes, and appears to have a formula either $(C_5H_8)_n$ or $(C_{10}H_{16})_n$.

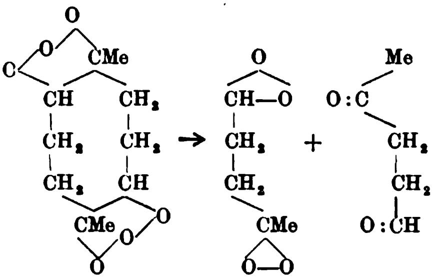
When isoprene is heated to 100°–200° in contact with a small quantity of acetic acid or is kept in contact with a small quantity of air for a long time, it is converted into rubber. Rubber is also formed by contact of isoprene with metallic sodium (Matthews and Strange, Eng. Pat. 24790 [1910]). When heated alone to a temperature of about 280° isoprene is converted into dipentene. Isoprene having been shown by Mokiewsky (Chem. Zentr. 1899, i. 589) to be *β*-methyldivinyl $CH_2:CH{\cdot}CMe:CH_2$, the condensation into dipentene is easily represented by the following formula, in which two molecules of isoprene are supposed to be united at the points indicated by the dotted lines, the valencies adjusting themselves, but without shifting of the hydrogen atoms—



The conversion of isoprene into caoutchouc is, however, open to several explanations. On the one hand, Harries (Ber. 1905, 38, 3985) assumes the formation of an octadiene as the first product of the union of two molecules of isoprene—



This hypothesis is chiefly based on the fact that when rubber, in chloroform solution, is brought into contact with ozone a compound is formed with two molecules of that substance. This compound has the *molecular* formula $C_{10}H_{16}O_6$. When boiled with water it splits up into lævulic aldehyde or lævulic acid and lævulic aldehyde diperoxide—



Diozonide. Diperoxide. Lævulic aldehyde.

On the other hand, it has been suggested with greater probability that the caoutchouc molecule consists of long chains. One form of hypothesis (Pickles, Chem. Soc. Trans. 1910, 1088) is expressed in the following formula in which an indefinite number of C_5H_8 groups may be linked together—

$$CH_2:CMe{\cdot}CH:CH_2 + CH_2:CMe{\cdot}CH:CH_2, + \&c.$$

becoming

$$\ldots CH_2{\cdot}CMe:CH{\cdot}CH_2{\cdot}CH_2{\cdot}CMe:CH{\cdot}CH_2,\ldots \&c.$$

The direct conversion of isoprene into rubber with its indefinitely large molecule is in this way easily represented, and it may be remarked that the ready depolymerisation of rubber into isoprene by heat seems to support the view that it is directly resolved into C_5H_8 groups, and not into groups of $C_{10}H_{16}$. The dipentene which accompanies isoprene in the destructive distillation of rubber is probably a secondary product of the polymerisation of isoprene by heat.

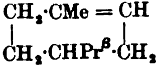
One great objection to Harries' formula is the fact that it represents the chemical molecule of rubber as consisting of $C_{10}H_{16}$, whilst it is certain that the actual physical molecule of the colloid is very much more complex, and there seems no way of accounting for the chemical association together of a number of octadiene molecules without loss of free valency, and hence reduction of the saturating power.

Hydroterpenes.

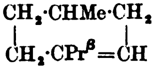
Menthene $C_{10}H_{18}$. This compound stands in the same relation to menthone $C_{10}H_{18}O$ and menthol $C_{10}H_{19}\cdot OH$, as does camphene to camphor and borneol. It is obtained by treating menthol with phosphorus pentoxide at the common temperature or with zinc chloride at the boiling-point (Brühl and others, 1892, Ber. 25, 142). Menthene boils at 167°. It forms a nitrosochloride, m.p. 113°, and an oily dibromide.

Carvomenthene $C_{10}H_{18}$. Dihydrocarveol produced by the reduction of carvone, by means of sodium and alcohol, yields with acetic anhydride an acetate, b.p. 232°–234°. This takes up hydrogen iodide, and the resulting hydriodide, when reduced with zinc-dust and acetic acid, yields tetrahydrocarveol acetate which on saponification[4] yields tetrahydrocarveol. If this compound is converted into its hydrobromide, and the latter is heated with quinoline, *carvomenthene*, b.p. 175°–176° is obtained. This is isomeric with the menthene obtained from menthol (Baeyer, Ber. 1893, 26, 820). Carvomenthene obtained by heating carvomenthyl chloride or bromide with alcoholic potash appears to be divisible into two portions by fractional distillation, about 90 p.c. of the whole distilling at 17-°–174·5°, the rest at a few degrees higher (Kondakoff and Lutschinin, J. pr. Chem. 1899, [ii.] 60, 257).

The following formulæ are attributed by Baeyer (*l.c.*) to carvomenthene and menthene respectively—



$$\begin{array}{l} CH_2\cdot CMe = CH \\ | \qquad\qquad\quad | \\ CH_2\cdot CHPr^{\beta}\cdot CH_2 \end{array}$$



$$\begin{array}{l} CH_2\cdot CHMe\cdot CH_2 \\ | \qquad\qquad\quad | \\ CH_2\cdot CPr^{\beta} = CH \end{array}$$

Action of Heat upon the Terpenes.

The terpenes heated to temperatures of 250°–300° lose their rotatory power and are slowly polymerised (Berthelot, Ann. Chim. Phys. [iii.] 39, 5). When ordinary turpentine oil is passed through a tube heated to redness scarcely visible in the dark, it yields a quantity of gas and various liquid products, of which the most important are isoprene C_5H_8, dipentene $C_{10}H_{16}$, *p*-cymene $C_{10}H_{14}$, and colophene $(C_{10}H_{16})_n$, with relatively small quantities of benzene, toluene, and *m*-xylene (Tilden, Chem. Soc. Trans. 1884, 45, 410). At higher temperatures no isoprene is obtained, but a larger quantity of gas, and the most volatile liquid product is benzene, which is accompanied by some of its homologues, besides naphthalene, anthracene, &c. (Schultz, Ber. 1877, 10, 113).

It has been found by Staudinger and Klever that limonene or dipentene, when diluted with an indifferent gas, such as nitrogen, or under reduced pressure, yields a much larger quantity of isoprene, amounting to 60 p.c. and upwards. The temperature required is produced by a platinum spiral electrically heated to redness (Ber. 44, 2212). The isoprene thus obtained is said to be purer than the isoprene previously obtained. According to these authors the yield of isoprene under the same circumstances is much smaller when pinene, camphene, terpinene, or terpinolene is employed.

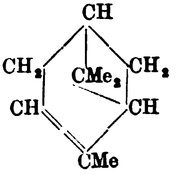
A convenient arrangement of the spiral within a flask connected with a vertical condenser has been described by Harries and Gottlob (Annalen, 1911, 383, 228). The unchanged terpene drops back into the flask, the isoprene passing off into a properly cooled receiver.

Camphene, when heated, yields other products which have not been fully examined.

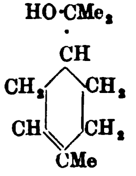
Constitution of the Terpenes.

The terpenes generally exhibit many of the properties of olefinic hydrocarbons combining with two or four molecules of bromine, with one or two molecules of hydrogen chloride, and with one or two molecules of water. They also form characteristic compounds with nitrosyl chloride. By the loss of two atoms of hydrogen the terpenes yield a considerable, though varying, amount of common cymene, *methyl*-p-iso*propyl benzene* (G. Williams, Proc. Roy. Soc. 10, 516; Oppenheim, Ber. 5, 628; Wright, Chem. Soc. Trans. 1873, 686). All the terpenes, when exposed to heat, polymerise into viscous products, and at a temperature of about 400° yield a considerable quantity of isoprene $CH_2:CH\cdot CMe:CH_2$, a hydrocarbon, which by prolonged heating at a lower temperature is converted into limonene $C_{10}H_{16}$. Pinene is distinguished by the readiness with which it undergoes isomeric change, especially under the influence of diluted acids, whereby it is converted into terpin, terpineol, and dipentene. The product of its union with hydrogen chloride is, according to conditions, either bornyl chloride $C_{10}H_{17}Cl$ or dipentene dihydrochloride $C_{10}H_{18}Cl_2$, and from neither of these can pinene be regenerated. The only compound from which pinene can be recovered is the nitrosochloride $(C_{10}H_{16}NOCl)_2$, as already mentioned (*v.* Pinene).

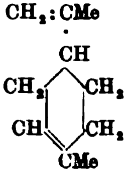
These facts can be accounted for by the following formulæ which were proposed in 1894 by G. Wagner (Ber. 27, 1636).



Pinene.

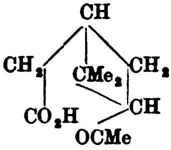


Terpineol.

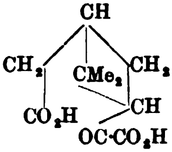


Limonene.

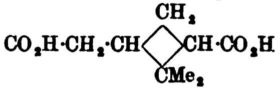
The dimethylated tetramethylene ring in the formula of pinene is very readily broken up by the action of dilute acids, which cause the addition of the elements of water as shown above, yielding terpineol, or the closely connected glycol, terpin. It is, however, very stable under the action of neutral or alkaline oxidising agents such as permanganate. This tetramethylene group has been named 'picean' by Baeyer. The products of the oxidation of pinene by permanganate include α-pinonic acid $C_{10}H_{16}O_3$—



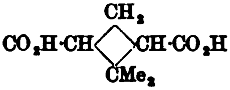
and dibasic pinoyl-formic acid $C_{10}H_{14}O_5$.



These compounds retain the picean ring which is capable of hydrolytic rupture in both of them, much as in the case of pinene itself. Further oxidation leads to the production from both of these acids of the same pinic acid—

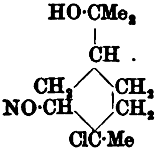


and ultimately of norpic acid—

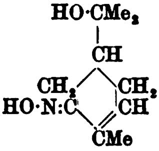


The constitution of limonene was first indicated by the discovery that the nitroso compound $C_{10}H_{15}NO$, obtained from the nitrosochloride $C_{10}H_{16}NOCl$ by the action of alkali, is identical with carvoxime $C_{10}H_{14}:NOH$ (Goldschmidt and Zürrer, Ber. 18, 2220).

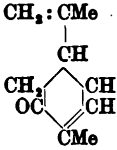
The nitrosochloride of terpineol is also convertible into carvone by removing the elements of hydrogen chloride so as to produce the oxime of the hydroxy ketone from which carvone is obtained by the action of acids (Wallach).



Terpineol nitrosochloride



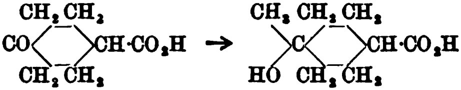
Oxime



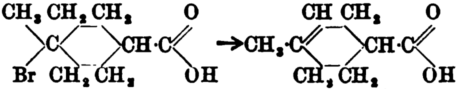
Carvone

More recently the formulæ of terpineol and limonene have been completely established by synthesis, the principal steps in the process being the following:—

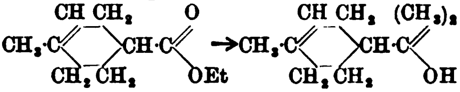
The esters of β-iodopropionic acid and sodiocyanacetic acid are brought together and after interaction the product is hydrolysed. Pentane-αγε-tricarboxylic ester is thus obtained from which δ-ketohexhydrobenzoic acid is formed by treatment with acetic anhydride and distillation. The ester of this acid in contact with magnesium methyl iodide yields δ-hydroxyhexhydro-*p*-toluic acid—



Hydrogen bromide converts this toluic acid into the corresponding bromo derivative, which, when treated with weak alkalis or pyridine, loses hydrogen bromide and yields Δ'-tetrahydro-*p*-toluic acid—



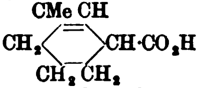
The ester of this unsaturated acid is converted by magnesium methyl iodide in ethereal solution into inactive *terpineol*—



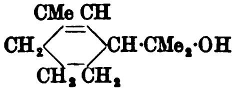
By the simple abstraction of water from terpineol by means of potassium hydrogen sulphate dipentene results, and hence the position of the second ethylenic bond in that compound is determined. These formulæ are identical with those proposed by Wagner (W. H. Perkin, junr., Chem. Soc. Trans. 1904, 654).

Optically active *d*- and *l*-terpineols were afterwards prepared by Perkin and Fisher (*ibid.* 1908, 1871).

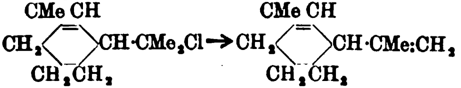
The great majority of the terpenes found in nature are compounds in which the side chains occupy the *para-* position as in limonene. The sylvestrene (*q.v.*) discovered by Atterberg in Swedish turpentine has, however, been shown by Perkin to be a *meta-* compound. Proceeding from Δ'-tetrahydro-*m*-toluic acid—



a dextrorotatory hydrocarbon identical with natural sylvestrene has been built up by synthesis. The *d*-acid was first isolated from the inactive mixture by means of brucine and the ester was made to interact with magnesium methyl iodide. The resulting *d*-dihydrocarvestrenol is the representative of terpineol in the meta series and is represented by the following formula—

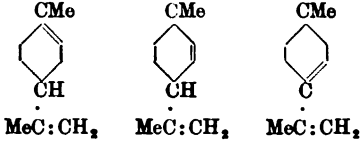


By the action of hydrogen chloride it yields *d*-carvestrene dihydrochloride which melts at 72° and is identical with the hydrochloride obtained from natural sylvestrene. The hydrocarbon is isolated from the hydrochloride by heating it with aniline—

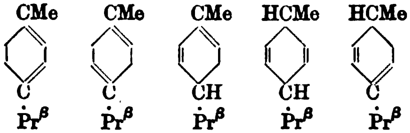


(Perkin, Chem. Soc. Proc. 1910, 97).

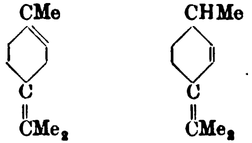
It is now apparent that the formulæ of some of the other natural terpenes are probably closely related to the formula of limonene. Thus there may be theoretically three compounds containing ·Me and ·CMe : CH_2 in the para- position, while there is one double bond in the ring—



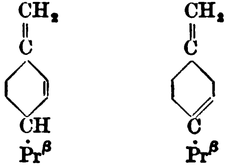
There may also be five isomeric dihydrocymenes—



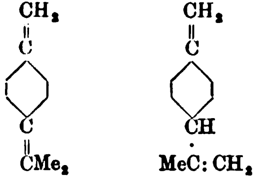
There may be two other isomerides of the type—



Two more of the following form—



And lastly two isomerides in which the double linking is wholly external to the ring—



Of some of these there are also geometrical isomeric forms.

It is sometimes convenient to adopt a system of numbering the carbon atoms as introduced by Baeyer in the case of the terpenes. The para- series is based on the formula of hexhydrocymene—

According to this system dipentene, for example, is Δ1·8(9)-*p*-menthadiene and terpineol is Δ1-*p*-menthenol 8.

The hydrocarbons enumerated above are only the varieties in which the *para-* position is assumed by the side chains, but these and others already known may be arranged under the following divisions.

MENTHADIENES $C_{10}H_{16}$.

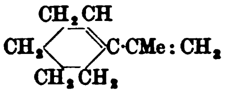
I. Derivatives of cyclohexene—
  1. *Para-*. Limonene and dipentene, terpinene, phellandrene.
  2. *Meta-*. Sylvestrene.
  3. *Ortho-*. Synthetical products unknown in nature.

II. Derivatives of *cyclo*hexene with bridged rings—
  1. *Para-* containing two pentamethylene rings: fenchene, camphene (?).
  2. *Meta-* containing one tetramethylene ring: pinene.
  3. *Meta-* containing one trimethylene ring: sabinene, thujene.

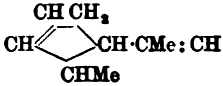
III. Olefinic terpenes with open chains. Myrcene, ocimene.

The production of a terpene of the *ortho-* type has been accomplished by Ray and Perkin (Chem. Soc. Trans. 1905, 1066).

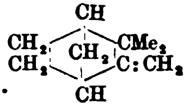
Perkin has also made progress in the synthesis of lower homologues of the terpenes. The hydrocarbons C_9H_{14} prepared belong to two types. One of these is derived from *cyclo*hexane containing no methyl group in the ring (Matsubara and Perkin, *ibid.* 1905, 661).



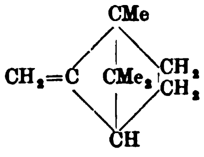
The other is framed on a cyclo*pentene* containing a methyl group (Haworth and Perkin, *ibid.* 1908, 573).



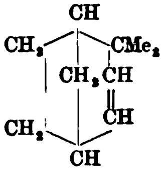
Among the questions which remain unsettled is the identity of the terpinenes, concerning which a summary of researches has been published by Wallach (Annalen, 1910, 374, 217). The constitution of the solid terpene, camphene, is also a subject of dispute. The formula assigned to it long ago by Wagner, namely—



(Ber. 1900, 33, 2121) is not found to account for all the products of oxidation of the hydrocarbon. An alternative formula has been proposed by Semmler (Ber. 1900, 33, 3420), as follows—



and another more recently by Aschan (Annalen, 1910, 375, 336).



On the other hand, according to Auwers (Annalen, 1912, 387, 40) the specific refraction of camphene is definitely in favour of Wagner's formula given above. See also Haworth and King, Chem. Soc. Trans. 1912, 101, 1975.

For the optical properties of the terpenes, such as specific rotatory power and especially refractivity, and their relation to the constitution of the hydrocarbons, a useful summary will be found in Smiles' Relations between Chemical Constitution and Physical Properties (Longmans' Text-books of Physical Chemistry).

OXIDISED COMPOUNDS RELATED TO THE TERPENES.

1. **Absinthol** $C_{10}H_{16}O$, identical with thujone.
2. **Borneol** $C_{10}H_{17}OH$, *v.* vol. i., CAMPHORS.
3. **Cajeputol** $C_{10}H_{18}O$, identical with cineol.
4. **Carveol** $C_{10}H_{16}O$, *v.* vol. i., CAMPHORS.
5. **Carvone** $C_{10}H_{14}O$, *v.* vol. iii., KETONES.
6. **Camphor** $C_{10}H_{16}O$, *v.* vol. i.
7. **Cineol** $C_{10}H_{18}O$, *v.* vol. i., CAMPHORS, SANTONICA.
8. **Citronellol** $C_{10}H_{19}\cdot OH$, an alcohol similar to geraniol found in citronella and rose oils.
9. **Coriandrol** $C_{10}H_{17}OH$, identical with *d*-linalool.
10. **Eucalyptol** $C_{10}H_{18}O$, identical with cineol.
11. **Fenchone** $C_{10}H_{16}O$, *v.* vol. iii., KETONES.
12. **Geraniol** $C_{10}H_{17}\cdot OH$. Indian oil of geranium (*Andropogon Schœnanthus* [Linn.]) consists chiefly of this compound (Semmler, Ber. 23, 1098, 2965, 3556; 24, 682).

Geraniol is an optically inactive compound with a smell of roses. It boils at 229°–230°.

When oxidised by chromic acid it yields the corresponding aldehyde, citral or geranaldehyde $C_{10}H_{16}O$. Further oxidation yield geranic acid $C_{10}H_{16}O_2$, which is monobasic.

Geraniol heated with potassium hydrogen sulphate yields a terpene, geraniene, which boils at 172°–176°.

13. **Citral,** the aldehyde, occurs as a natural constituent of the oil of lemon, lemon grass, and many other essential oils. It boils at 228°–229° under ordinary pressure, and is optically inactive. It unites with four atoms of bromine, and is characterised by the readiness with which by the action of potassium hydrogen sulphate it yields ordinary cymene. In other respects it gives the usual reactions of aldehydes. It reduces silver solutions, combines to form a crystalline compound with sodium hydrogen sulphite, and reproduces the colour of rosaniline from a sulphite solution.

It also yields an aldoxime and a semicarbazone.

Geranic acid, which is best formed from the nitrile by boiling with potash, is a colourless oil possessing an odour like that of the higher fatty acids. When distilled under ordinary pressure it yields carbon dioxide and a hydrocarbon, geraniolene C_9H_{16}, which boils at 142°–143°. Geraniolene forms a liquid tetrabromide $C_9H_{16}Br_4$.

14. **Linalool** $C_{10}H_{17}\cdot OH$. This substance is very widely distributed in essential oils derived from various plants. The name has reference to the wood of the lignum aloes (*Aquilaria Agallocha* [Roxb.]), in which it was originally recognised, but the alcohol or its acetate is found in the oils of lavender, bergamot, petit grain (leaves and shoots of orange) neroli, &c. It is distinguished from geraniol, with which it is isomeric, by its lower boiling-point and by its lævorotatory action on the polarised ray. The boiling-point under atmospheric pressure is about 198°–199°.

15. **Coriandrol** is dextrorotatory linalool (Semmler, Ber. 24, 206; Tiemann and Semmler, *ibid.* 26, 2713).

Linalool treated with acetic anhydride yields, at the ordinary temperature, an acetate which regenerates linalool on saponification, but if the acetate is heated to 100° and upwards it undergoes isomeric change, and on saponification it yields geraniol (Bouchardat, Compt. rend. 116, 1253).

d- or *l*-Linalool and geraniol, shaken with dilute sulphuric acid, are converted almost quantitatively into terpin hydrate (Tiemann and Schmidt, Ber. 1895, 28, 2137).

Linalool on oxidation by means of acid reagents yields citral, the aldehyde of geraniol.

The following constitution is assigned to these compounds (Tiemann and Semmler, Ber. 1895, 28, 2126).

Linalool

$Me_2C : CH\cdot CH_2\cdot CH_2\cdot CMe(OH)CH : CH_2$

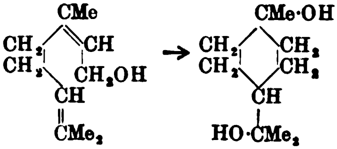
Geraniol

$Me_2C : CH\cdot CH_2\cdot CH_2\cdot CMe : CH\cdot CH_2\cdot OH$

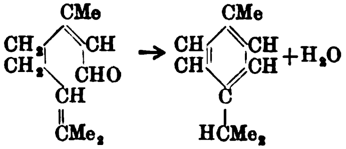
Citral

$Me_2C : CH\cdot CH_2\cdot CH_2\cdot CMe : CH\cdot CHO$

These open chain compounds are, however, readily converted into cyclic compounds, especially by the action of acids, for example, in the production of terpin from geraniol—



and in the production of cymene from citral.



16. **Menthol** $C_{10}H_{19}OH$ *v.* vol. i., CAMPHORS.
17. **Pinole** $C_{10}H_{16}O$, *see* under *Pinene.*
18. **Pulegone** $C_{10}H_{16}O$, *v.* vol. iii., KETONES.
19. **Sobrerol** $C_{10}H_{18}O_2$, *see* under *Pinene.*
20. **Sobrerone** $C_{10}H_{16}O$, identical with pinole.
21. **Tanacetone** $C_{10}H_{16}O$, *v.* vol. iii., KETONES.
22. **Terpineol** $C_{10}H_{17}OH$. *Terpinol* was the name given by List (Annalen, 1848, 67, 362) to the liquid obtained by the action of dilute acids upon terpin hydrate.

When crystallised terpin is boiled with water and a small quantity, say 1 p.c., of hydrochloric acid is added, the crystals disappear and a turbid fluid results, from which by distillation an oily liquid, lighter than water and possessing a peculiar fragrant odour, resembling that of lilac, is obtained. When the oil is dried and distilled, the whole comes over, with the exception of a few drops at first, between 205° and 215°. Treated with sodium, terpineol dissolves one atom of the metal; and by contact with excess of hydrochloric acid it becomes coloured deep purple, but the colour disappears and the whole is converted into dipentene hydrochloride $C_{10}H_{18}Cl_2$ (m.p. 50°); when mixed gradually with a nearly equal volume of sulphuric acid diluted with half its bulk of water, very little heat is evolved, but solution is complete, and on adding to the mixture three or four volumes of water a mass of crystallised terpin hydrate is obtained. Terpineol is also quickly converted into terpin hydrate by a mixture of nitric acid and alcohol (Tilden, Chem. Soc. Trans. 1878, 247; 1879, 287). Terpineol absorbs two atoms of bromine (Tilden, *ibid.* 1888, 882), and it is, therefore, an unsaturated tertiary alcohol $C_{10}H_{17}(OH)$, of which the corresponding glycol is terpin $C_{10}H_{18}(OH)_2$. By *boiling* with potassium hydrogen sulphate terpineol splits into water and dipentene.

Terpineol yields a nitrosochloride

$$C_{10}H_{18}O{\cdot}NOCl$$

from which a piperidide [m.p. 159°–160°] and anilide [m.p. 155°–156°] are obtainable (Wallach and Kerckhoff, Annalen, 1893, 275, 103).

More recent researches have shown that liquid terpineol obtained as described or by hydrolysis of the corresponding acetate contains two distinct compounds. Bouchardat and Voiry (Compt. rend. 1887, 104, 996) were the first to obtain crystals by cooling. The m.p. was found to be 35° (Wallach). Distilled under reduced pressure liquid terpineol yields two principal fractions, boiling at 212°–215° and 218°–220° at ordinary pressure. Both solidify on cooling, the former having the m.p. 32°–33°, and the latter 35°–36°.

The terpineol [m.p. 35°–36°] forms a nitrosochloride [m.p. 122°], which yields the piperidide mentioned above [m.p. 159°–160°]. Its phenylurethane $NHC_6H_5{\cdot}CO{\cdot}OC_{10}H_{17}$ melts at 112°–113°. The new terpineol [m.p. 32°–33°] gives a nitrosochloride [m.p. 102°–103°], but does not readily yield a piperidide. The phenylurethane melts at 85°.

Both these terpineols have been produced synthetically by W. H. Perkin (Chem. Soc. Trans. 1904, 85, 654), starting from ethyl β-iodopropionate and ethylsodiocyanoacetate. Their constitution is therefore now fully established. *See* below.

These compounds are optically inactive, but active terpineols have been obtained from other sources, *l*-linalool $C_{10}H_{18}O$, when heated with acetic acid containing a small quantity of sulphuric acid yields *d*-terpineol, together with geraniol, while in similar way *d*-linalool yields *l*-terpineol (Stephan, J. pr. Chem. 1898, [ii.] 58, 109).

Optically active terpineols have been produced synthetically by Perkin and Fisher (Chem. Soc. Trans. 1908, 93, 1871) by resolving the corresponding *dl*-cyclohexene carboxylic acid by means of brucine or strychnine.

Active terpineols also occur in certain essential oils, *e.g.* oil of *Asarum canadense* [Linn.] (Power and Lees, *ibid.* 1902, 81, 63).

23. **Terpin** $C_{10}H_{18}(OH)_2$ and **Terpin hydrate** $C_{10}H_{18}(OH)_2{\cdot}H_2O$. This compound is occasionally found in old samples of turpentine oil containing a little water, and in furniture polish of which turpentine is an ingredient. It is easily obtained by the action of a mixture of nitric acid and alcohol upon turpentine oil (Wiggers, Annalen, 1846, 57, 251). Hempel recommends (*ibid.* 180, 71) 4 parts oil of turpentine to 1 part of alcohol and 1 part of nitric acid. In any case, the mixture is shaken up at intervals until in the course of about two days the smell of turpentine has disappeared. The liquid is then poured out into shallow dishes, a little alcohol being added occasionally as long as crystals are deposited (Tilden, Chem. Soc. Trans. 33, 247). No crystals are formed under the same circumstances from the limonenes, but from the hydrochlorides of these hydrocarbons terpineol, and hence terpin is easily obtained by the action of water or dilute alcohol.

Terpin hydrate [116°–117°] dissolves in about 200 parts of cold, and in 22 parts of boiling, water. It is easily soluble in alcohol, but not in petroleum. It is optically inactive, and is chemically saturated. Anhydrous terpin melts at 104°–105°, and boils at 258°. The crystals have been examined by List (Annalen, 67, 362), by Rammelsberg (Poggendorff's Annalen, 63, 570), and by Maskelyne (Phil. Mag. 1879, 132).

Exposed to hydrogen chloride the crystals deliquesce, become purple, and finally give a mass of the colourless dipentene dichloride $C_{10}H_{18}Cl_2$ [m.p. 50°]. Boiled with water slightly acidified with hydrochloric or sulphuric acid it yields terpineol. Boiled with moderately strong sulphuric acid it yields a mixture of dipentene, terpinene, and terpinolene.

Cis- and *trans-* terpins have been obtained by Baeyer from the corresponding *cis-* and *trans-* hydrobromides of dipentene (Ber. 1894, 26, 2861). *Cis*dihydrobromide when treated successively with silver acetate and alcoholic potash gives ordinary terpin. The *trans-* dihydrobromide, when similarly treated, yields the *trans*-terpin which crystallises without water, melts at 156°–158°, and boils at 263°–265°.

24. **Thujone** $C_{10}H_{16}O$, identical with tanacetone. W. A. T.

TERPENYLIC ACID *v.* Lactones.

TERRA ALBA *v.* Gypsum.

TERRA CATECHU. Syn. with Catechu (*q.v.*).

TERRA CHE BRUCIA or *Val d'Arno Superiore Resin v.* Resins.

TERRA DI SIENNA. *Raw Sienna v.* Pigments.

TERRA FOLIATA TARTARI. Potassium acetate.

TERRA JAPONICA. Syn. with Catechu (*q.v.*).

TERRA LEMNIA *v.* Lemnian earth.

TERRA MIRACULOSA. An old name for bole (*q.v.*).

TERRA MURIATICA. An obsolete name for magnesia.

TERRA PONDEROSA. An old name for baryta (*q.v.*).

TERRA UMBRA. Umber (*q.v.*).

TESTADEN *v.* Synthetic drugs.

TETRADECYLMALONIC ACID $C_{17}H_{32}O_4$. Prepared by heating α-cyanopalmitic acid with alcoholic potash (Hell and Iordanoff, Ber. 1891, 991), m.p. 117°–118°.

TETRADYMITE *v.* Tellurium.

TETRAETHYL- and **TETRAMETHYL-DIAMINOBENZOPHENONE** *v.* Ketones.

TETRAHEDRITE *v.* Fahl-ore.

TETRAHYDROXYBENZENE *v.* Phenol and its homologues.

TETRAIODOPYRROLE *v.* Iodole.

TETRAKETONES *v.* Ketones.

TETRAMETHYLAPIONOL *v.* Phenol and its homologues.

TETRAMETHYLBENZENES *v.* Cymenes.

TETRAMETHYLHYDROXYBENZENE *v.* Phenol and its homologues.

TETRAMETHYLSAFRANINE *v.* Azines.

TETRATHIONIC ACID *v.* Sulphur.

TETRAZO- COMPOUNDS *v.* Disazo- and Tetrazo- compounds.

TETRONAL (*diethylsulphonediethylmethane* or *ethyl sulphonal*) $(C_2H_5)_2C(SO_2C_2H_5)_2$ is prepared like sulphonal from diethylketone and ethyl mercaptan (Baumann and Kast, Zeitsch. physiol. Chem. 14, 61; D. R. P. 49366; Frdl. 1887–1890, ii. 523). It forms colourless, odourless, glistening leaflets, or radiating almost round fibrous groups similar to urea oxalate; m.p. 85°, soluble in 450 parts of cold water, but more readily soluble in boiling water, in alcohol, and in ether. It is employed in medicine as a substitute for sulphonal.

Adulteration of tetronal and trional with sulphonal, which is cheaper than the two former, may be detected by treating the suspected sample with ether, in which sulphonal is much less soluble, the residue will, therefore, contain sulphonal which may be detected by its melting-point and its known reactions (Gabutti, J. Pharm. Chim. 1907, 25, 183); *v.* Sulphonal.

TETRYL *v.* Butyl.

THALLIUM, sym. Tl., at.wt. 204·0, was discovered spectroscopically by Crookes in 1861 (Chem. News, 1861, 3, 193) in a seleniferous deposit from a sulphuric acid manufactory. It occurs in many iron and copper pyrites, in some micas, in zinc blendes, in the minerals *marcasite*, *hæmetite*, *crookesite* $(CuTlAg)_2Se$, *lorandite* ($TlAsS_2$), *orbaite* $TlAs_2SbS_5$, and in various other iron and manganese ores (Igelström, Z. Kryst. Min. 1895, 25, 94; Antipoff, J. Russ. Phys. Chem. Soc. 1896, 28, 384; Hartley and Ramage, Chem. Soc. Trans. 1897, 533). It also occurs in small quantities in various mineral springs.

Its presence has been observed in crude zinc (Kosmann) and in platinum and its ores (H. N. Warren, Chem. News, 1887, 55, 241).

Thallium is prepared from flue dust by boiling it with dilute sulphuric acid and precipitating the chloride or iodide by treatment with hydrochloric or hydriodic acid, after which the metal can be obtained by electrolytic deposition, by the action of potassium cyanide or by electrolysis (Bunsen, Phil. Mag. 1865, [iv.] 29, 168; Foerster, Zeitsch. anorg. Chem. 1897, 15, 71). Traces of lead, tin, copper, and aluminium occur as impurities in commercial thallium (Pollock, Sci. Proc. Roy. Dublin Soc. 1909, 11, 338).

Thallium is a bluish-white, lead-like, crystalline, extremely soft metal, malleable, but of low tenacity. It exists in two modifications, the transition temperature being 226°. Its sp.gr. is 11·85, its m.p. 303° (Petrenko, Zeitsch. anorg. Chem. 1906, 50, 133), its b.p. in vacuum 818° (Krafft and Knocke, Ber. 1909, 42, 202); at ordinary pressure 1515±2° (Isaac and Tammann, *ibid.* 1907, 55, 58); but its b.p. should be 1462° at 760 mm. Its vapour density is 14·25 at 1728°. It commences to volatilise at 174° *in vacuô*. At a high temperature it may be distilled in a current of hydrogen. When heated it burns with a beautiful green flame, and its flame spectrum is characterised by a single green line.

Thallium oxidises before the blowpipe. It dissolves readily in dilute nitric and sulphuric acids, but more slowly in hydrochloric acid, and at a red heat decomposes water.

Thallium and its salts are very poisonous (Curci, Chem. Zentr. 1895, ii. 999; Swain and Bateman, J. Biol. Chem. 1910, 7, 137). Thallium forms alloys with a large number of metals, and an amalgam with mercury.

Compounds.—Thallium forms two series of compounds—

(1) Thallic (TlX_3) compounds in which the metal is trivalent, corresponding to its position in the aluminium group. Like the compounds of aluminium, the thallic salts undergo hydrolysis in aqueous solution and form complex salts more readily than the corresponding thallous compounds (Spencer and Abegg, Zeitsch. anorg. Chem. 1905, 44, 379). Metallic thallium reduces the thallic salts to the thallous condition. In the absence of oxidising agents, even in the presence of thallous salts, thallic salts give the blue coloration of indophenols when α-naphthol and dimethyl-*p*-phenylene diamine are added to an alkaline solution of the salt (Marino, Gazz. chim. ital. 1907, 37, i. 55).

(2) Thallous (TlX) compounds in which thallium is monovalent. The thallous salts closely resemble the salts of the alkali metals; thus the hydroxide and carbonate are readily soluble and give an alkaline aqueous solution. Many of the thallous salts, like the sulphate phosphate, &c., are isomorphous with the corresponding potassium salts and give double salts with platinic chloride Tl_2PtCl_6. The alum $Tl_2SO_4Al_2(SO_4)_3,24H_2O$ and other double sulphates are also closely analogous to the corresponding potassium salts. The thallous halides and sulphides, on the other hand, resemble the corresponding lead and silver salts.

Thallous salts react with a clear aqueous solution of antimony chloride and potassium iodide, giving a characteristic voluminous orange precipitate of the compound $3TlI,2SbI_3$ (Ephraim, Zeitsch. anorg. Chem. 1908, 58, 353).

Oxides. Thallium trioxide (thallic oxide) Tl_2O_3 is formed when an alkaline solution of a thallous salt is treated with 3–5 p.c. solution of hydrogen peroxide. When the precipitation is made in the cold, the oxide is brown, is readily soluble in acids, and has sp.gr. 9·65 at 21°, but when the solutions are hot, the oxide is black, is sparingly soluble in acids, and has the sp.gr. 10·19 at 22°. The brown oxide is partly reduced when boiled with water, but the black oxide remains unchanged. At 100° the brown slowly changes into the black variety, and at 520° this change is complete within 24 hours (Rabe, Zeitsch. anorg. Chem. 1906, 48, 427; *ibid.* 50, 158; *ibid.* 1907, 55, 130). The crystalline oxide obtained by heating the nitrate has sp.gr. 9·97 (Thomas, Compt. rend. 1904, 138, 1697; *see* also Fortini, Gazz. chim. ital. 1905, 35, ii. 450).

Thallium monoxide (thallous oxide) Tl_2O is obtained by exposing the metal to the air or by heating the corresponding hydroxide at 100° out of contact with air. It is a black powder, m.p. 300°, readily dissolving in water with formation of the *hydroxide* TlOH, which crystallises with 2 molecules of water in yellow needles. The hydroxide turns turmeric brown, and finally destroys the colouring matter (Erdmann, J. pr. Chem. 1863, 89, 381).

The *oxide* $(TlO)_x$, probably Tl_2O_3,Tl_2O, is prepared by adding 175–200 grms. of 20 p.c. potassium hydroxide to 15 grms. of a 10 p.c. aqueous solution of thallous sulphate. The solution is filtered, cooled to −15°, and 3·5 grms. of a 3 p.c. solution of hydrogen peroxide is added with constant shaking. The oxide forms a bluish-black, lustrous precipitate, is readily decomposed into thallic oxide and thallous hydroxide by cold water and by dilute acids. It readily absorbs carbon dioxide, and, unlike thallous salts, is oxidised by a current of oxygen at ordinary temperature to thallic oxide (Rabe, Zeitsch. anorg. Chem. 1908, 58, 23).

.When a mixture of thallous sulphate and oxalic acid is electrolysed at the ordinary temperature with a current of 3–4 volts and 0·15–0·2 ampères, the oxide Tl_3O_5 or TlO_2,Tl_2O_3 is deposited on the anode. When the deposit is dissolved in dilute hydrochloric acid, chlorine is evolved and a yellow salt $TlCl_3,3TlCl$ is formed (Gallo and Cenni, Atti R. Accad. Lincei, 1908, [v.] 17, ii. 276).

For the halogen and mixed halogen compounds of thallium, *see* Wells and Penfield (Zeitsch. anorg. Chem. 1894, 6, 312); Meyer (*ibid.* 1900, 24, 321; *ibid.* 1902, 32, 72); Thomas (Compt. rend. 1900, 131, 892, 1208; *ibid.* 1901, 132, 80, 1487; *ibid.* 133, 735; *ibid.* 1902, 134, 545; *ibid.* 135, 1051; *ibid.* 1906, 142, 838; *ibid.* 143, 282; Ann. Chim. Phys. 1907, [viii.] 11, 204); Cushman (Amer. Chem. J. 1900, 24, 222; *ibid.* 1901, 26, 505); Maitland and Abegg (Zeitsch. anorg. Chem. 1906, 49, 341); Stolzenberg and Huth (Zeitsch. physikal. Chem. 1910, 71, 641). Thallium halides form double salts with many other metals (Meyer, *l.c.*; Thomas, *l.c.*; Pratt, Zeitsch. anorg. Chem. 1895, 9, 19; Wells and Foote, Amer. J. Sci. 1897, 3, 466; Ephraim and Heymann, Ber. 1909, 42, 4456; Ephraim and Barteczko, Zeitsch. anorg. Chem. 1909, 61, 238; Gewecke, Annalen, 1909, 366, 217; Delépine, Compt. rend. 1909, 149, 1072).

Thallic sulphide Tl_2S_3 is formed when the metal is fused with excess of sulphur. It is black and above 12° is plastic, but below 12° it is hard and brittle. When sulphuretted hydrogen is passed into a solution of a thallous salt, *thallous sulphide* Tl_2S is formed as a black precipitate, which can be obtained in a crystalline form (Staněk, Zeitsch. anorg. Chem. 1898, 17, 117; *see* also Loczka, Chem. Zentr. 1898, i. 657; Hamley, J. Amer. Chem. Soc. 1907, 29, 1011). According to Pélabon (Compt. rend. 1907, 145, 118) the sulphides Tl_8S_7, Tl_2S_5 also exist (*see* Hofmann and Höchtlen, Ber. 1903, 36, 3090). Double sulphides with copper and tin are also known (Bruner and Zawadski, Bull. Acad. Sci. Cracow, 1909, 312; Hawley, J. Phys. Chem. 1906, 10, 654).

Thallium sulphates and their double salts are described by Stortenbeker (Rec. trav. chim. 1902, 21, 87); Kohn (Zeitsch. anorg. Chem. 1908, 59, 111); Piccini and Fortini (*ibid.* 1902, 31, 451); Locke (Amer. Chem. J. 1902, 27, 280); Meyer and Goldschmidt (Ber. 1903, 36, 238).

Thallium sulphite is a white granular crystalline powder (Scubert and Elten, Zeitsch. anorg. Chem. 1892, 2, 434; *ibid.* 1893, 4, 44).

Thallium nitrates are described by Wells and Beardsley (Amer. Chem. J. 1901, 26, 257); Meyer (*l.c.*); Thomas (Compt. rend. 1904, 138, 1697); van Eyk (Zeitsch. physikal. Chem. 1905, 51, 721).

Thallium mercurous nitrate, m.p. 76°, sp.gr. 5·3°, gives a clear mobile liquid miscible with water and not reacting with sulphides. It forms a useful liquid for the separation of mineral sulphides (Retgers, Jahrb. Min. 1896, ii. 183).

Thallium nitrite forms double salts with cobalt and other metals (Przibylla, Zeitsch. anorg. Chem. 1898, 18, 448; Cunningham and Perkin, Chem. Soc. Trans. 1909, 1569; Tanatar and Petroff, J. Russ. Phys. Chem. Soc. 1910, 42, 94).

Thallium azoimide or *nitride* TlN_3 remains unchanged when heated to 340°, but explodes when heated more strongly or when struck (Curtius and Risson, J. pr. Chem. 1898, [ii.] 58, 261; also Dennis and Doan, J. Amer. Chem. Soc. 1896, 18, 970).

Thallium oxalate $HTl(CO_2)_4 3H_2O$ is prepared by treating the freshly precipitated hydroxide at 25° with a large excess of a cold saturated solution of oxalic acid. When suspended in absolute alcohol, cooled to 0°, and treated with dry ammonia, the compound $Tl(CO_2)_4NH_4(NH_3)_2$ is formed; at a higher temperature the compound $Tl(CO_2)_4NH_4$ separates. The pyridine salt $Tl(CO_2)_4HC_5H_5N$ and the salt $Tl(CO_2)_6(NH_4)_3$, as well as other oxalates $Tl(CO_2)_3(CO_2H)_2,3H_2O$ and $Tl_2(CO_2)_4,3H_2O$ have also been obtained (Rabe and Steinmetz, Ber. 1902, 35, 4447).

Thallous carbonate and *cyanide* are also known.

For a number of other thallium salts, *see* Stavenhagen, J. pr. Chem. 1895, [ii.] 51, 1; Giorgis, Gazz. chim. ital. 1894, 24, ii. 474; Joly, Compt. rend. 1894, 118, 649; Mauro, Real. Accad. Lincei, 1893, ii. 382; Hofmann, Zeitsch. anorg. Chem. 1896, 12, 55; Piccini, *ibid.* 1897, 13, 441; Piccini and Marino, *ibid.* 1901, 27, 62; Marino, *ibid.* 1909, 62, 173; Glauser, *ibid.* 1910, 66, 437; Dennis and Doan, *l.c.*; Wyrouboff, Bull. Franc. Min. 1896, 19, 219; Hawley, J. Amer. Chem. Soc. 1907, 29, 300; Kurowski, Ber. 1910, 43, 1078.

THALLOCHLORE. A name given by Knop and Schnedermann to the green colouring matter of lichens (Annalen, 56, 147).

THAPSIC ACID $C_{16}H_{30}O_4$. Obtained from the dried roots of *Thapsia garganica* (Linn.) (Canzoneri, Gazz. chim. ital. 13, 514; 24, ii. 437); m.p. 123°–124°. The anhydride melts at 71°.

THEBAINE *v.* VEGETO-ALKALOIDS.

THEINE or *Caffeine* *v.* VEGETO-ALKALOIDS.

THENARD'S BLUE. *Cobalt blue* *v.* PIGMENTS.

THENARDITE. A mineral consisting of anhydrous sodium sulphate (Na_2SO_4), crystallised in the orthorhombic system. It is found as large crystals, 6 ins. or more in length, on the shores of salt lakes in arid regions, and sometimes forms beds of considerable extent, together with glauberite, &c. Localities are: Borax Lake in San Bernardino Co., California; on the Rio Verde in Arizona; Rhodes Marsh in Nevada; Tarapaca and elsewhere in Chile; Espartinas near Madrid; and the salt lakes north of the Caspian. L. J. S.

THEOBROMA CACAO *v.* Cocoa.

THEOBROMIC ACID $C_{19}H_{39}COOH$ is obtained from cocoa butter and melts at 72°; it is apparently identical with arachidic acid (*q.v.*).

THEOBROMINE *v.* Vegeto-alkaloids.

THEOBROMOSE, THEOCIN, THEOLACTIN, THEOPHORIN, THEOPHYLLIN, *v.* Synthetic drugs.

THEOPHYLLINE *v.* Vegeto-alkaloids.

THERMIT PROCESS. 'In a thermit reaction a metallic compound (*e.g.* an oxide) is reduced by one or several metals or metallic alloys in such a way that when the mixture is ignited at one place, the reaction continues to go on spontaneously with complete oxidation of the reducing element, a fluid slag being formed, whilst the reduced metal is obtained as a compact uniform regulus; if the oxide is used in excess, the reduced metal is free, or practically free, from the element used as reducing agent' (H. Goldschmidt, Electrochem. and Metall. Ind. 1908, 6, 360).

In 1898 Goldschmidt (Stahl and Eisen, 1898, 18, 408; J. Soc. Chem. Ind. 1898, 17, 543, 584, 649; Zeitsch. für. Elektrochem. 1898, 4, 494; 1899, 6, 53) succeeded in reducing the oxides of chromium, manganese, iron, copper, titanium, boron, tungsten, molybdenum, nickel, cobalt, zirconium, vanadium, columbium, tantalum, cerium, thorium, barium, calcium, sodium, potassium, lead, and tin very conveniently by means of aluminium. Such reduction processes had been anticipated, owing to the fact that measured with respect to the same quantity of oxygen, aluminium has a greater heat of oxidation than almost any other metal. Earlier attempts to carry out such experiments had, however, proved very unsatisfactory; either the reactions would not begin, or they occurred with explosive violence. Goldschmidt overcame the difficulty by mixing the finely-divided oxide intimately with powdered or granulated aluminium, and starting the action at one point by raising its temperature sufficiently high. The reaction being once initiated, the enormous heat developed causes it to spread quickly throughout the entire mass, the time of reaction not varying appreciably with the quantity of material employed, and being about 30 seconds in the case of iron oxide and aluminium. To start the reaction at one spot, Goldschmidt placed a small heap of a mixture of powdered aluminium (or magnesium) and barium peroxide on top of the mixture to act as a fuse, and inserted therein a strip of magnesium ribbon. On lighting the latter, the fuse ignites, and the thermit reaction is started.

Owing to the heat developed in these reactions and the rapidity with which they occur, an enormous temperature is produced, second only to that of the electric arc. It has been estimated at 2600°–3000°, and direct observation with a Féry radiation pyrometer has shown that the temperature of a stream of steel produced from iron oxide and aluminium, as it was poured from the crucible, was 2300° (the melting-point of steel is approximately 1350°). At such temperatures the entire contents of the crucible remain liquid; the reduced metal sinks to the bottom, covered with a layer of molten alumina.

Other metals have been tried for the reduction of metallic oxides. Perkin (Faraday Soc. Trans. 1907, 3, 115, 179), and also Goldschmidt have tried calcium, but the reactions are too violent to be of much use, whilst the slag is difficultly fusible. Silicon (made in the electric furnace) has also been tried; but the reactions are too slow. The so-called mixed-metal, which consists essentially of cerium has, however, been successfully employed in the preparation of pure vanadium, columbium, and tantalum (Muthmann, Weiss, and Riedelbauch, Annalen, 1907, 355, 58; Weiss and Aichel, *ibid.* 1904, 337, 370).

A number of mixtures may be used in place of aluminium, and some have been patented. A mixture of equal parts of *calcium*-thermit and *silicon*-thermit, so that the active elements, calcium and silicon, are in the ratio of 2 to 1, is especially effective (Fr. Pat. 361197, 1905). It reacts like an ordinary aluminium-thermit, yielding a thin fluid slag having approximately the composition $4CaO{\cdot}3SiO_2$, and melting at 1425° (Boudouard, Iron and Steel, 1905, 352). The active mixture may be prepared either by mixing or alloying calcium with silicon (*v.* Fr. Pat. 388638, 1908). A mixture of *magnesium* and *silicon* may also be used to replace aluminium, giving a reaction like ordinary thermit (Eng. Pat. 3089, 1906; Fr. Pat. 364313, 1906; U.S. Pat. 902871, 1908), whilst magnesium itself acts similarly to calcium in its reactions with metallic oxides. *Magnesium-silicon* thermit is best mixed in proportions which yield a slag of the composition $7MgO{\cdot}4SiO_2$. A third mixture, viz. *aluminium*-thermit and *calcium*-thermit, gives very good results. The proportions may vary between wide limits, avoiding too large an excess of calcium, and the calcium aluminate slag is more fusible than alumina. A mixture containing 40 p.c. calcium-thermit produces a very fluid slag $3CaO{\cdot}2Al_2O_3$, and has a heat effect greater than that of aluminium-thermit (Fr. Pat. 361197, 1905; addn. Jan. 1906; U.S.A. Pats. 875345, 1907; 875666, 1907; 906009, 1908; Eng. Pat. 926, 1906). *See* also Watts and Breckenridge, Electrochem. & Metall. Ind. 1908, 6, 237; Weston and Ellis, Faraday Soc. Trans. 1907, 3, 170; 1908, 4, 60, 130; 1910, 6, 144; and Skinder, Chem. Zentr. 1909, i. 629.

Technical applications. Although the thermit reaction (Goldschmidt's reaction) only dates from 1898, it has acquired great technological importance, and the subject of 'aluminothermics' has been extensively developed.

Preparation of metals and alloys. The following are obtained by reducing the requisite metallic oxides (or mixtures of oxides) with a slight deficit of aluminium; chromium, manganese, molybdenum, ferro-titanium, ferro-vanadium, ferro-boron, manganese-copper, manganese zinc, manganese-tin, manganese-titanium, chromium-manganese. They are of great value in the iron and steel and other metallurgical industries; chromium, in particular, is largely employed in the manufacture of high-speed tool steel and armour plate. The metals and alloys produced are *carbon-free.* The crucibles in which the preparations are carried out must be lined with magnesia (Eng. Pat. 9610, 1905; Fr. Pat. 354597, 1905), one of the few oxides that aluminium is unable to reduce. The best method of procedure to ensure a maximum yield of chromium or manganese consists in mixing 1–4 p.c. of higher oxide with the bulk of lower oxide to be reduced to metal (Eng. Pat. 20004, 1905; Fr. Pat. 358071, 1905; U.S. Pat. 895628, 1908).

For experimental purposes, steel of any grade can be made by the thermit process, since the heat developed is sufficient to melt thoroughly small portions of even the most refractory metals. The thermit steel is free from carbon, but may be converted into high carbon steel by the addition of cast-iron shot.

The *slag* produced is also of commercial value. It may be employed in the preparation of aluminium, or used in place of natural corundum. It is especially valuable for use in the manufacture of pottery, for which purpose it is mixed with clay and burned (D. R. P. 160780, 1901). *Corubin*, an abrasive material for making emery wheels, emery cloth, &c., is prepared by crushing the slag obtained as by-product in the manufacture of chromium.

Welding iron and steel, and repairing broken steel castings. The advantages of the thermit process for these applications are that it is simple, rapid, requires no special skill, and enables repairs to be made *in situ*, when any other process would necessitate a dismantling of apparatus.

The mixture employed is composed of powdered aluminium and magnetic iron oxide, and when ignited yields half its weight of molten steel. Its registered trade name is 'thermit.' The reaction

$$8Al+3Fe_3O_4=4Al_2O_3+9Fe$$

indicates that approximately 3 parts of aluminium powder require 10 parts of magnetic oxide, and produce 7 parts of iron. Early literature on the subject gives the reaction as

$$2Al+Fe_2O_3=Al_2O_3+2Fe,$$

but examination of thermit with a magnet will show that the magnetic oxide is now employed. It is added in the form of granulated rolling-mill scale.

The firing of a charge of thermit produces a pure mild steel of the following average composition—

Carbon	0·05–0·10
Manganese . . .	0·08–0·10
Silicon	0·09–0·20
Sulphur	0·03–0·04
Phosphorus . . .	0·04–0·05
Aluminium . . .	0·07–0·18

Two methods of welding are in use, (*a*) the reaction serving merely as a source of heat (Eng. Pat. 18328, 1899), and (*b*) the steel produced by the reaction being utilised as well (Eng. Pat. 10859, 1901; 20894, 1900; U.S. Pat. 729573, 1903). In process (*a*) pure materials need not be used, and, if necessary, the thermit may be diluted with a cheap oxide, *e.g.* iron ore or sand, to lower the final temperature reached. This process is used in the butt-welding of pipes and bars. The ends are cut square, smoothed, and clamped together. A mould is then clamped round the junction. A charge of thermit is fired in an ordinary magnesia-lined crucible, allowed to stand half a minute so that slag and steel may separate (the volume of the molten slag is three times that of the iron produced), and then poured out so that the slag comes first. As the slag is poured in the mould on to the pipe, it forms a hard casing around the metal, and the liquid which follows distributes its heat uniformly through this casing to the metal. In about a minute the pipes have been raised to welding heat. The ends are then pressed tightly together by means of screws arranged in position beforehand. The mould is then removed, the slag collar carefully knocked off, and the red-hot joint allowed to cool. Process (*b*) has been largely employed in welding together tram and railway line sections. The ends are brought together and clamped accurately in position. A refractory clay mould is clamped round the ends and the requisite charge of thermit fired in a crucible placed over the pouring gate of the mould. At the end of the reaction, the crucible is tapped from the *bottom* (*see* Fig. 1), and the liquid steel flows into the mould, passes upwards from the bottom of the mould, surrounds the base and web of the rail, with which it fuses on account of its enormously high temperature, and on cooling makes a solid steel joint.

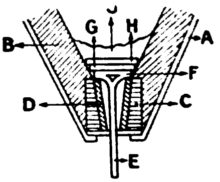


Fig. 1.—Tap-hole of Thermit Crucible.

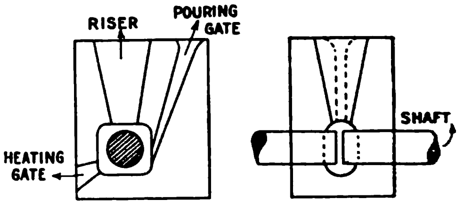
A, iron casing; B, magnesia lining; C, hollow cylindrical magnesia stone; D, conical magnesia thimble; E, iron tapping pin, with flattened end F; G, asbestos washer; H, iron washer; J, layer of sand.

The welding of rails is a typical instance of the application of process (*b*) above, which is also employed for all kinds of repairing work, *e.g.* mending broken engine frames, driving rods and spokes, crank shafts, rudder and propeller shafts, stern-posts, &c., in fact, in the majority of cases where it is cheaper to repair than to replace. Where necessary, the fracture is opened out by drilling holes. A wax matrix is then built up over the break of the exact shape that the thermit steel collar to be fused into the casting is to have. Over this, in a sheet iron box, is constructed a mould, having a pouring gate, a preheating gate, and a large riser (Fig. 2). A gasoline torch, fed with compressed air, is then directed through the preheating gate. It melts out the wax, dries the mould, and heats the junction to be repaired to a bright red heat. Meanwhile, the crucible containing the thermit is arranged over the pouring gate. The quantity



Sectional views through mould

Fig. 2.

of thermit required is given by the rule: take 32 times the weight of the wax used, or 18 times as many ounces of thermit powder as there are cubic inches of surplus space in the mould. The crucible (Fig. 1) is designed so as to be tapped from the bottom (Goldschmidt, Zeitsch. Elektrochem. 1901, 7, 935; Cohn, J. Gasbeleucht. 1901, 44). The gasoline torch is withdrawn when the junction is red hot, the preheating gate plugged with a sand core held in readiness, and the thermit fired without delay. After the reaction is over, and the molten liquid has stood 30 seconds to allow the slag to rise, the crucible is tapped. The molten steel passes down the pouring gate, around the fractured joint, and up into the riser. The ends of the casting melt into the liquid steel, and on cooling, one homogeneous mass is formed. The projecting collar of thermit steel around the joint is left on whenever possible.

The average tensile strength of a thermit steel joint is about 30 tons per square inch cross-section. If the projecting collar of thermit steel has to be planed off, and the tenstile strength of the joint is less than that of the body of the casting, the weld may be made stronger by introducing *nickel* into the composition of the thermit; 1 p.c. of nickel increases the tensile strength of the weld about one-third. For a 1 p.c. alloy, 2 p.c. of nickel thermit may be added to the usual steel thermit, or 5 oz. of metallic nickel may be added to each 100 lbs. of thermit.

Thermit powder is supplied in 50 or 100 lbs. drums. For use in repair work, about 2 p.c. of manganese and 5 p.c. of mild steel punchings are added. The former acts as a purifier of the steel produced; the latter serves to lower the final temperature of the reaction and so prevent the contents of the crucible from boiling over.

Use of thermit in foundry practice. (*a*) The thermit reaction provides a ready means of introducing in an iron ladle a material which will stir up or pole the entire contents of the ladle, and at the same time produce an increase of temperature. For this purpose, the thermit is contained in cylindrical cans with a sleeve in the middle, suitable for passing on an iron rod. The can is held by the iron rod under the surface of the metal, where the reaction takes place. This procedure prevents the iron from becoming too dull to pour (U.S. Pat. 733957, 1903).

(*b*) A convenient means of purifying the iron in the ladle, by reducing the presence of harmful nitrogen in the molten metal, consists in holding a can of *titanium-thermit* under the surface as described in (*a*). This thermit is a mixture of pulverised aluminium and a titanium-iron oxide. The titanium set free in the reaction is sufficient to combine with the nitrogen in the ladle, titanium cyanonitride being produced. During this formation, the entire contents of the ladle are stirred up, to give the gases an opportunity of escaping. The iron is thereby rendered hotter and distinctly more fluid, and castings made from it are distinguished by their closeness of grain, being especially well adapted for withstanding pressure, *e.g.* cylinders, valves, &c.

(*c*) The enormous heat developed may be utilised to decrease the size of the risers of steel castings. The thermit, contained in suitable cans, is held in the neck of the riser, which is thus kept in the liquid state for a longer time than would otherwise be the case, thereby facilitating the proper feeding of the casting. The same principle is successfully applied to reduce the size of lost heads of steel ingots.

(*d*) In foundries where it is of importance to occasionally make a steel casting in a hurry, burning down the requisite quantity of thermit with an admixture of steel punchings affords by far the easiest method of procedure.

THERMOFUGIN, THERMODIN, *v.* SYNTHETIC DRUGS.

THERMOMETERS. Changes of temperature are measured by the corresponding alterations produced in one or other of the physical properties of a substance. Thus the expansion of solids, liquids, and gases, the vapour pressures of liquids, the electrical resistance of metals, and other properties have been utilised for the determination of temperature.

In nearly every case the amount of change produced by a given rise or fall of temperature depends on the nature of the substance, and must therefore be carefully determined beforehand for the particular material employed.

There is, indeed, only one known method of measuring temperature which is theoretically perfect, that is to say, which is entirely independent of the nature of the substance; this method, proposed by Lord Kelvin, depends on the ratio of the work done by a reversible heat engine to the heat supplied to it, and the temperature, reckoned from absolute zero, may be defined as the reciprocal of Carnot's function. The method is not one, however, that is capable of practical application.

It has been found that within certain limits of temperature and pressure the expansion of all gases is very nearly the same for equal changes of temperature. Hence it is possible to devise a method of measuring temperature which, while practically independent of the nature of the (gaseous) substance employed, is at the same time fairly convenient for many purposes. It is important also to remark that the values given by an air or gas thermometer are in very close agreement with Lord Kelvin's thermo-dynamical temperatures.

The relation of the volume of a gas to its temperature and pressure may be stated simply as follows: The volume of a gas varies inversely as the pressure and directly as the absolute temperature, or $pv=c\text{T}$, where p is the pressure, v the volume, T the absolute temperature, and c a constant depending on the units chosen. If the volume remains constant the pressure varies directly as the absolute temperature, or $p=c'\text{T}$, while if the pressure is kept constant the volume varies directly as the absolute temperature, or $v=c''\text{T}$.

It is true that the co-efficients of expansion of different gases are not absolutely identical, and that the law holds good only within certain limits of temperature and pressure; but under pressures not greatly exceeding that of the atmosphere the deviations are extremely small in the case of nitrogen, hydrogen, helium, and some other gases, except at very low temperatures. Very accurate investigations of the properties of gases at extremely low temperatures have been carried out by Kamerlingh Onnes and his collaborators at Leiden, and their results show that the constant volume hydrogen thermometer gives nearly accurate results down to −250° and the helium thermometer to still lower temperatures.

An 'air' thermometer may be so constructed that (1) the pressure remains constant and the alteration of volume is measured; (2) the volume remains constant and the change of pressure is observed; (3) both pressure and volume are allowed to alter, and both are measured. The air or other gas is contained in a bulb of glass, or for very high temperatures of some other material, connected by means of a capillary tube with a mercury or sulphuric acid manometer. The bulb is heated to the required temperature while the other parts of the apparatus remain at the temperature of the room. If the pressure be kept constant the gas will expand, and at high temperatures a considerable portion of it will pass into the cold part of the apparatus and must be measured at the ordinary temperature; it is therefore usually considered better to raise the pressure so as to keep the volume of gas as nearly constant as possible. The vessel containing the gas expands, however, when the temperature rises, and a correction on account of this expansion must be introduced.

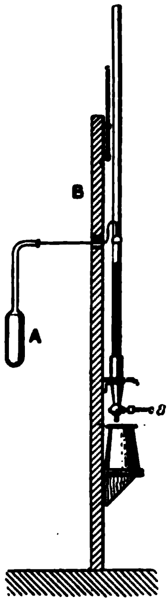

FIG. 1.

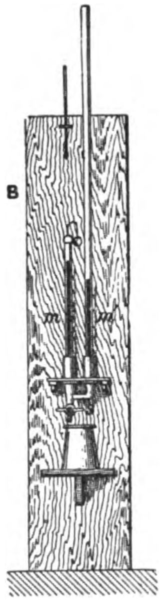

FIG. 2.

There are also three sources of error which are difficult to estimate, but they may be almost entirely eliminated by taking suitable precautions. The first depends on the fact that at ordinary temperatures air condenses to a slight extent as a sort of film on the surface of glass, while at high temperatures this condensed air is converted into gas, so that the apparent expansion is a little greater than the real. If, however, the bulb, after thorough exhaustion at a high temperature, is filled with air from which all moisture and carbon dioxide have been removed, the error becomes practically negligible (Callendar, Phil. Trans. 178A, 161).

The second is due to slight changes of volume which a glass vessel is liable to undergo after being strongly heated and allowed to cool again. The magnitude of the possible error becomes extremely small, however, if the bulb is heated for some hours to at least the highest temperature which is to be registered, before its volume is determined. This point will be more fully discussed when dealing with mercurial thermometers. The third source of error is due to the deformation of the bulb or to leakage of gas through it when the temperature and the internal gaseous pressure are greatly raised. This difficulty has been overcome by Day and Clement (Amer. J. Sci. 26, 1908), who employed a platinum-iridium bulb containing nitrogen, by surrounding the bulb with nitrogen at the same pressure as that within the bulb.

Of the numerous forms of air thermometer which have been devised, the three shown in the diagrams may serve as examples. The first (Fig. 1) represents a form of instrument employed by Regnault in his classical researches. The bulb A of the thermometer is connected by a capillary tube (passing through a perforation in the screen B) with the mercury manometer *mm'*, a front view of which is shown in Fig. 2. By addition of mercury to the open limb *m'*, or by its removal by means of the stopcock *s*, the mercury in the limb of the manometer connected with the air thermometer may be always kept at the same height, so that there is no alteration of the volume of air except that due to the expansion of the bulb when heated.

The calculation of the temperature is based on the fact that the mass of air remains constant, although its temperature, its pressure, and, to a small extent, its volume undergo change. Let

V=volume of bulb A at 0°;

v=volume of capillary tube, together with the small portion of the manometer above the mercury in m, also at 0°;

α=coefficient of increase of pressure of dry air at constant volume;

κ=coefficient of expansion of glass;

D=mass of 1 c.c. of air at 0° and 76 cms. pressure;

P=observed pressure—that is to say, the barometric pressure, *plus* or *minus* the difference of level of the mercury in m and m'.

When the bulb is placed in melting ice, while the capillary tube and manometer are at the temperature t° of the room, the total mass of air will be

$$D.P.\left\{V+\frac{v(1+\kappa t)}{1+\alpha t}\right\}$$

When the bulb is heated to the unknown temperature x, the temperature of the capillary tube and manometer being now t', the mass of air will be

$$D.P.'\left\{\frac{V(1+\kappa x)}{1+\alpha x}+\frac{v(1+\kappa t')}{1+\alpha t'}\right\}$$

Therefore

$$P\left\{V+\frac{v(1+\kappa t)}{1+\alpha t}\right\}=P'\left\{\frac{V(1+\kappa x)}{1+\alpha x}+\frac{v(1+\kappa t')}{1+\alpha t'}\right\}$$

an equation in which everything is known but x.

Values of α for several gases for the temperature range 0° to 100° are given below, p_0 being the initial pressure (at 0°).

	p_0	a
Hydrogen	760 mm.	0·0036627
Helium	700 „	0·0036626
Nitrogen	760 „	0·0036714
Oxygen	663 „	0·003674

If the volume of air be allowed to vary, the limb *m* of the manometer must be graduated, and should be surrounded by cold water of known temperature. In this case the additional volume *v′* at the temperature of the water must be brought into the equation.

Sulphuric acid may be employed with advantage in place of mercury, since it moves more freely in a narrow tube, and, being lighter, allows of more delicate readings; or a small sulphuric acid gauge may be interposed between the thermometer and the mercury manometer. An apparatus which can be employed either as a constant volume or constant pressure manometer has been described by Callendar (*l.c.*) and more fully by Callendar and Griffiths (Phil. Trans. 182A, 119). It is represented in Fig. 3.

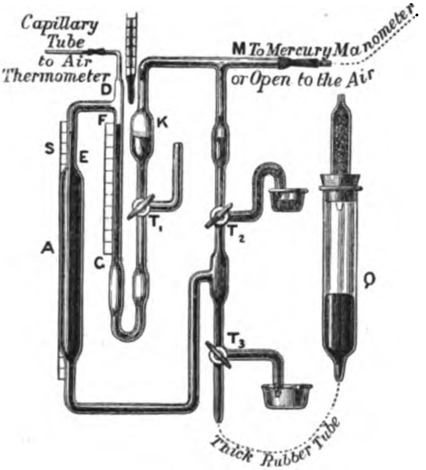

FIG. 3.

When the measurement is to be made at constant volume the mercury in A is brought up to the zero point, and the stopcocks T_2 and T_3 are closed. The level of the sulphuric acid in the gauge is then regulated by means of an ordinary mercury manometer, not shown in the diagram, and the pressure is the algebraical sum of the barometric pressure, that registered by the mercury manometer, and the slight difference in level, if any, of the sulphuric acid in the two limbs of the gauge FK, divided by the specific gravity of mercury compared with that of sulphuric acid.

If the pressure is to be kept constant, the tube A is first filled from the reservoir Q until the level of the mercury stands at some point in the tube DE, recorded by the scale S, the pressure of the air in the bulb being equal to that of the atmosphere, as shown by the sulphuric acid gauge. (In this case the tube M is not connected with the mercury manometer, but is open to the air.) When the bulb is heated, mercury is allowed to escape by the three-way tap T_2 into the weighed beaker, the tap being closed as soon as the sulphuric acid gauge indicates that the pressure is again equal to that of the atmosphere. The increased volume is calculated from the weight of mercury expelled. The narrow tubes DE and FG are calibrated and provided with scales. For the advantages of the sulphuric acid gauge see also Bottomley (Phil. Mag. 1888 (Aug.), 149).

Callendar has (Nature, 1891, 45, 212) described a modified constant-pressure air thermometer which appears to possess marked advantages over those previously devised, and gives extremely accurate results. The pressure of the air in the thermometer is not adjusted to equality with that of the atmosphere, but always with the same constant pressure, obtained by connecting the outer limb of the sulphuric acid gauge to a glass bulb filled with air and kept in melting ice.

The effect of changes of temperature of the connecting tubes on the readings is entirely eliminated by the employment of compensating tubes of the same size, and thus the troublesome and somewhat uncertain correction hitherto necessary is obviated. The compensation is perfect when (1) the two sets of connecting tubes are of equal volume and at the same mean temperature; (2) the mass of air inclosed in the standard pressure-bulb is equal to that in the thermometric and mercury bulbs; (3) the pressures are adjusted to equality. Under these conditions, the temperature of the thermometer bulb (on the air-thermometer scale) is given by the simple equation $\theta_1 = V_1\theta_0/(V_0 - Vm)$, where V_1 is the volume of air in the thermometer bulb at θ_1°, V_0 and Vm are the volumes of air at 0° in the standard pressure bulb and the mercury reservoir (this being also surrounded by melting ice), and θ_0 is the temperature of melting ice on the air-thermometer scale.

For moderate ranges of temperature, and when extreme accuracy is not required, the apparatus may be greatly simplified, and may be so constructed that the temperatures are read directly on the sulphuric acid gauge; it is stated that such thermometers can be made to read to the tenth of a degree at 450°. This form of direct reading thermometer has been patented and is recommended for technical purposes.

Other forms of air thermometer have been described by Balfour Stewart, Phil. Trans. 153, 425; Codazza, Dingl. poly. J. 210, 255; Jolly, Pogg. Jubelband, p. 82; Mitscherlich, Annalen, 12, 146; Crafts, Ann. Chim. Phys. [v.] 14, 409; Andrews, Ber. 14, 2116; Pettersson, J. pr. Chem. [ii.] 25, 102; Cailletet, Compt. rend. 106, 1055; Berthelot, Ann. Chim. Phys. [iv.] 13, 144; Murray, J. Phys. Chem. 1897, 1, 714. A platinum bulb was recommended by Pouillet (Compt. rend. 3, 782), but it was pointed out by Becquerel (Ann. Chim. Phys. 58, 49) that at high temperatures air passes through the platinum. A porcelain bulb was employed by Weinhold (Pogg. Ann. 149, 188), by Deville and Troost (Ann. Chim. Phys. [iii.] 58, 265), and others. According to Holborn and Day (Wied. Ann. 68, 817; Amer. J. Sci. 8, 165; 10, 171), however, porcelain does not give satisfactory results at high temperatures. They recommend bulbs of Jena boro-silicate glass, No. 59^{III}, containing hydrogen for temperatures up to 500°, and bulbs of a platinum-iridium alloy (10 p.c. Ir) with pure nitrogen gas from 500° to 1300°. The

Pt-Ir bulbs should be heated electrically or else protected from gaseous combustion products, which are liable to pass through the alloy. Day and Sosman (Amer. J. Sci. 1910, 29) have measured temperatures up to 1550°. Harker proposes to make bulbs of rare earths such as those used for Nernst filaments.

For very low temperatures, the glass bulbs should contain hydrogen or helium. A very complete account of the hydrogen thermometer in use at the cryogenic laboratory at Leiden is given by Kammerlingh Onnes and Clay (Communication No. 95*e*).

As regards the theory of the subject and the comparison of the temperatures registered by different gas thermometers with each other and with the thermodynamical scale, reference may be made to the following memoirs and papers: D. Berthelot, Sur les thermomètres à gaz, Paris, 1903; Ann. d. poids et mesures, 1907, 13*b*, 3; Chappuis, Phil. Mag. 50, 433, 1900; 3, 243, 1902; Phil. Trans. 1900, 194, 37, 131,; J. Phys. 1904, 3, 833; Ann. d. poids et mes. 1907 13*a*, 3; Kammerlingh Onnes, Comm. 97*a* and *b*, 102*b* and *d*; Holborn, Ann. Physik. 1901, [vi.] 2, 242; Buckingham, Bureau of Standards, 1907, 3, 237; Phil. Mag. 1908, 15, 526; Rose-Innes, *ibid.* 1908, 14, 301.

Air thermometers for technical purposes are generally provided with scales which are calibrated empirically by heating the bulbs to two or three known temperatures, so as to obtain a certain number of fixed points. The scales are then constructed by interpolation.

Thermometers of this class have been described by P. Schoop, D. R. P. 20345, 1882; Witz, Compt. rend. 91, 164; Beilby, J. Soc. Chem. Ind. 1885, 41; Coleman, *ibid.* 1885, 43; Heisch and Folkard, and by Bristol (Mech. Eng. 1900, 6, 916). They consist of a porcelain bulb, a copper capillary, and a pressure gauge constructed with two spiral tubes on the Bourdon principle. They can be constructed as recording instruments. The thermometer of Heisch and Folkard is very simple, and has been found by Hurter (J. Soc. Chem. Ind. 1886, 635) to give good results. The bulb A (Fig. 4) contains air under reduced pressure, and there is a vacuum over the mercury in the manometer M.

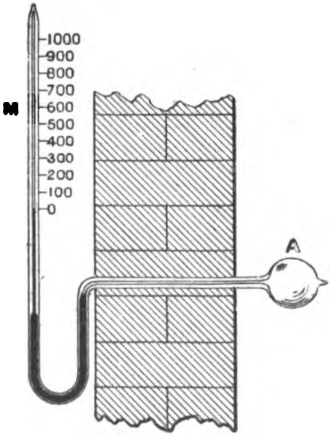

FIG. 4.

The mercurial thermometer. For ordinary purposes the mercurial thermometer is the most convenient, for it may be made of any required size, is easily portable, and the bulb, if elongated, need not be wider or, indeed, so wide as the stem. The instrument consists of a spherical or cylindrical bulb fused to a capillary tube of suitable length. The bulb is filled with pure mercury, which must be boiled for some time to remove the film of gas or aqueous vapour which adheres obstinately to the surface of the glass. If the thermometer is required for low temperatures only, there is usually a vacuum in the stem of the thermometer, but for high temperatures it is necessary, and for temperatures above 70° or 80° advisable, to fill the capillary tube with nitrogen to prevent distillation of the mercury, a small bulb being blown at the upper end of the tube in order that when the mercury expands and compresses the nitrogen the pressure shall not rise too high.

An ordinary thermometer is graduated by placing it *first* in the steam from water boiling under known pressure and then in melting ice (*v.* Guillaume, Traité pratique de la Thermomètrie de Précision, p. 112). The variation of the melting-point of ice with the pressure is so minute that this point may be taken as absolutely fixed, but the boiling-point of water varies considerably with the pressure, and therefore some standard pressure must be chosen. This is 760 mm. or 29·922 ins. of mercury measured at 0°C. and at the latitude of Paris for the Centigrade scale, and 29·905 ins. of mercury at 32°F. at the latitude of London for the Fahrenheit scale.

The position of the mercury in the stem is marked off a these two temperatures, and the space between these two fixed points is then usually divided into a certain number of equal parts—100 on the Centigrade scale, 180 on the Fahrenheit, and 80 on the Réaumur. On the Centigrade and Réaumur scales, the melting-point of ice is taken as the zero point, but on the Fahrenheit the zero of the scale is placed 32 divisions lower down, so that the melting-point of ice is 32°, and the boiling-point of water 212°.

A thermometer graduated in this manner does not, however, register true temperatures except at the two fixed points, for the following reasons:—1. It is impossible to obtain an absolutely cylindrical capillary tube, so that the volume corresponding to a scale division is not quite the same in all parts of the tube. Various methods have been devised for calibrating the stem (*v.* Brit. Assoc. Report, 1882, 145–204, also Guillaume, *l.c.* 43–99), but when this is done there remain other sources of error. 2. The position of the mercury in the stem at any temperature depends on the expansion both of the mercury and of the glass, and in each case the rate of expansion increases with rise of temperature. Moreover, different kinds of glass have different rates of expansion, so that two thermometers made of different materials—even if the capillary tubes were perfectly cylindrical—would give different readings at the same temperature. The only really satisfactory method of correction of such a thermometer is to compare its readings either directly with an air thermometer, or with another mercurial thermometer which has previously been standardised by means of an air thermometer. Or a series of fixed points may be determined by immersing the thermometer in a number of freezing liquids (melting solids) or by heating it with the vapours of a series of pure liquids boiling under known pressures. The following table contains a list of suitable substances with their melting-points, transition-points, or boiling-points, and the variation of pressure corresponding to 1° at the boiling-points, temperatures outside the range of the mercurial thermometer being included for convenience :—

Temperature	Fixed point
—183·0°	b.p. of oxygen ; $dp/dt=75{\cdot}9$ mm. per degree.
—158·0	m.p. of *iso*pentane.
—116·8	m.p. of ethyl ether.
—94·5	m.p. of toluene.
—63·3	m.p. of chloroform.
—38·7	m.p. of mercury.
—22·9	m.p. of carbon tetrachloride.
0	m.p. of ice.
32·38	tr.p. of sodium sulphate.
46·2	b.p. of carbon disulphide ; $dp/dt=24{\cdot}8$.
50·67	tr.p. of sodium bromide.
78·3	b.p. of ethyl alcohol ; $dp/dt=30{\cdot}5$.
100·0	b.p. of water ; $dp/dt=27{\cdot}1$.
132·0	b.p. of chlorobenzene ; $dp/dt=20{\cdot}2$.
156·2	b.p. of bromobenzene ; $dp/dt=19{\cdot}4$.
184·1	b.p. of aniline ; $dp/dt=19{\cdot}6$.
218·0	b.p. of naphthalene ; $dp/dt=17{\cdot}2$.
231·9	m.p. of tin.
305·8	b.p. of benzophenone ; $dp/dt=15{\cdot}8$.
321·0	m p. of cadmium.
356·7	b.p. of mercury ; $dp/dt=13{\cdot}3$.
419·3	m.p. of zinc.
444·5	b.p. of sulphur ; $dp/dt=11{\cdot}1$.
630·7	m.p. of antimony.
756·0	b.p. of cadmium ; $dp/dt=8{\cdot}1$ (calculated).
916·0	b.p. of zinc ; $dp/dt=7{\cdot}0$ (calculated).
960·9	m.p. of silver.
1083	m.p. of copper.
1452±2	m.p. of nickel.
1549±2	m.p. of palladium.
1755±5	m.p. of platinum.
2910	m.p. (approx.) of tantalum.
3080	m.p. (approx.) of tungsten.

For additional fixed points between 0° and —160°, *v.* Timmermans, Sci. Proc. Roy. Dubl. Soc. 1912.

In this way a table or curve of corrections may be constructed showing the error at any scale reading of the thermometer. 'Normal' thermometers may now be purchased ; they are compared with a standard thermometer before graduation, and nearly true temperatures are registered by them ; or the thermometers may be sent to the National Physical Laboratory, the Reichsanstalt, or the Bureau of Standards, and the necessary table of corrections obtained.

Tables of correction of readings of mercurial thermometers to true air-thermometer temperatures have been published by various observers ; but as these tables must necessarily vary for different kinds of glass—the further correction for unevenness of bore being also required—they do not seem to possess much *general* value. It may be useful, however, to give references :—Rudberg, Annalen, 36, 121 ; Bosscha, Compt. rend. 69, 875, 1185 ; Regnault, *ibid.* 69, 879, and Mémoires, 21, 239 ; Crafts, *ibid.* 95, 836 ; Recknagel, Pogg. Ann. 123 ; Guillaume, Traité pratique de la Thermométrie de Précision.

Even when the above corrections to true air-thermometer temperatures have been made, there remain some sources of error, the most important of which is the alteration of the capacity of the bulb, and doubtless also of the capillary tube after long-continued heating, and, indeed, after any considerable change of temperature. A vast amount of experimental work has been done on this subject, and the explanation of the observed changes has given rise to a great deal of discussion. The following references may be made to the literature of the subject :—Despretz, Compt. rend. 4, 926 ; Person, *ibid.* 19, 1314 ; Legrand, *ibid.* 4, 173 ; Crafts, *ibid.* 91, 291, 370, 413 ; 94, 1298 ; Pernet, *ibid.* 91, 471 ; E. J. Mills, T. Ed. 29, Part 2, 587, and Nature, 41, 100, 227, 538 ; Young, *ibid.* 41, 152, 271, 488 ; Tomlinson, *ibid.* 41, 198 ; Pernet, Travaux et Mém. du Bureau Int. des Poids et Mesures, i., B. 52, and I., 17 ; Guillaume, Traité pratique ; Marchis, Zeitsch. physikal. Chem. 1899, 29, 1 ; 1901, 37, 553, 605. The most important facts regarding the alteration of zero point may be shortly described as follows :—

1. If a thermometer be graduated shortly after the bulb has been blown, the zero point will rise with comparative rapidity at first, then more and more slowly, and the elevation of the zero point may go on for many years. Joule (Scientific Papers, i. 558) took observations with one thermometer over a course of thirty-eight years, and the change, which then amounted to almost exactly 1°F., was still proceeding.

2. If a thermometer be maintained at a high temperature for a considerable time, the rise of the zero point takes place with much greater rapidity, and so far as is known the higher the temperature the more rapid is the rise, and *apparently* the higher is the final point reached. A total elevation of over 20° in the case of German soda glass has in several cases been observed, while larger glass bulbs, after continuous heating to 445°, or in one case 511°, have been found by Regnault, Crafts, and Callendar and Griffiths to suffer a contraction of from 0·25 to 0·34 per cent. In all cases the rise or contraction, which is rapid at first, becomes slower and slower, and it seems doubtful whether at any given temperature actual constancy of zero point or capacity has ever yet been attained. If, however, a thermometer has been heated for many hours to a given high temperature and then allowed to cool very slowly, subsequent heating to lower temperatures has very little effect on the zero point, and it is advisable to subject a thermometer to this process before determining the fixed points. According to Marchis (*l.c.*), a fluctuating high temperature is more effective than a steady one in raising the zero point. Hecker (Zeitsch. f. Instrumentenkunde, Beib. 1901, 5, 41) describes a method of electrical heating and slow cooling. Böttcher (*ibid.* Beib. 1903, 17, 154) states that the thermometer bulb

should be heated for a short time to a temperature 100° above the initial softening temperature of the glass, and that slow cooling is unnecessary. The question is discussed by Dickinson (Bureau of Standards, 1906, 2, 189) and methods of treatment are recommended.

3. Not only is the zero point liable to change, but the interval between the zero and 100° points may at the same time be increased, for the coefficient of expansion of glass suffers diminution after prolonged heating.

4. Internal or external gaseous pressure on the bulb appears to have little or no influence on the rise of zero point.

5. If a thermometer—even after its zero point has been rendered as permanent as possible—be heated and then cooled very rapidly, a fall of the zero point will be observed, but after a day or two the greater part of this fall will be recovered, and the remainder after a longer period. The alteration of the zero point depends greatly on the nature of the glass, and a special hard glass is used by Tonnelot of Paris, while Schott and Co. in Germany employ two kinds of glass, 'normal thermometer' glass, 16^{III}, and a boro-silicate glass, 59^{III}, for the best thermometers. The latter glass is now generally used; it has a very high melting-point and can be used up to 550°, the mercury being prevented from boiling by the introduction of carbon dioxide under pressure (*cf.* Murrie, J. Soc. Chem. Ind. 1885, 45, 189, 655).

Other possible sources of error are the following:—If the mercury in the stem of the thermometer—or a portion of it—is not heated to the same temperature as that in the bulb, a correction is required, *v.* DISTILLATION. In order to ascertain the mean temperature of the unheated column, Guillaume (Compt. rend. 1891, 112, 87) places a supplementary thermometer without a bulb at the side of the thermometer stem. Modifications of this method have been proposed by Mahlke, Zeitsch. Instr. 1893, 13, 58; 1894, 14, 73; and by Adam, *ibid.* 1907, 27, 101.

The bulb is slightly compressible, and considerable changes of external pressure affect the readings to some extent.

Mercury does not move very freely in a capillary tube, and in delicate thermometers, when the temperature changes, the movement of the mercury may take place in jerks instead of smoothly. This may be avoided by tapping the thermometer (Pickering, Phil. Mag. 1886, 21). Greater freedom of motion is attained (Duclaux and Hamelin, J. Phys. 1910, 9, 600) by placing dilute sulphuric acid over the mercury, and electro-capillary effects are prevented by means of a recess full of mercury at the upper end of the capillary, the mercury in recess and bulb being connected by a platinum wire. The increase in sensitiveness was found to be so great that variations in the melting-point of ice with moderate change of pressure were readily observed.

For temperatures below the freezing-point of mercury, −38·7°, various liquids have been suggested to take the place of that metal. Alcohol and toluene thermometers have been in use for many years, and more recently, pentane has been found specially suitable for very low temperatures (Kohlrausch, Wied. Ann. 1897, 60, 463; Baudin, Compt. rend. 1901, 133, 1207; Rothe, Zeitsch. Instr. 1902, 22, 192; Hoffmann and Rothe, *ibid.* 1907, 27, 265). Baudin and Rothe recommend 'technical' in preference to pure pentane on account of its lower freezing-point. The b.p. is 25° to 33°, and the pentane thermometer can be used between 30° and −190°.

The molecular weight of a dissolved substance is very frequently calculated from the depression of the freezing-point or the rise of the boiling-point of a solvent. Thermometers of small range but great sensitiveness have been devised for these determinations by Beckmann, and a full description of various forms of the instrument is given by him (Zeitsch. Chem. 1905, 51, 329). The bulb is of large size and the same thermometer can be used for different temperature ranges by transferring part of the mercury from the bulb to a receptacle at the other end of the capillary. The value of a scale division is thereby slightly altered, and the necessary corrections are discussed and a table is given by Grützmacher (Zeitsch. Instr. 1896, 16, 171, 200).

Useful general information about mercurial thermometers is contained in the following papers: Chree (Phil. Mag. 1898, 45, 205, 299; Kohlrausch (Zeitsch. Instr. 1898, 18, 76); Scheel, *ibid.* Beib. 1899, 9–13).

Platinum resistance thermometers. The measurement of temperature by the alteration of the resistance to electricity of a platinum wire was suggested by Siemens (Bakerian Lecture, Proc. Roy. Soc. 1871), but in consequence of an adverse report to the British Association in 1874 this method was abandoned. Subsequently, however, the subject was investigated by Callendar, Phil. Trans. 1887, 178 A, 161; Phil. Mag. 1891, 32, 104; 1899, 47, 191; Griffiths, Phil. Trans. 182 A, 43, and both authors, *ibid.* 182 A, 119, with very satisfactory results. In order to insure accuracy the platinum wire must be pure in the first place; it must be prevented from alloying with silicon, carbon, tin, or other impurities, and it must not be subjected to strain—such as elongation. When these conditions were fulfilled, the resistance of a wire was always found to be constant at a given temperature. The form of thermometer recommended by Callendar and Griffiths is shown in Fig. 5. Two platinum wires are inter-wound in a double-screw thread, passing through holes in a thin mica plate AB. Each spiral is provided with a double and single electrode, symmetrically arranged. The six electrodes are insulated, and kept in place by passing through holes in thin mica wads (one of which is shown at C) which are cut to fit the glass tube containing the thermometer. The electrodes are best made of platinum, the ends of the wires being fused to them by the oxyhydrogen flame.

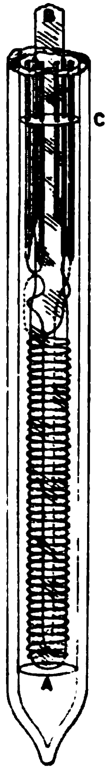

FIG. 5.

If R_0 and R_1 be the resistance at 0° and 100°, and R that at any other temperature, the corresponding value of the 'platinum' temperature *pt* is deduced by the formula

$$pt = 100\ (R - R_0)/(R_1 - R_0).$$

To reduce the platinum resistance temperature to that of the air thermometer the following formula is employed

$$T - pt = \delta\left[\left(\frac{T}{100}\right)^2 - \frac{T}{100}\right]$$

the value of δ, generally 1·5, depending on the wire and being determined for each thermometer from observations at 0°, 100°, and 444·5°. The formula has been found to hold up to 1000° or 1100°. To avoid errors due to variation of the room temperature, compensating leads are used, and other improvements have been adopted from time to time. For further details *v.* PYROMETRY.

For moderate temperatures, nickel is recommended in place of platinum by Marvin (Phys. Rev. 1910, 30, 522).

Dewar (Proc. Roy. Soc. 1904, 73, 244) states that platinum does not give good results at very low temperatures and recommends gold or silver. Meilink also (K. Akad. Wet. Amsterdam, 1904, 13, 212, 221) obtained better results with gold than with platinum. The resistance of gold, platinum, and other metals at low temperatures has been accurately determined by Kamerlingh Onnes and Clay, Comm. 99*c* and 107*c*.

Comparisons of the platinum scale of temperature with the hydrogen, nitrogen, or air scale have been carried out by Harker and Chappuis (Phil. Trans. 1900, 194, 37) at Sevres; Meilink (K. Adak. Wet. Amst. 1902, 10, 495); Holborn (Ann. Physik. 1901, [vi.] 2, 242); Harker (Proc. Roy. Soc. 1904, 73, 217); Travers and Gwyer, *ibid.* 1905, 74, 528), and Kamerlingh Onnes and Clay, *l.c.*, and of the platinum, gold, and hydrogen thermometers by Kamerlingh Onnes and Clay, Comm. 95*c*, *d*, and *e*; *v.* also Timmermans, *l.c.*

Thermo-electric thermometers. The first attempt to employ a thermo-couple for the measurement of high temperatures was made by Becquerel in 1826, but he failed to obtain concordant results. In 1886, however, Le Chatelier devised an instrument which gave good results and came into practical use, and since then great improvements have been introduced.

The thermo-electric thermometer consists essentially of two fine wires of different metals or alloys, fused together at one end, and connected through a galvanometer at their other ends, the fused end being placed in the source of heat. An E.M.F. is developed, which is roughly proportional to the difference in temperature of the two ends of the couple. Le Chatelier employed wires of Pt and Pt·Rh (10 p.c of Rh), and this couple may be used up to 1600°. The other couples which have been employed most frequently are Pt and Pt·Ir (10 p.c. Ir), and Cu and constantan (a Cu-Ni alloy with 40 p.c. Ni); the former may be used for temperatures as high as 1200°, the latter up to 500°. For full account of these thermometers *v.* PYROMETRY.

A great variety of couples have been tried for both high and low temperatures. For high temperatures the couples mentioned have been found to give the best results, but the Pt·Ir alloy has the disadvantage that the Ir volatilises, very slowly even at 900°, and much more rapidly at 1200°. For low temperatures, Holborn and Wien (Wied Ann. 1896, 59, 213) have recommended Fe—constantan; Pellat (Compt. rend. 1901, 133, 921), Fe—Zn; Dewar (Proc. Roy. Soc. 1905, 76, 316); Pt—German silver; whilst Kamerlingh Onnes and Clay (Comm. 107*b*), find that Ag—Au gives the best results. At about −256° this couple is about twice as sensitive as one of constantan—steel.

Comparisons of the thermo-electric scale of temperature with the air or hydrogen scale have been made by Holborn and Wien (Wied. Ann. 1895, 55, 95; 1896, 59, 213); Harker (Proc. Roy. Soc. 1904, 73, 217); and at low temperatures (−59° to −259°) by Kamerlingh Onnes and Crommelin, Comm. 95*a*; and with the platinum resistance scale by Waidner and Burgess, Bureau of Standards, Bull. 1909, 6, 149.

The question of the calculation of the true temperature of the hot junction when the cold one is not at 0° has been fully discussed by Offenhaus and Fischer, Electrochem. Ind., New York, 6, 1908, 362.

Vapour pressure thermometer. This form of instrument was recommended by Lord Kelvin (Pr. E. 1880, 432), and was introduced into practice under the name of the 'Thalpotassimeter' by Schäffer and Budenberg (Dittmar, J. Soc. Chem. Ind. 1885, 44). If the vapour pressures of a given liquid have been accurately determined through a certain range of temperature, any temperature within these limits may be afterwards determined by observing the pressure exerted by the vapour of the liquid.

The method possesses the great advantage that alteration of the capacity of the vessel containing the liquid and vapour is entirely without influence on the pressure, which is solely dependent on the temperature.

Probably the most serious objection to the method is the difficulty of filling the vessel or reservoir with the pure liquid *entirely free from air*, and if this difficulty be not overcome large errors may be introduced. For high temperatures, a mercury vapour pressure thermometer is sometimes serviceable (Ramsay and Young, Chem. Soc. Trans. 47, 651). The mercury must be well boiled to remove the film of air adhering to the glass, but this may be done without much difficulty. A liquid oxygen vapour pressure thermometer is recommended for temperatures between −183° and −200° by Stock and Nielson, Ber. 1906, 13, 39, 2066, and excellent results have been obtained with such an instrument by Kammerlingh Onnes and Braak, K. Akad. Wet. Amsterdam, 1908, 11, 333. Vapour pressure thermometers and pyrometers have been devised by Fournier, and an account of these instruments is given by Marieni (Electricità, Milan, 1908, 30, 82).

The following papers or memoirs on the subject of thermometry may be consulted: Sur les thermomètres à gaz, D. Berthelot, Paris, 1903; Kohlrausch, Zeitsch. Instr. 1898, 18, 16; Guillaume, Thèrmomètrie de précision; Chree, Phil. Mag. 1898, 45, 205, 299; Scheel, Zeitsch. Instr. 1899; Callendar, Nature, 1899, 59, 494, 519; Phil. Mag. 1899, 47, 191; Barus, Int. Phys. Congress, Paris, Rep. 1, 1900, 148.

THERMONATRITE *v.* NATRON; TRONA.

THERMOSTATS. A thermostat may be defined to be an apparatus so arranged as to maintain the temperature of a space constant between certain definite limits. Previous to 1860, the forms of apparatus employed were comparatively few and simple, but during the last half century the refinement of physical and chemical experimental methods has led to the design of very numerous varieties of thermostats. Some few of these have been adapted to technical uses; in general these applications present little complexity and do not call for any detailed description. They have mainly been applied to the temperature regulation of steam and gas heating systems and more recently to the control of electrical heating. Among other purposes the temperature control of incubators heated by gas or electricity, of acetylene heated germinating stoves, and of pasteurising apparatus used in the sterilisation of milk are noteworthy. The automatic regulation of the temperature of fermenting worts, of dye-vats, of evaporating pans and vacuum stills, has resulted in improvements in the sugar, spirit, and dyeing industries. Similarly, thermo-regulators are extensively adapted to secure the more exact and economical working of lacquering, brazing, tempering, annealing, and roasting ovens and kilns. Numerous systems for the central heating of public buildings and houses by steam, hot water, gas, and hot air are now automatically regulated by thermometric or electrical control apparatus. Similar thermostatic arrangements are also used in connection with steam-heating devices in railway carriages. In gas-testing stations, rooms are maintained at a uniform temperature by thermostats controlling the gas-heating system. Automatic fire-alarm devices are usually supplied with thermometric or electrical thermostats arranged to give warning by telegraphic or mechanical signals.

The thermostats and thermo-regulators suggested may be classified as:—

I. Thermostats depending on a flow of heated liquid for the maintenance of a constant temperature.

II. Thermostats utilising the latent heat of the alteration of the state of aggregation or change of phase of a body:

(*a*) Change of phase at freezing-point or cryohydric-point.
(*b*) Change of phase at boiling-point.
(*c*) Change of phase at inversion-point.

III. Other thermostats not automatically regulated through mechanical or electrical means.

IV. Self-regulating thermostats, including—

(*a*) Mercurial or other single-liquid thermometers:
  1. Acting directly on the gas supply or other heat source;
  2. Acting on the source of heat through electrical arrangements;
  3. Acting on the source of heat through mechanical arrangements;
(*b*) Gas thermometers:
  1. Acting on the gas supply by transmission of pressure through a liquid column;
  2. Acting through electrical arrangements;
  3. Acting through mechanical arrangements;
(*c*) Vapour-tension thermometers:
  1. Air and vapour;
  2. Vapour in contact with its own liquid only;
(*d*) Thermostats depending on the differential expansion of solid substances;
(*e*) Electrically heated thermostats with electrical control;
(*f*) Other mechanical regulators.

The limits of this article preclude the description of more than a few of the more typical examples of each of these classes; details of other forms and references may be obtained from: Temperature Regulators, J. T. Brown; Laspeyres, Pogg. Ann. 152, 132; H. Hammerl, Carl's Rep. 18, 1882; K. Arndt, Zeitsch. Chem. Apparatenkunde I. 255–263; Fr. Grützmacher, Zeitsch. Instrumentenkunde, 22, 184, 193, 201; W. C. Geer, J. Phys. Chem. 6, 85–105, 1902, who gives a general discussion and a useful bibliography; M. Bodenstein, Zeitsch. physikal. Chem. 1899, 30, 113–139, who supplies a detailed account of thermostats used in gas-reaction researches, and H. W. Fischer and O. Bobertag, Zeitsch. Elektrochem. 1908, 14, 375

I. *Thermostats depending on a flow of heated or cooled liquid for the maintenance of a constant temperature.* The form of apparatus invented by C. Blaufus-Weiss may be adapted for use either as a pressure or temperature regulator (D. R. P. 43574, 1887). As used in the latter capacity, it consists essentially of a cylindrical valve controlling the supply of hot or cold currents of either liquid or vapour to a worm arranged in the vat to be maintained at a uniform temperature. The valve is formed by an elliptical slit in a sheet cylinder which passes half round the circumference of the cylinder, and, when the latter revolves, is brought more or less opposite to tubes opening into the sides of the drum, which serves as a valve-box. The space within the revolving cylinder is furnished with tubes passing through the head of the drum to serve as supply or exit pipes. The valve is worked by the rise and fall of a vertical piston, actuated by the expansion and contraction of a quantity of mercury, which is contained in a bell-shaped vessel of which the wider end is applied to a small chamber which forms a side continuation of the vat. The vertical movement of the piston is transformed into the circular motion of the valve in a horizontal plane by means of a pin working in a screw slot on a hollow cylinder.

A simple thermostat for use in connection with the refractometric examination of oils and fats, by T. E. Thorpe (Chem. Soc. Trans. 1904, 257), uses a constant current of liquid, under a defined pressure head, heated by passing through a coil in the vapour of a boiling liquid (*v.* vol. iv. 555).

W. Behrens (Zeitsch. Wiss. Mikrosk. 1895, 12, 1) describes a neat air-worked expansion valve for controlling a hot-water current supplied to the hot stage of a microscope.

Other forms using this principle are given by J. Ph. Grünig, D. R. P. 75882, 1893; J. C. Schalkwijk, Zeitsch. Inst. 1901, 21, 338; and T. M. Lowry, Trans. Faraday Soc. 1907, 3, 119.

II. *Thermostats utilising the latent heat of the alteration of the state of aggregation or change of phase of a body.* (*a*) References to types using the change of phase at the freezing-point and cryohydric point will be found in Geer's bibliography (*l.c.*). To these may be added Travers (Zeitsch. physikal. Chem. 1905, 52, 443), using alcohol and carbon dioxide snow for low temperatures.

(*b*) The change of phase at the boiling-point is more generally utilised. The vapour from a liquid boiling at the required temperature is caused to surround the oven or bath to be heated. Here the temperature will vary according to the pressure under which the liquid is boiled.

The liquids used for this purpose are:—Water, ether, methyl and ethyl alcohols, benzene, toluene, acetic acid, carbon disulphide, amyl alcohol, xylene, turpentine, aniline, naphthalene, glycerol, diphenylamine, the monohydrate of sulphuric acid, mercury, paraffin, sulphur, zinc.

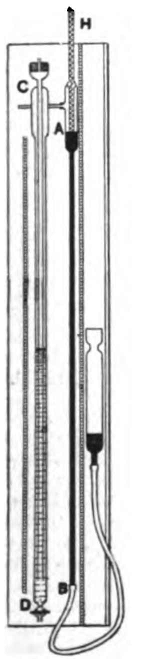

Fig. 1.

The temperatures so obtained lie between 22° and 1040°. At the ordinary atmospheric pressure one definite temperature is obtained for each substance used. Intermediate temperatures may be obtained in several ways:—(1) The pressure under which the vapour is formed is varied; (2) mixtures of liquids in various proportions are used; (3) a solid is dissolved in a liquid, the boiling-point being thus raised, and the vessel or bath is surrounded by the boiling liquid.

L. Meyer devised an apparatus for determining the boiling-point of a liquid at any pressure below that of one atmosphere. It may be used to control a constant-temperature bath (Annalen, 15, 303). The apparatus (see Fig. 1) is a pressure control valve. The mercury in AB cuts off the connection with the air-pump through H as soon as the pressure is reduced to the required point; CD is a mercury valve which admits air to the apparatus immediately the pressure falls below that fixed upon.

Brown has improved this apparatus, rendering it possible to use it for pressures higher, as well as lower, than one atmosphere. A mercury manometer is so constructed that, immediately the pressure falls below or rises above that determined upon, an electro-magnetic clutch, actuating a suitable stopcock, is placed in a battery circuit, and thus connection is made between the reservoir and the pump or outer air, as may be required for adjustment (Phil. Mag. 1879 [v.] 7, 411).

A. Fock has constructed a very serviceable bath, in which common petroleum is used as the mixture of liquids of different boiling-points. A double cylinder AB (Fig. 2), serving as a vapour-jacketed bath, is connected by means of the side tubes *a* and *b* with the reflux condenser G. The tube C connected with the condenser communicates, through the stopcock *r* and tube *d*, with the reservoir flask K. A mixture of liquids (*e.g.* common petroleum) is placed in the bath and distilled, the distillate passing through the open stopcock *r* into the flask K. At the moment when the required temperature is attained, as indicated by the thermometer T, the stopcock *r* is closed; the distillate now returns through the tube *b* to the bath, hence the temperature of B will remain constant for any length of time (Ber. 1885, 18, 1124).

Ramsay has used a vapour-bath in which the temperature is controlled by regulating the pressure under which a selected pure liquid is boiled (Chem. Soc. Trans. 1885, 640).

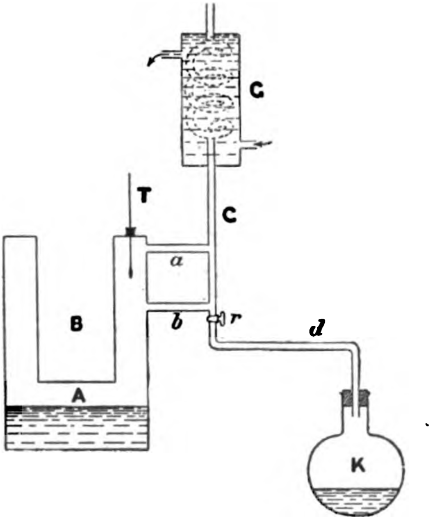

Fig. 2.

J. Traube and L. Pincussohn (Zeitsch. Inst. Beib. 1897, 17, 49) have also devised a simple thermostat using a boiling liquid under a controlled pressure. For other forms *see* Geer (*l.c.*).

(*c*) Richards and Churchill (Zeitsch. physikal. Chem., 1898, 28, 313) have similarly used the change at inversion points.

III. *Other thermostats not automatically regulated.* Instruments serving as indicators only have been devised by Hall (Q. J. Sci. 1818, 5, 52); Doyère (Ann. Chim. Phys. 1850, [iii.] 28, 5); A. Fraser (Jour. Gas Lighting, 1881, 38, 798); J. Barnes (Chem. Soc. Trans. 1881, 39, 463); A. V. Harcourt (Proc. Roy. Soc. 1882, 34, 166); U. Kreusler (Chem. Zeit. 8, 1321); and C. Winkler (Ber., 1885, 18. 2533).

Bunsen's thermostat (Annalen, 141, 273) is historically interesting.

Exner's thermostat is of especial value, as it allows of constant temperatures being maintained between 0° and 10° (see Fig. 3). It consists of an inner flask, surrounded by two concentric glass vessels, with an air space between the three vessels are fastened above to a zinc plate. A delicate thermometer and a thermo-element are placed in the centre of the flask; the stem and wires pass through a leaden pipe attached to the zinc plate. Between the two surrounding vessels is coiled a German-silver wire, the coils hanging freely without contact with either vessel; wires pass from the coil to a battery through the leaden tube. The whole is completely immersed in melting ice, contained in a fourth vessel; the leaden tube alone projects, and serves to keep the wires from contact with the ice. By passing an electric current through the German-silver coil, the temperature of the central vessel can be maintained at any desired point above 0° (Sitz. W. 1873, 68, 2).

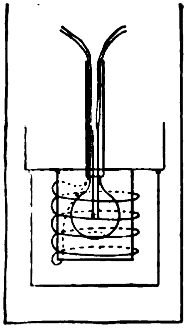

FIG. 3.

The same principle is applied by H. Crew (Phil. Mag. [v.] 33, 89). The accompanying illustration (Fig. 4) shows the points in which this instrument differs from the preceding one. Julien storage cells are used as the source of a constant current, which is regulated by alteration of the length of a resistance wire through which the current flows, by means of a slider and controlled by means of a Thomson balance.

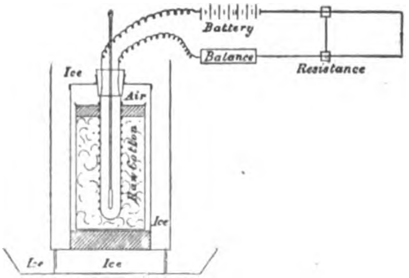

FIG. 4.

Other non-automatic instruments are described by Mahlke (Zeitsch. Inst. 1893, 13, 197), Pulfrich (Zeit. Inst. 1898, 18, 49), and Rothe (*ibid.* 143. 1899, 19).

IV. *Self-regulating thermostats*: (a) *Single-liquid thermometers* (1) *acting directly on the gas supply or other heat source.* Thermostats of this and allied types have been frequently utilised in connection with technical processes and heating systems; references to a number of these are given at the end of this article.

Reichert's form of regulator is essentially that of a mercury thermometer, with a reservoir at the top of the column. The gas-supply tube is placed so that its contracted opening is vertically over and near to the surface of the top of the mercury column. The leading tube takes off gas at the side of the reservoir. A small side tube on the stem is supplied with a screw by means of which the mercury level may at any time be adjusted, and the temperature maintained thus altered at will (Fig. 5) (Zeitsch. anal. Chem. 11, 34; Pogg. Ann. 144, 467).

Gerhardt's modification permits the instrument to be filled easily with mercury.

Regulators of the same type, but varying somewhat in form, have been constructed by Page (Chem. Soc. Trans. 1876, 24), Fletcher (*ibid.* 1876, 488), and Roulin (Dingl. poly. J. 227, 263). The instrument devised by Roulin is made of iron and steel (*v.* Fig. 6). The height of the mercury column is adjusted by means of a sliding tempered-steel rod, held in position by the set screw *f*. As this rod passes down the centre of the gas-supply tube, the gas can only reach the burner tube by passing through the ring-shaped aperture *d*, near the surface of the mercury. A small tap *g* maintains a sufficient supply of gas to the burner to avoid extinction of the flame by the complete interruption of the supply at *d*.

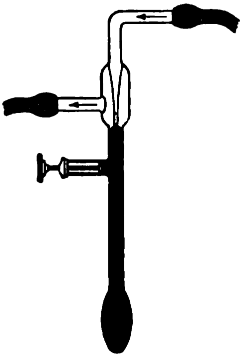

FIG. 5.

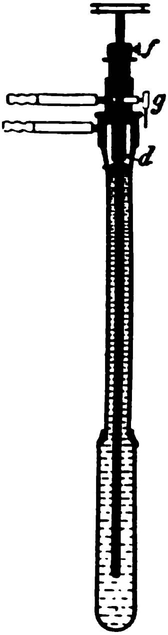

FIG. 6.

In the thermostatic battery by Dibdin and Smith, in use at the metropolitan gas stations, large mercurial thermometers are employed. The tubes by which they communicate with the supply tube are provided with stopcocks, so that any one or more of them may be thrown out of action. They control the gas supply to the boiler connected with the hot-water pipes.

For more accurate work, the mercury has been replaced by 30 p.c. calcium chloride solution, alcohol, benzoline, petroleum, xylene, or toluene. The toluene regulator has gained general acceptance: a simple and easily constructed form, designed by H. Lunden and W. Tate (Zeitsch. Chem. Apparat. II. 1, 13, 1907), is shown in the sketch (Fig. 7) with dimensions in millimetres. The column of calcium chloride solution prevents contact of the toluene with the mercury and with the stopcock R, thus doing away with the slow evaporation of the expanding liquid and allowing the use of ordinary lubricants with the stopcock provided to make temperature adjustments. This regulator, without the aid of any form of pressure regulator (the gas pressure varying from 50 to 60 mm. of water), maintained the temperature of a water-bath of 150 litres capacity during 30 days constant in a room varying considerably in temperature. The greatest difference between the extreme temperatures (observed at regular and frequent intervals) was 0·02°. A small part of the heating gas only passed through the valve D, sufficient to heat the bath within a short interval of the required temperature was supplied direct from the main.

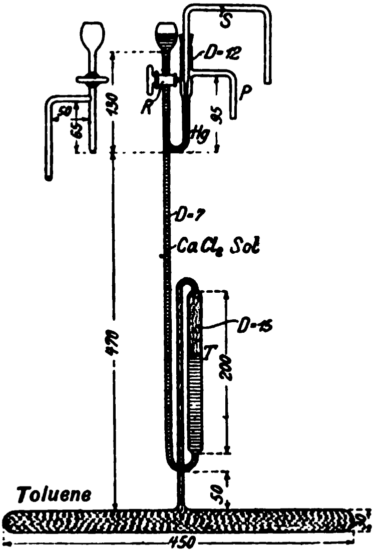

Fig. 7.

Another convenient form of toluene regulator is described by Lowry (J. Soc. Chem. Ind. 1905, 1033): there is a helical toluene reservoir tube coiled round a straight vertical stem containing mercury; it is provided with a wide bye-pass but has no provision for ready adjustment of the temperature, and the mercury and toluene are in contact near the lower end of the helix.

Hannay (Mon. Sci. [iii.] 16, 1021) and F. W. Dafert (Chem. Zeit. 1886, 52, 789) have designed thermostats belonging to this class. Further references are given by Geer (J. Phys. Chem. 1902, 6, 85).

(2) *Thermostats acting on the source of heat through electrical arrangements.* The usual type of this class employs a mercury thermometer with one pole of a battery permanently connected with the mercury and a second adjustable pole which completes the circuit at the desired maximum temperature. An electromagnetic arrangement in the circuit actuates a gas-cock, or works a gas valve either directly, or, by means of a plunger, indirectly controls a mercury valve of the usual type. This form of thermostat can be made very rapid in action and practically independent of variations in the gas pressure.

Scheibler has constructed an electro-thermostat, with the usual form of electric thermometer (Fig. 8). The electro-magnet is contained in the square box A; the upper end of the armature is provided with a leather pad, which works against the continuation of the gas-supply tube *b*, and with it forms a valve which cuts off the gas when the mercury comes into contact with the upper platinum wire. The extinction of the flame is avoided by having a small hole at *c* in the tube *b*, more or less closed by means of the screw *d*, through which a small stream of gas can escape into the box, and hence into the burner tube (Zeitsch. Anal. Chem. 1868, 88).

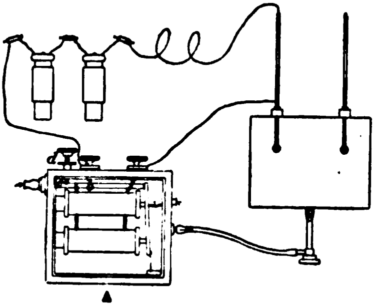

Fig. 8.

Kohlrausch adapted this principle to the regulation of the temperature of a hothouse (Dingl. poly. J. 389, 175). E. E. Reid (Amer. Chem. J. 1909, 41, 148–152) employs a mercury valve worked by a plunger controlled by an electromagnet.

Other forms are quoted by Geer (see iv. 1); to these we may add Clerget (Dingl. poly. J. 134, 23), Pfaundler (Carl's Rep. 18, 443), and Salet (Bull. Soc. chim. 1865).

(3) *Thermostats acting on the source of heat through mechanical arrangements.* Randall's apparatus (Dingl. poly. J. 224, 478) admits of direct technical applications, as it is adapted to the heating of large masses of water to a constant temperature by the use of steam. In Fig. 9 *b* is a thin-walled tubular vessel containing some expansible liquid, the movements of the surface of which are followed by the piston K. This piston works a valve *v*, which controls the steam supply. The spring *f* insures the return of the piston, the movements of which are recorded by the indicator I, which thus acts as a thermometer.

D'Arsonval constructed a very delicate thermostat (Fig. 10) by surrounding his oven with a chamber completely filled with water, which is introduced through an opening *v*, closed by a screw or by a cork through which a thermometer passes. Connected with this water chamber is the side tube O, closed by a caoutchouc membrane. Near to the centre of the surface of the membrane the gas-supply tube terminates, in a small metallic valve-box, from which the gas is led off to the burner by the tube *d*. The expansion or contraction of the large volume of water

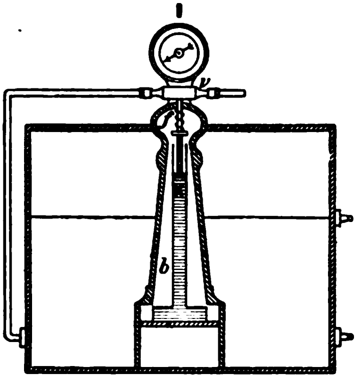

FIG. 9.

in the outer chamber causes the caoutchouc membrane to lessen or increase the distance between the supply tube and its own surface, thus forming a very sensitive valve, which controls the supply of gas to the burner. This regulator is said to keep the temperature constant to $\frac{1}{200}$° (J. Pharm. Chim. [iv.] 26, 474).

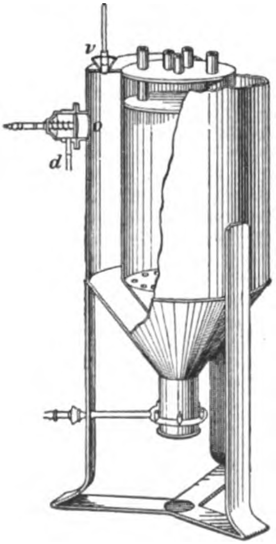

FIG. 10.

To maintain constant higher temperatures than can be employed with water, D'Arsonval substitutes a brass tube (Fig. 11), containing petroleum or glycerol, for the surrounding water chamber. The membrane is replaced by a corrugated metallic plate such as would be used in an aneroid barometer; *b* is a leaden tube prolonging the brass tube; it is hermetically closed after charging the tube. The chamber at the back of the aneroid plate communicates with the main tube by two small tubes *m* and *n*.

Several other forms of this regulator, retaining the same kind of valve, have been constructed. The valve itself has been mounted separately on a stand, and provided with a funnel and stop-cock to adjust the amount of liquid in the connected reservoir and the lower part of the valve, and with a bye-pass to insure that the flame be never quite extinguished. The same type of valve has also been adapted to the regulation of the flow of a cooling mixture, used for obtaining temperatures below that of the surrounding air.

G. Dorian (Bull. Soc. Ind. Mulhouse, 1900. 71, 249) described a combined heat and moisture regulator, in which the expansion of the liquid of a thermometer with a reservoir of spirally twisted tube controls a cock regulating the current of heating fluid and a hydrometer regulator works the moisture supply. T. S. Patterson (J. Soc. Chem. Ind. 1902, 21, 456), N. A. Randolph (Jour. Franklin Institute, 1883, 116, 465), V. H. Veley (Chem. Soc. Trans. 43, 370), and Nauman (Dingl. poly. J. 226, 276), give other forms, and various technical adaptations will be found in the list given at the end of this article.

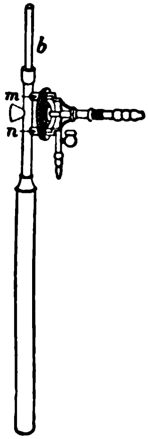

FIG. 11.

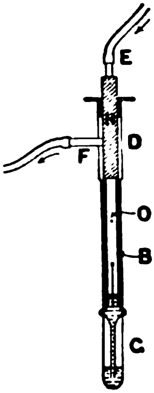

FIG. 12.

(*b*) *Gas thermometer regulators.*

(1) *Acting on the gas supply through a liquid piston.* A thermostat on this principle was devised by Kemp (Dingl. poly. J. 117, 352) and improved by Westly.

Bunsen's thermostat is a modification of Kemp's. The gas supply and exit tubes are arranged as shown in Fig. 12; the supply tube E passes through a brass cylinder H, which screws into the loose brass cap D. At its lower end is a slit, and it is provided with a minute orifice at O; the exit tube F is joined on to the side of the cylinder H, the latter being continued by the glass tube B to the same depth as the supply tube. The cap is fitted on a brass tube supplied with a slit in which the tube F can slide. A glass cylinder closed at the lower end continues this brass tube. In the lower part of this glass vessel is a glass air-chamber opening downwards and closed by the mercury contained in the cylinder; this air-chamber preferably takes the form shown at G. The expansion of air in the chamber causes the mercury to rise in the cylinder, and thus partially closes the slit; the position of the slit is regulated by the screw cap until the required temperature is attained. The minute orifice O insures that the gas supply should never be completely cut off (Dingl. poly. J. 143, 342).

Bunsen's low-temperature regulator has a larger air chamber, and is provided with a side tube and stopcock, by means of which the amount of mercury present can be readily altered (Desaga's Catalogue). Pontallie divides the gas supply after passage through a Bunsen's regulator, using one part to heat the regulator only, the remainder heating the bath. As these quantities are in exact and determined proportion, the temperature of the bath is maintained constant when that of the regulator does not vary.

Schorer separates the air-thermometer reservoir from the valve to enable the instrument to be used for high temperatures (Zeitsch. anal. Chem. 9, 213).

D'Arsonval adapted his thermostat for use at temperatures between 150° and 1200° by substituting an air reservoir for the petroleum reservoir employed at lower temperatures. The reservoir was made of glass or porcelain. The aneroid valve was at the same time furnished with a lever-arm and weight P, by means of which the pressure on the lower surface of the aneroid plate could be more or less compensated, and the amount of gas supplied altered at will (Fig. 13) (J. Pharm. Chim. [iv.] 26, 474).

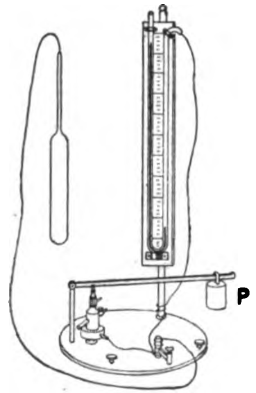

FIG. 13.

Although a number of varieties of this type have been used (*see* Geer's bibliography; J. Martenson, Chem. Zentr. 1872, 513; Clowes, Chem. Soc. Trans. 24, 639; L. Saarbach, J. Amer. Chem. Soc. 18, 511, 1901), and the principle has been technically applied in connection with furnaces of moderately high temperature, for low temperature work the toluene thermometer forms are to be preferred for accurate long period temperature regulation; all gas and vapour thermostats suffer from the defect of needing regulation with the changes in pressure of the air.

(2) *Acting through electrical arrangements.* These devices resemble the instruments in group iv. *a* (2). Pfaundler's apparatus (Carl's Rep. 18, 443) is similar to Scheibler's, the points of difference are sufficiently evident from the annexed figure (Fig. 14).

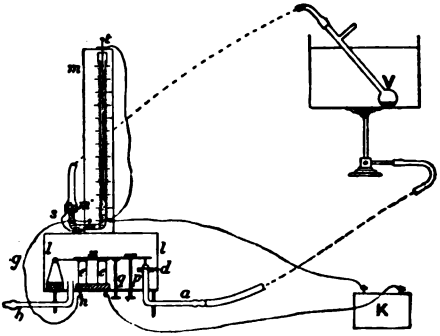

FIG. 14.

(3) *Acting through mechanical arrangements.* Jeannel's thermostat (Fig. 15) is an air-thermometer thermostat in which the air reservoir consists of a metallic vessel of 300–400 c.c. capacity. This is connected with one limb of a U-tube containing glycerol. In the other limb a float G carries a steel needle working loosely in a fine caoutchouc tube O. By a rise of the liquid in F, the float, guided by the steel needle, brings the flat upper surface of the sealing-wax H, in which the needle is mounted, near to the mouth of the tube O, thus forming a valve controlling the current of gas from the supply tube J to the exit tube P, of which O is a continuation. The pressure of the air in A is modified at pleasure by means of the caoutchouc pump S, with which connection is made through the tap R on a side tube (Ann. Chim. Phys. [iv.] 25, 386).

W. T. Richmond (Amer. Chem. J. 5, 287), Bendix and Lohse (D. R. P. 1880, 14242; Ber. 14, 2608), and Bechem (D. R. P. 1881, 18077; Ber. 15, 1226) have also devised self-acting thermo-regulators of this type.

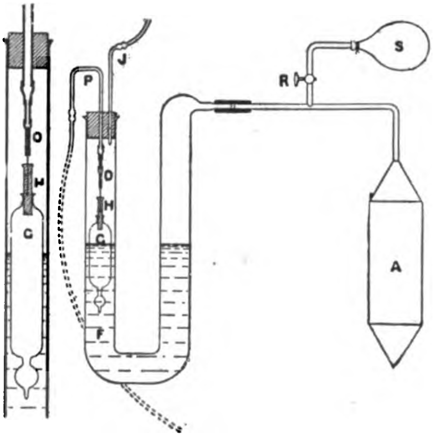

FIG. 15.

(*c*) *Vapour-tension thermometers.*

(1) *Air and vapour.* Andreæ's thermo-regulator is a Kemp thermostat in which the expansion of the air in the reservoir is increased by the addition of a small quantity of some readily

volatile liquid. Such liquids as ether, alcohol, acetone, light petroleum and water may be employed for the purpose. Ether is particularly suitable, on account of the rapid increase of its vapour tension with increase of temperature. A thermostat of this form will maintain the temperature of a water-bath constant within 0·04–0·05° (Wied. Ann. 4, 614).

Lothar Meyer has also made use of the same principle (Ber. 16, 1088).

Benoit's thermo-regulator has the thermometer reservoir separated from the valve, connection being made by means of a caoutchouc tube containing mercury.

The reservoir consists of a thin tube, drawn out at one end for convenience in filling, which contains a small quantity of air, and a few drops of some volatile liquid; the remainder of the space in the tube is occupied by mercury in connection with the mercury in the valve by means of the caoutchouc tube. The valve differs somewhat from the ordinary form. It is provided with a side tube A (Fig. 16), by which a small amount of gas can directly pass from the supply tube x to the burner tube y. Mercury can be added by means of the side tube B, or withdrawn from the cock C to adjust the level within the valve. The whole is mounted upon a sliding board, fixed by the clamp-screw M, at any convenient height (Wied. Beibl. 4, 296; Guillaume's Thermométrie, 130).

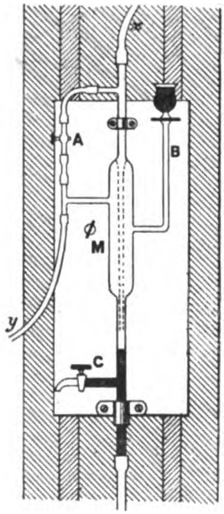

Fig. 16.

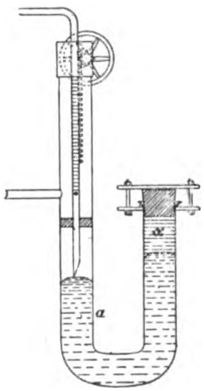

Fig. 17.

(2) *Vapour in contact with its own liquid only.* The instrument devised in 1886 by G. W. A. Kahlbaum belongs to this class. There is the usual mercury valve, the supply tube being bevelled off at the open end at an angle, and having a small hole opposite the exit tube to provide against total extinction of the flame. It may be adjusted according to the temperature required by the rack and pinion shown (Fig. 17). The other limb of the U-tube contains a liquid of boiling-point just below the temperature required in the bath or oven. For facility in changing the liquid, this end of the tube is closed by a tightly-fitting cork held in place by a clamp working against an india-rubber seat fixed on the collar of the glass tube.

The temperature rises just above the boiling-point of the liquid x, a portion of this volatilises, and mercury is forced up the limb a; the pressure on the liquid being now greater, its boiling-point is raised, and the temperature must increase for further volatilisation to occur. Owing to the rise of mercury in a, the gas supply is diminished, and hence the temperature falls. Consequent on the fall of temperature, a portion of the vapour condenses, the valve is opened to a greater extent, and the temperature again rises. These actions soon reach a point of equilibrium, and a constant temperature is then maintained (Ber. 19, 2860).

(*d*) *Thermostats depending upon the differential expansion of solid bodies.* Bonnemain (Dingl. poly. J. 16, 285) and Ure (*ibid.* 42, 173) devised regulators depending upon the expansion of simple or compound metallic bars.

Hipp's thermostat is only available for temperatures between 30° and 40° (see Fig. 18). It consists of a copper vessel K, surmounted by a wooden box C, having glass front and back. A system of tubes on the walls of the oven communicate with the vessel K, and serve for the circulation of the water heated in that vessel. They are provided with openings for filling in water, and to serve as escape vents in case the water may be accidentally boiled. The temperature is controlled by a regulator consisting of a bent compound metallic bar fixed upon the back wall of the oven at A; the free end B is connected by a copper wire with the lever h working a conical valve v; z is a regulating screw, by means of which any desired initial opening of the valve may be obtained; s is the gas-supply tube, and t draws off gas for the burner from the valve-box R (Dingl. poly. J. 191, 366).

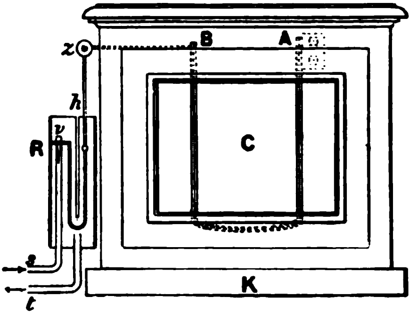

Fig. 18.

Lothar Meyer in 1884 devised a sensitive temperature regulator on this principle (Fig. 19). It consists of a long brass tube placed vertically in the bath, and closed at its lower extremity: in this tube a slightly longer glass rod is placed. The tube supports a rod carrying a movable lever-arm A, from which depends a floating valve B. The valve may be placed at varying distances along the lever-arm A, so that the difference between the expansions of the brass tube and glass rod may be magnified to a greater or less extent in the amount of movement imparted to the valve. The supply tube is a narrow-bore tube passing up the arm x of the valve working in the glycerol seal tube *m*. The supply tube and seal may be adjusted to any required height. A precisely similar arrangement allows of the drawing off through *o* of the gas for the burner. The valve *z* is essentially a Bunsen mercury-and-slit-tube valve. The mercury vessel is adjustable to any required height (Ber. 17, 478).

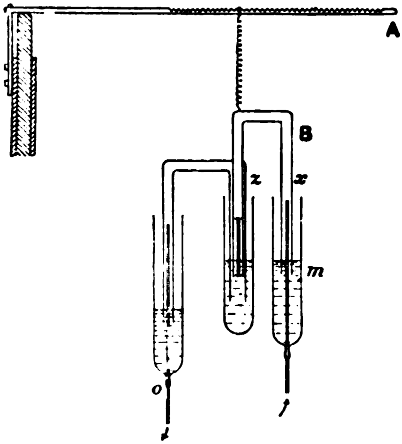

Fig. 19.

L. von Babo arranged a gas regulator, in which the control valve depends for its action upon the unequal expansion of glass and copper. In Fig. 20, A is a copper tube, B a glass rod. The valve x, which regulates the flow of gas from the supply G to the burner tube E, is fixed in position by the glass rod B, against which it is pressed by a spiral spring C. The screw D serves to adjust the position of the glass rod, and renders it possible to obtain a greater or smaller supply of gas at will. As the temperature rises, the expansion of the copper tube being greater than that of the glass rod, the valve x is pressed by the spring C nearer to its seat, and so there is less gas supplied; the temperature then falls, and the valve partially re-opens, and so on (Ber. 13, 1221).

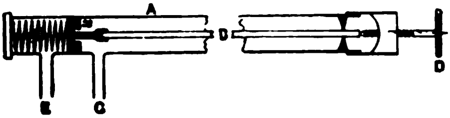

Fig. 20.

Kohlrausch employed a Breguet's metallic thermometer to make and break an electric current, which heated a fine platinum wire (Pogg. Ann. 125, 626).

E. Gumlich (Zeitsch. Inst. 1898, 18, 317) claims, by the use of a nickel and brass Brequet's spiral governing the gas supply through intermediary electrical arrangements, to have maintained a dry oven within 0·4° for long intervals.

Rieth's instrument consisted of a compound metallic bar working a cone valve. supplied with a regulator screw (Chem. Zentr. 1871, 615).

(*e*) ***Electrically heated thermostats with electrical control.*** Thermostats of this type allow of more sensitive and rapid adjustment than any other; they are particularly suitable for accurate scientific work but are not without technical applications.

Rothe (Zeitsch. Inst. 1899, 19, 143) gives a very complete account (with illustrations) of a thermostat designed for use in thermometer work at the Phys. Tech., Reichsanstalt. The same author (Zeitsch. Inst. 1902, 22, 14) adapts this principle to the construction of an instrument for use with very low temperatures. A Dewar's vessel serves to prevent conduction of heat from without; the heating coil is of constantan wire wound on the ebonite ring of a stirrer, the stem of which is of glass tubing through which pass the leading wires for the current.

W. C. Geer (J. Phys. Chem. 1902, 6, 94) claims for his thermostat a variation of 0·002° only for a 9 hours' run with a 30-litre bath. A somewhat simpler form, which is essentially a modified Geer thermostat, is described by F. A. Osborn (*ibid.* 1905, 9, 297). The accompanying diagram (Fig. 21) shows its essential features. The heating of the 50-litre bath is accomplished by means of an iron wire CC carrying a current from the large storage battery B. The wire forms a layer of five turns against the sides of the bath, which latter is encased in a non-conducting layer of felt. E is a glass worm, 9·5 cm. diameter and 16 cm. long and holding 110 c.c. of mercury, serving as reservoir of a regulating thermometer with a capillary stem. The bath is stirred by a mechanically-driven stirrer represented by D. A platinum fused-in wire permanently connects an electro-magnet R with the mercury of the thermometer. R is connected through a storage cell B′ with a second adjustable wire P. When the required temperature is reached, the mercury completes the circuit with P and the main current is broken at AA by the movement of the armature. The spring shown establishes the main circuit as soon as the mercury breaks contact with P.

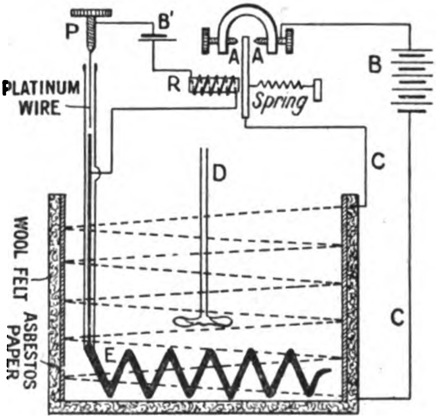

Fig. 21.

This form can be brought to the required steady temperature in 15 minutes and shows no change of a hundredth of a degree in 8 hours.

Other forms are given by S. W. Young (J. Amer. Chem. Soc. 1901, 23, 327); C. Marie and R. Marquis (Compt. rend. 1903, 136, 614), who use an acetone thermometer with mercury make and break and current through platinum wire; R. A. Macumber and C. G. L. Wolf (J. Path. Bact. 1904, 10, 105); H. Darwin (Phil. Mag. [vi.] 7, 408, 1904); J. P. Magnusson (J. Phys. Chem. 1907, 11, 25); Regaud and Fouilland (Ann. Chim. anal. 1909, 14, 141); L. Kolowrat (J. Phys. 1909, 8, 495), who describes the automatic regulation of an electric oven.

(*f*) *Other mechanical regulators* have been devised by J. W. Eichler and H. Hartig (D. R. P. 5492, 1878), and by Appold, whose instrument was a balance regulator (Proc. Roy. Soc. 1866, 15, 144).

The invention of G. J. Meurlin (D. R. P. 4703, 1878) consists of a self-regulating cone valve to control the pressure of a gas supply, and hence the temperature of a space heated by the flame. The pressure of the gas in the chamber *a* raises the cone *b* (Fig. 22), partially closing the hole in the plate *x*, and thus restricting the current. The hole in the summit of the cone *b* prevents extinction of the flame.

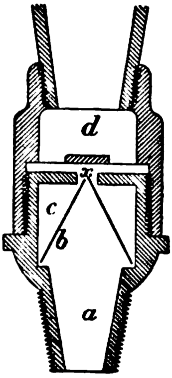

FIG. 22.

A. Schwabe (D. R. P. 93152, 1896) describes a device by which an areometer works a chain controlling the source of heat.

The choice of the type of thermostat most suitable will be governed by the requirements in each special case. Technical applications of these instruments are most frequently adequately met by the use of the simple mercury thermometer valve at moderate temperatures and the air-thermometer mercury-valve at higher temperatures, some form of differential expansion instrument being used when the liability to vibration or shock has to be provided for.

For accurate work, the reliability, sensitiveness, and independence of atmospheric changes are the most important consideration. Electrical thermostats with electrical control appear best able to fulfil the necessary conditions (*see* Geer, J. Phys. Chem. 1902, 6, 85); W. P. Bradley and A. W. Browne (*ibid.* 1902, 6, 118) claim to have constructed a thermostat sensitive to one thousandth of a degree. The toluene thermometer mercury-valve thermostat has found wide use; T. M. Lowry (J. Soc. Chem. Ind. 1905, 1030) discusses the conditions governing its sensitiveness and A. W. C. Menzies (Chem. News. 1902, 85, 68), in dealing with the same subject, shows that this type is able to keep a bath at 6° above room temperature constant within one hundredth of a degree.

The principal ways in which thermostats have been applied to technical purposes have been mentioned; recent instances of such applications are to be found in the following, not otherwise readily accessible, references.

Central heating and ventilating systems. Consolidated Car-heating Co., Wheeling, U.S.A., D. R. P. 67775, 72164, 1892; Senff, Ges. Ing. 1901, 24, 393; Johnson thermostat control of steam heating, Eng. THESPASIA MACROPHYLLA (Blume) [*T. Lampas* (Dabz.).] This is a small bush common to the tropical jungles of India, Burma, and Ceylon. In Watts' Dictionary of the Economic Products of India, there is no mention of the use of this plant as a dyestuff, but, on the other hand, the capsules and flowers of the allied *T. populnea* (Soland.) are stated to give a yellow dye.

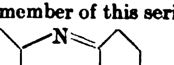
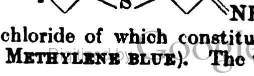
According to Perkin (Chem. Soc. Trans. 1909, 95, 1859) the flowers of the *T. macrophylla* yield quercetin and some quantity of *protocatechuic acid.*

With mordanted woollen cloth the flowers produce fairly good shades, but are in no way superior to the better-known Indian natural yellow dyestuffs. A. G. P.

THIAZINE COLOURING MATTERS. The thiazines are colouring matters containing the group

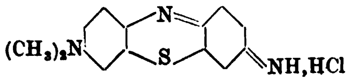


The simplest member of this series is *thionine*



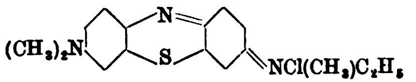
the hydrochloride of which constitutes Lauth's violet (*see* METHYLENE BLUE). The tetramethyl derivative is methylene blue (*q.v.*), which is by far the most important dyestuff of this class. The general method of preparation of these colouring matters has already been indicated (*see* METHYLENE BLUE).

Gentianine



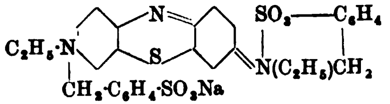
is prepared by the conjoint oxidation of *p*-phenylenediamine and dimethyl-*p*-phenylenediamine in presence of hydrogen sulphide, and comes on the market as the zinc chloride double salt. It is a reddish-brown powder which dissolves in water with a blue violet colour and dyes mordanted cotton bluish violet (Geigy and Co., Fr. Pat. 180487; U. S. Pat. 368716, 1887).

Thionine blue G



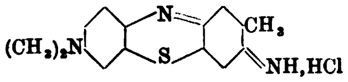
is prepared like methylene blue except that dimethyl-*p*-phenylenediaminethiosulphonic acid is oxidised together with methylethylaniline instead of dimethylaniline. It dyes tannin mordanted cotton blue.

Thiocarmine R



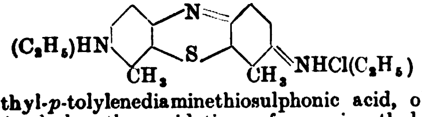
Benzylethyl-*p*-phenylenediaminesulphonic acid is oxidised in presence of sodium thiosulphate to sulphobenzylethyl-*p*-phenylenediaminethiosulphonic acid; the latter is oxidised together with benzylethylanilinesulphonic acid and the sulphoindaminethiosulphonate thus obtained is heated to boiling. The dyestuff is an indigo-blue powder giving a pure blue solution in water and dyeing wool and silk from an acid bath in blue shades (Cassella and Co., Eng. Pat. 4596, 1890; U. S. Pat. 434493; *see* also J. Soc. Chem. Ind. 1892, 11, 30).

Toluidine blue C



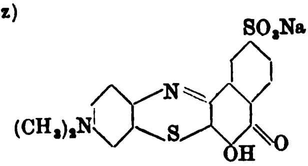
Dimethyl-*p*-phenylenediaminethiosulphonic acid (*cf.* METHYLENE BLUE) is oxidised together with *o*-toluidine. The insoluble green indamine formed is boiled with a solution of zinc chloride and the resulting leuco compound is oxidised. The colouring matter is a dark green powder giving a bluish-violet aqueous solution and dyeing mordanted cotton blue (Badische Anilin und Soda Fabrik; Eng. Pat. 10314, 1888; D. R. P. 47374; U. S. Pat. 416055; Meister, Lucius und Brüning, D. R. P. 47345).

New methylene blue N



Ethyl-*p*-tolylenediaminethiosulphonic acid, obtained by the oxidation of *p*-aminoethyl-*o*-toluidine in presence of sodium thiosulphate, is oxidised together with ethyl-*o*-toluidine and the green indamine obtained is heated. The solution of the dyestuff in water is violet-blue when cold and pure blue when hot. Tannin-mordanted cotton is dyed in redder and fuller shades than those produced by methylene blue (Cassella and Co., Eng. Pat. 8407, 1891; U. S. Pat. 469329).

Brilliant alizarin blue (Bayer); **Indochromine T** (Sandoz)



1:2-Naphthaquinone-6-sulphonic acid is condensed with dimethyl-*p*-phenylenediaminethiosulphonic acid. The dyestuff gives fast blue shades on chromed wool, cotton or silk, and is suitable for calico printing (F. Bayer and Co., D. R. P. 83046, 86717). J. C. C.

THIAZOL DYESTUFFS *v.* PRIMULINE AND ITS DERIVATIVES.

THIET-SIE. A resinous substance used as a varnish by the Burmese. It exudes from a tree in the form of a light-brown, very viscid liquid of the consistence of treacle, but on exposure to the air for a few minutes becomes quite black and hard on the surface. The same change takes place instantly in contact with potassium hydroxide. The resin spread in a thin layer on wood or other solid body quickly forms a hard deep-black coating of great brilliancy. On digesting the unaltered substance with alcohol of 80 p.c. at a gentle heat, the greater part gradually dissolves; and on decanting the clear liquid from the insoluble residue, and distilling off the alcohol, there remains a very tenacious gummy residue of a rich-brown colour, which undergoes no change of colour on exposure to the air, but very slowly hardens. In contact with potassium hydroxide, however, it blackens like the original substance.

The residue, insoluble in alcohol, dissolves for the most part in ether, forming a dark-brown solution, and leaving a light-brown solid resin. The ethereal solution, when evaporated, leaves a residue which, on exposure to the air, instantly becomes quite black, and after a short time nearly solid. This, then, is the portion of the original substance to which the property of blackening on exposure to the air is due.

The solid resin, insoluble in alcohol and ether, which forms but a small part of the original substance, is quite unalterable in the air. When heated with nitric acid, it yields a crystalline acid which may be sublimed and which exhibits the characters of succinic acid.

THIOACETAMIDE $CH_3 \cdot CS \cdot NH_2$ is prepared by the action of hydrogen sulphide on acetonitrile (Bernthsen, Annalen, 192, 46); or of phosphorus pentasulphide on acetamide in benzene solution (Hantzsch, *ibid.* 250, 264; *cf.* Hofmann, Ber. 1878, 11, 340). It crystallises in monosymmetric plates or prisms, m.p. 107·5°–108·5°, and is readily soluble in water or alcohol, less so in ether. Acids or bases decompose thioacetamide, yielding acetic acid, ammonia and hydrogen sulphide, whilst with silver nitrate solution, a precipitate of silver sulphide is obtained. It gives difficultly soluble compounds with mercuric chloride and with other metallic chlorides (Kurnakow, J. Russ. Phys. Chem. Soc. 1893, 25, 613).

THIOACETANILIDE $CH_3\cdot C(SH){:}N\cdot C_6H_5$ or $CH_3\cdot CS\cdot NH(C_6H_5)$ is prepared by the interaction of acetanilide and phosphorus pentasulphide (Jacobson, Ber. 1886, 19, 1067; Hofmann, *ibid.* 1878, 11, 339), or of the chloride of acetanilide, $CH_3\cdot CCl{:}N\cdot C_6H_5$ and hydrogen sulphide (Leo, *ibid.* 1877, 10, 2134). It crystallises from water in needles, m.p. 75°. On distillation it yields phenylamino-phenylimino-ethane

$$C_6H_5\cdot NH\cdot C(CH_3) : N\cdot C_6H_5.$$

It is soluble in sodium hydroxide solution, from which it is precipitated by the addition of acids. The sodium derivative

$$CH_3\cdot CS\cdot NNa(C_6H_5)$$

is formed by the action of sodium ethoxide. Thioacetanilide yields two series of alkyl derivatives, *viz.* the normal alkyl thioacetanilides $CH_3\cdot CS\cdot NR(C_6H_5)$ and the alkyl *iso*thioacetanilides $CH_3\cdot C(SR) : N\cdot C_6H_5$. The former are obtained by the action of phosphorus pentasulphide on alkylacetanilides, and the latter by the action of alkyl iodides on the sodium derivative of thioacetanilide.

THIOACETIC ACID CH_3COSH is best prepared by heating glacial acetic acid with phosphorus pentasulphide (Tarugi, Gazz. chim. ital. 1895, 25, i. 273; Schiff, Ber. 1895, 28, 1205; *cf.* Kekulé and Linnemann, Annalen, 123, 278; Kekulé *ibid.* 90, 311). It may also be prepared by the interaction of acetyl chloride and potassium hydrosulphide (Jacquemin and Vosselmann, J. 1859, 354), or of lead acetate and anhydrous sodium thiosulphate (Frohde, Zeitsch. Chem. 1866, 543). It is an unpleasant smelling liquid, b.p. 93°, sp.gr. 1·074 at 10°, soluble in water and in alcohol: for electrical conductivity *v.* Ostwald, Zeitsch. physikal. Chem. 3, 182. By heating in a sealed tube with water at 180°–200° or by boiling with zinc and sodium hydroxide, the sulphur is removed (Schulze, Zeitsch. physiol. Chem. 1898, 25, 16). Strong sulphuric or nitric acid reacts explosively with thioacetic acid. Phosphorus pentachloride yields acetyl chloride, phosphorus thiochloride and hydrogen chloride, whilst zinc chloride yields ethenyl trisulphide, $C_4H_4S_3$, acetic acid and hydrogen sulphide. Thioacetic acid condenses with aldehydes, ketones and ketonic acids in the presence of hydrogen chloride (Bongartz, Ber. 1886, 19, 1934). It has been recommended as a substitute for hydrogen sulphide in qualitative analysis (Schiff and Tarugi, *ibid.* 1894, 27, 3437; Tarugi and Marchionneschi, Boll. Chim. Farm. 45, 629). For *salts*, *v.* Ulrich, Annalen, 109, 275; Tarugi, Gazz. chim. ital. 1895, 25, i. 341; 1897, 27, i. 316; ii. 153.

Ethyl ester. Prepared by the interaction of acetyl chloride and ethyl hydrosulphide, but not from ethyl acetate and phosphorus pentasulphide (Michler, Annalen, 176, 182). Unpleasant smelling liquid, b.p. 116·0°–116·2° at 749·3 mm. (Beckmann, J. pr. Chem. [ii.] 17, 461).

Dithioacetic acid, *methylcarbithionic acid* $CH_3\cdot CS\cdot SH$ is prepared by the action of carbon disulphide on magnesium methyl iodide in well-cooled ethereal solution. The product is decomposed with ice and hydrochloric acid. It is a reddish-yellow oil, b.p. 37°/15 mm., sp.gr. 1·24 at 20°, readily soluble in organic solvents. It displaces acetic and formic acids from their salts. It is readily oxidised to thioacetyl disulphide by water and produces black spots on the skin. The alkali, alkaline earth, silver and magnesium salts are soluble in water, giving coloured precipitates with the salts of the heavy metals (Houben and Pohl, Ber. 1907, 40, 1303).

Methyl ester. Prepared as the acid, substituting ammonium chloride for hydrochloric acid. The product is shaken with methyl sulphate, and the red oil so formed distilled; b.p. 140°/760 mm., 80°–81°/95 mm., 71°/70 mm.; sp.gr. 1·096 at 21°/4° (Houben and Schultze, Ber. 1910, 43, 2481).

THIOANTIPYRINE or **THIOPYRINE,** $C_{10}H_{12}N_2S$. Prepared by treating the methochloride or methiodide of 1-phenyl-3-methyl-5-chloropyrazole with potassium hydrogen sulphide. Large soluble crystals, m.p. 166° (Michaelis and Bindewald, Ber. 1900, 2873).

THIODIALURIC ACID

$$\mathrm{CO}\left\langle\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right\rangle\mathrm{CH\cdot SH},1\tfrac{1}{2}\mathrm{H_2O}$$

obtained by hydrolysing with dilute potassium hydroxide thio*pseudo*uric acid

$$\mathrm{CO}\left\langle\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right\rangle\mathrm{CH\cdot SC}\begin{matrix}\diagup\mathrm{NH}\\ \diagdown\mathrm{NH_2}\end{matrix}$$

(Nencki, Ber. 1871, 4, 772), or potassium thiocyanobarbiturate  $\mathrm{CO}\left\langle\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right\rangle\mathrm{CH\cdot SCN}$ (Trzcinski, *ibid.* 1883, 16, 1057); forms bright microscopic plates. The *potassium salt* is a yellow crystalline compound, sparingly soluble in water. Thiodialuric acid dissolves in nitric acid to form a pale red solution, and on warming a violent reaction takes place and dilituric acid is formed.

THIOFLAVINE T S *v.* PRIMULINE AND ITS DERIVATIVES.

THIOFORM THIOGENOL, *v.* SYNTHETIC DRUGS.

THIOGLYCOLLIC ACID $SH\cdot CH_2\cdot CO_2H$ was first prepared by Carius (Annalen, 1862, 124, 43) by heating 3 parts of monochloracetic acid in concentrated aqueous solution with 5 parts of potassium hydrogen sulphide. Thiodiglycollic acid is formed at the same time, thus:

$$CH_2Cl\cdot CO_2H+2KSH=CH_2(SH)CO_2K+H_2S+KCl,$$
$$CH_2(SH)CO_2K+CH_2ClCO_2K=S(CH_2CO_2K)_2+HCl$$

(*v.* Claessen, *ibid.* 1877, 187, 113).

Thioglycollic acid is also formed by treating sulphochloracetylchloride, $SO_2Cl\cdot CHCl\cdot COCl$ with tin and hydrochloric acid (Siemens, Ber. 1873, 6, 659); by treating glyoxylic acid with sulphuretted hydrogen in presence of silver oxide, thiodiglycollic acid also being formed in this case (Böttinger, Annalen, 1879, 198, 215); by boiling thiohydantoïn or rhodanic acid with baryta (Andreasch, Ber. 1879, 12, 1385; Ginsburg and Bondzynski, *ibid.* 1886, 19, 117); or by treating salts of chloracetic acid with alkali or alkaline earth polysulphides and subjecting the products thus formed to the action of reducing agents (Kalle and Co., D. R. P. 180875).

Thioglycollic acid is an uncrystallisable oil, soluble in water, alcohol, and ether. It has a faint smell, acts as a strong acid and forms a number of metallic salts (Claessen, *l.c.*; Ber. 1877, 10, 1354).

If a drop of ferric chloride is added to a slightly acidified thioglycollate, a transient indigo blue colour appears, which changes to a deep violet red on adding excess of ammonia and shaking in air. On standing the colour disappears, but it is reproduced by shaking the solution with air (Andreasch, Ber. 1879, 12, 1390). Thiodiglycollic acid does not give this reaction. Thioglycollic acid reacts with aldehydes yielding compounds of the type

$$RCH(S{\cdot}CH_2{\cdot}CO_2H)_2,$$

with ketones to form the compounds

$$R_2C(S{\cdot}CH_2{\cdot}CO_2H)_2,$$

and also with ketonic acids (Bongartz, Ber. 1886, 19, 1931; *ibid.* 1888, 21, 478). It also unites with cyanamides forming hydantoïns (Andreasch, Monatsh. 1881, 2, 775; Ber. 1880, 13, 1421).

Thioglycollamide $CH_2(SH)CONH_2$ forms thin white leaflets, m.p. 149° (Holmberg, J. pr. Chem. 1905, [ii.] 71, 264).

Ethylthioglycollate $CH_2(SH)CO_2C_2H_5$, is formed by boiling the acid with absolute alcohol in the presence of a few drops of sulphuric acid (Claessen). It is an offensive smelling heavy oil, b.p. above 155° (decomp.), insoluble in water and in alcohol. For some of its derivatives, *see* Wisliscenus, Annalen, 1868, 146, 145; Heintz, *ibid.* 1865, 136, 223; Letts and Collie, J. 1878, 685.

Ethylthioglycollic acid $CH_2(C_2H_5S)CO_2H$ is formed by the interaction of ethyl chloracetate and sodium mercaptide, the ethyl ester thus formed being hydrolysed with baryta water (Claessen, Bull. Soc. chim. [ii.] 23, 444). It is an oil soluble in water, alcohol and ether, and yields metallic salts and esters. Its *amide*

$$CH_2(C_2H_5S)CONH_2$$

has m.p. 440°.

Nitrosothioglycollic acid $(SH)CH(NO)CO_2H$ is obtained, together with cyanamide and dicyanamide, by boiling nitrosothiohydantoïn with baryta water. A number of its metallic salts have been prepared (Andreasch, Ber. 1880, 13, 601).

Dithioglycollic acid $(SCH_2{\cdot}CO_2H)_2$ forms leaflets or prisms, m.p. 100°, gives metallic salts, an *ethyl* ester, b.p. 280° (decomp.), and is reduced by zinc and hydrochloric acid to thioglycollic acid (Claessen, Ber. 1881, 14, 410; Ginsburg and Bondzynski, *l.c.*).

Thiodiglycollic acid $S(CH_2{\cdot}CO_2H)_2$ may be prepared by treating calcium chloracetate with calcium hydrogen sulphide in presence of hydrogen sulphide (Schreiber, J. pr. Chem. [ii.] 13, 472); or by mixing a concentrated aqueous solution of sodium chloracetate with an equivalent amount of sodium sulphide dissolved in the smallest quantity of water. The mixture is acidified with sulphuric acid and the thiodiglycollic acid is shaken out with ether (Lovén, Ber. 1884, 17, 2818; *ibid.* 1894, 27, 3059). It forms rhombic tablets, m.p. 129°; gives metallic salts; a *dimethyl ester,* b.p. 135°/11 mm. (Anschütz and Biernaux, Annalen, 1893, 273, 69), and a *diethyl ester*, b.p. 267°–268° (corr.) (Wislicenus, *l.c.*). Also a *chloride* $S(CH_2COCl)_2$, an *anhydride*

$S{<}\begin{matrix}CH_2{\cdot}CO\\CH_2{\cdot}CO\end{matrix}{>}O$, m.p. 102°, b.p. 158°/10 mm. (Anschütz and Biernaux, *l.c.*), and amides.

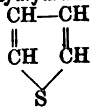
THIOPHEN. *Thiofurfuran*

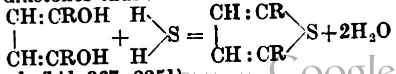
C_4H_4S or



Discovered by Victor Meyer in coal-tar benzene, which contains about 0·5 p.c. of thiophen (Ber. 1883, 16, 1465; *see* also Bull. Soc. chim. 1900, 23, 384; *ibid.* 24, 357; Heusler, Ber. 1895, 28, 488; Witzeck, Chem. Zentr. 1903, i. 1053). In order to extract the thiophen, a large quantity of the best commercial benzene was shaken for some hours with one-tenth of its volume of concentrated sulphuric acid, the black acid layer separated, diluted with water, and converted into the lead salt of the sulphonic acid thus obtained. This lead thiophen-sulphonate, which was contaminated with lead benzene-sulphonate, was dried, mixed with one-fourth of its weight of ammonium chloride, and distilled. The sulphonic acid was thus hydrolysed, and an oil passed over which was purified by shaking with caustic alkali to remove mercaptans, dried over calcium chloride and rectified.

K. E. Schulze (Ber. 1885, 18, 497) recommends that the thiophen-sulphonic acid, after diluting the crude acid with water, should be hydrolysed by steam-distillation. Thiophen may also be completely removed from commercial benzene by treating the latter with form- or acet-aldehyde or with phthalic anhydride (D. R. P. 211239; Frdl. 1908–1910, 9, 96).

According to Steinkopf (Chem. Zeit. 1911, 35, 1098), thiophen may be very readily prepared by passing acetylene over pyrites or marcasite heated to 300°, the thiophen being separated from the other products by fractional distillation. Among the products occurs a substance $C_4H_6S_2$, b.p. 36°–38° of garlic-like smell which, when treated with alkalis, loses some sulphur and also its unpleasant smell. Thiophen has been artificially prepared by numerous methods: amongst others by passing ethylene or acetylene into boiling sulphur (Victor Meyer and Sandmeyer, Ber. 1883, 16, 2176); by heating succinic anhydride with phosphorus pentasulphide, or better, sodium succinate with phosphorus trisulphide (Volhard and Erdmann, Ber. 1885, 18, 454; Friedburg, J. Soc. Chem. Ind. 1890, 1062); and in a similar way from erythrol and phosphorus pentasulphide (Paal and Tafel, Ber. 1885, 18, 688); also by the action of sulphuretted hydrogen on diketones thus:



(Paal, *ibid.* 367, 2251).

Liquid, with a faint smell. Boils at 84° (corr.), sp.gr. 1·08844 at 0°. Gives with isatin and sulphuric acid a blue colouring matter, *indophenin*, $C_{12}H_7NOS$ (test for thiophen in benzene) (Schwalbe, Ber. 1904, 37, 1244; Bauer, *ibid.* 3128). Thiophen gives similar coloured condensation products with all compounds containing the group CO·CO (*see* Denigés, Bull. Soc. chim. [iii.] 13, 538; Meyer, Ber. 1883, 16, 1473; Liebermann, *ibid.* 1887, 20, 3231; Claisen, *ibid.* 2197; Oster, *ibid.* 1904, 37, 3348). It gives an intensely red coloration with lactic acid in the presence of sulphuric acid and copper sulphate (Fletcher and Hopkins, Chem. Zentr. 1907, i. 1442), and various colours with different aldehydes (Steensma, *ibid.* 1908, i. 1492).

Thiophen may be determined by shaking 1 grm. of it with 15·15 grms. of mercuric acetate in 60 grms. of water when a white insoluble crystalline powder separates, having the composition $C_4H_4S(HgC_2H_3O_2)_4$ and which may be weighed as such. When heated with aqueous sodium chloride it yields the corresponding chloride, $C_4H_4S(HgCl)_4$, as a white insoluble microcrystalline powder. When heated with alkalis, the chloro compound yields the hydroxy derivative $C_4H_4S(HgOH)_4$ which explodes on heating, metallic mercury separating in the form of a mirror (Paolini, Gazz. chim. ital. 1907, 37, i. 58).

Thiophen may be estimated colorimetrically in benzene by charging 2 measures with 25 c.c. of isatin solution (containing 0·5 grm. isatin in 1000 grms. of pure conc. sulphuric acid) and 25 c.c. pure conc. sulphuric acid. To one of these 1 c.c. of the benzene to be tested is added, to the other 1 c.c. of a test solution containing a definite quantity (from 0·01–0·5 p.c.) of thiophen in benzene and the colours after shaking for 5 minutes are compared on a white base (Schwalbe, Chem. Zeit. 1905, 29, 895).

When boiled with aluminium chloride, thiophen forms an insoluble resin (Heusler, Zeitsch. angew. Chem. 1896, 11, 750; Bödtker, Compt. rend. 1896, 123, 310; Haller and Michel, Bull. Soc. chim. 1896, 15, 1065).

Thiophen combines with mercuric chloride and sulphate (Dimroth, Chem. Zentr. 1901, i. 450; Schwalbe, Ber. 1905, 38, 2208), and also with the acetate as above.

A small quantity of thiophen, mixed with vanillin and concentrated sulphuric acid gives a green or bluish-green colour. A green colour is also formed gradually when wood is moistened with 1–2 drops of thiophen and 10 times the amount of alcohol mixed with an equal volume of sulphuric acid is added (Ihl, Chem. Zeit. 14, 1707). According to Thomas (Bull. Soc. chim. 1909, [iv.] 5, 182, 736), pure thiophen is not reduced by Sabatier and Senderens' method.

When treated with hydrogen peroxide (1–3 p.c. solution), thiophen yields *oxythiophen* $C_4H_4O_2S$, b.p. 130°, and *tetraoxythiophen*, b.p. 158°–160°. Both have a pleasant smell, a burning taste, and give a green coloration with isatin and sulphuric acid. If 25 p.c. hydrogen peroxide is used the oxythiophens are decomposed forming sulphuric acid and yellow resinous products (Lanfry, Compt. rend. 1911, 153, 73).

Both in its physical properties and in its chemical reactions, thiophen closely resembles benzene. Benzene boils at 80°, thiophen at 84°. Like benzene it combines with certain substances as thiophen of crystallisation (Liebermann, Ber. 1893, 26, 853; Prokofjeff, J. Russ. Phys. Chem. Soc. 1897, 29, 87). The halogens, nitric acid, and sulphuric acid react with thiophen, yielding substitution products corresponding with and very similar in properties to those of benzene, excepting that thiophen, owing to its unsymmetrical constitution, forms *two* series of mono-substitution compounds—α-compounds, in which a hydrogen atom adjacent to sulphur is replaced, and β-compounds, in which the substitution takes place with a hydrogen atom in the meta- position to sulphur (Bamberger, Ber. 1897, 30, 369; Willgerodt, J. pr. Chem. 1886, 33, 150; Rosenberg, Ber. 1886, 19, 650; Schleicher, *ibid.* 1885, 18, 3015; Ciamician and Angelli, *ibid.* 1891, 24, 74, 1347, Marcusson, *ibid.* 1893, 26, 2457; Töhl and Schultz, *ibid.* 1894, 27, 2834; *ibid.* 1895, 28, 2217; Eberhard, *ibid.* 2385).

Thiophen diiodide $C_4H_2I_2S$ forms crystalline plates, m.p. 40·5°, and is sometimes used as a substitute for iodoform in surgical cases.

In the presence of anhydrous ether, magnesium dissolves in 2-iodothiophen giving magnesium thiophen iodide which reacts with ketones forming tertiary alcohols, some of which products are described by Thomas (Compt. rend. 1908, 146, 642; *see* also Tschelinzeff, Chem. Zentr. 1905, i. 146).

Sodium thiophen sulphonate $C_4H_3S{\cdot}NaSO_3$ is a white crystalline powder which has been employed in prurigo, being non-toxic and non-irritant: it has proved more effective than β-naphthol. Nitrothiophen (Stadler, Ber. 1885, 18, 530), like nitrobenzene, yields, with reducing agents, the corresponding amino compound (Stadler, *ibid.* 1490; 2316; Goldschmidt and Schulthess, *ibid.* 1887, 20, 1701).

Homologues of thiophen are present in coal-tar benzene and may be separated by methods similar to those used for separating thiophen (Messinger, Ber. 1885, 18, 563, 1636; Keiser, *ibid.* 1896, 29, 2560). Many of these α- and β-homologues are known and may be obtained by a variety of synthetic methods. By treating a mixture of 2-iodo-thiophen and methyl iodide with sodium, 2-*methylthiophen* (thiotolene) can be obtained (Kues and Paal, Ber. 1886, 19, 555; Meyer and Kreis, *ibid.* 1884, 17, 1558). 2-*Ethyl thiophen* may be obtained similarly. For various homologues and their halogen and other derivatives, *see* Grünwald (Ber. 1887, 20, 2585); Zelinsky (*ibid.* 2017; *ibid.* 1888, 21, 1835); Thiele (Annalen, 1892, 267, 133); Opolski (Chem. Zentr. 1905, i. 1255; *ibid.* ii. 1796) amongst others.

2-*Phenylthiophen* is obtained by distilling β-benzoylpropionic acid or benzoylisosuccinic acid with phosphorus tri- or penta-sulphide (Kues and Paal, *ibid.* 1886, 19, 3142). It crystallises in small plates, m.p. 40°–44°.

3-*Phenylthiophen* is obtained by the interaction of thiophen and nitrosoacetanilide. The compound obtained by Möhlau and Berger (*ibid.* 1893, 26, 2001) from diazobenzene chloride and thiophen in the presence of aluminium chloride is a mixture of 2- and 3-phenylthiophens (Bamberger, *ibid.* 1897, 30, 36). 3-Phenylthiophen crystallises in plates, m.p. 90°–90·5°, b.p. 254°–260°. Renard (Compt. rend. 1889, 109,

699) describes another phenylthiophen, m.p. 330°, which was obtained by passing a mixture of the vapours of toluene and sulphur through an iron tube heated to redness.

Diphenyl-, *ditolyl-*, and other diarylthiophens may be obtained by heating mixed aliphatic aromatic ketones in the presence of water and ammonium sulphide at 215° under pressure (Willgerodt and Scholtz, Chem. Zentr. 1910, i. 1969). For another method of obtaining the diphenylthiophens, *v.* Baumann and Fromm (Ber: 1895, 26, 2001).

Dinaphthathiophen $C_{20}H_{12}S$, and *benzdithiophen* $C_{10}H_6S_2$, have been isolated from the product obtained from the interaction of the vapours of sulphur and naphthalene at a red heat. The former crystallises in pearly yellow scales, melts at 250·5° (corr.), and boils above 440°. It yields a hexabromo derivative $C_{20}H_6Br_6S$, m.p. 260°, and a tetranitro derivative

$$C_{20}H_8(NO_2)_4S,$$

m.p. 210° (*circa*). Oxidation with chromic acid gives phthalic acid. The latter crystallises in ruby red leaflets, melts at 118·5° (corr.), and boils at 345°. It gives the thiophen reaction with sulphuric acid and isatin. From it a tetrabromo derivative $C_{10}H_2Br_4S_2$, m.p. 247°–248°, and a tetranitro derivative $C_{10}H_2(NO_2)_4S_2$, decomposing at 300°, have been obtained (Lanfry, Compt. rend. 1911, 152, 92, 1254). Other naphthalenethiophens have been described by Dziewonski (Bull. Soc. chim. 1904, [iii.] 31, 925).

Dithiënyl $(C_4H_3S)_2$, m.p. 83°, is formed when the vapour of thiophen is passed through a red-hot tube, just as diphenyl $(C_6H_5)_2$ is formed under these conditions from benzene (Nahnsen, Ber. 1884, 17, 789). Töhl (*ibid.* 1894, 27, 665) obtained another dithiënyl, m.p. 33°, by the action of anhydrous feebly fuming sulphuric acid on ice cold thiophen. A third dithiënyl, m.p. 132°, was obtained by Auwers and Predt (*ibid.* 1741) by heating butane tetracarboxylic acid with phosphorus sulphide.

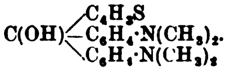
Thiophen carboxylic acids may be obtained by oxidising the corresponding alkyl thiophens and also by various other methods (Nahnsen, Ber. 1884, 17, 2197; Peter, Ber. 1885, 18, 542; Messinger, *ibid.* 563; Nahnsen, *ibid.* 2304; Schleichter, *ibid.* 3015; Damsky, *ibid.* 1886, 19, 3282; Levi, *ibid.* 656; Curtius, Chem. Zentr. 1902, i. 457; Holleman and Voerman, Proc. K. Akad. Wentesch. Amsterdam, 1907, 9, 514; Rec. trav. chim. 1907, 26, 293; Schorigin, Ber. 1910, 43, 1938). Thiophen-2-carboxylic acid, m.p. 126°–127°; thiophen-3-carboxylic acid, m.p. 136°; and three dicarboxylic acids are known.

Thiophen aldehyde $C_4H_3S{\cdot}CHO$, a pale yellow oil, b.p. 198°, having a pleasant smell, is obtained by the distillation of α-thienylglyoxylic acid $C_4H_3S{\cdot}CO{\cdot}CO_2H$ (Biedermann, Ber. 1886, 19, 1853) or by the action of sulphuretted hydrogen on chlordiketopentamethylene

$$\begin{matrix}CH_2\text{—}CHCl\\CH_2\text{——}CO\end{matrix}\!\!>\!CO$$

(Hantzsch, *ibid.* 1889, 22, 2838: Hantzsch and Witz, *ibid.* 1901, 34, 841). On oxidation it yields the α-acid. Many of its derivatives are known. Thiophen ketones and a large number of other derivatives of thiophen have been prepared.

Thiophen green



$$C(OH)\begin{cases}C_4H_3S\\C_6H_4{\cdot}N(CH_3)_2\\C_6H_4{\cdot}N(CH_3)_2\end{cases}$$

This compound, which was discovered by L. E. Levi (Ber. 1887, 20, 513), is an analogue of malachite green. The leuco base

$$CH(C_4H_3S)[C_6H_4{\cdot}N(CH_3)_2]_2$$

is first prepared by heating a mixture of one part of thiophenaldehyde, 2 parts of dimethylaniline with a little alcohol, and 3 to 4 parts of zinc chloride for 6 hours, adding the zinc chloride gradually, and, if the mass becomes thick, diluting slightly with water. The product is made alkaline with caustic soda, steam-distilled, extracted with ether, and the crystalline residue which is left on evaporating the ether recrystallised from alcohol. This crystalline leuco base is then oxidised with manganese dioxide and dilute sulphuric acid, when it yields thiophen green. The colouring matter is extracted with hot water, filtered from manganese dioxide, precipitated with ammonium chloride and ammonia, and extracted with ether. It is, as represented by the formula, the carbinol corresponding with the leuco base. Like malachite green, it forms a double salt with zinc chloride. It dyes silk and wool a shade very much like that of malachite green, but somewhat yellower.

W. Krause (Internat. Monatschr. Anat. u. Physiol. 4, 2; J. Soc. Chem. Ind. 1887, 507) recommends the use of the zinc double salt of thiophen green for staining sections, especially as a complementary colour to carmine. It dissolves readily in water, alcohol, and chloroform, but is insoluble in benzene.

THORIANITE. A heavy, black mineral consisting of thoria (51–80 p.c.) with uranium oxides (11–32·7 p.c.), &c. It is isomorphous with pitchblende (*q.v.*) and very similar to the crystallised varieties of this in most of its characters. The principal difference between the two minerals is in the relative amounts of the thorium and uranium oxides, thorianite being essentially $(Th,U)O_2$ and pitchblende $(U,Th)O_2$. Thorianite is known only from Ceylon, where it is found in the stream-beds and in the gem-bearing alluvial gravels at several spots in the Central, Sabaragamuwa, and Southern provinces. The heavy minerals occurring with it, and separated by the gemmers from the alluvia by a simple process of washing, are zircon, ilmenite, thorite, gold, &c. The largest amounts have been obtained from the Kuda Pandi-oya, a small stream in the Bambarabotuwa district, about 20 miles from Balangoda in the Sabaragamuwa province; but the deposits are of limited extent, and soon become exhausted. The occurrence of the mineral *in situ* has also been noted at one or two places (Gampola and Maddegama) in Central province, a few crystals having been found in pegmatite-veins. Prospecting for the original sources is, however, difficult, owing to the thick growths of jungle.

Thorianite is found as small, simple cubes, usually only a few mm. across, and only exceptionally reaching 2 or 3 cm. Interpenetratio twins, like those of fluor-spar, are occasionally met with. The colour is jet-black, and, when the surface is not water-worn and dulled, the lustre is bright and pitchy. The streak is brown with a tinge of green; thin sections are translucent and optically isotropic. The high sp.gr. of about 9·5 is a striking feature; hardness nearly 7. The mineral is soluble in nitric acid and in sulphuric acid, but is scarcely attacked by hydrochloric acid. It is the richest known source of helium, 8·2–9·5 c.c. per gram being given off when the mineral is heated or dissolved in acid. Its radioactivity is less than that of pitchblende, there being less radium but more radiothorium. Nipponium and some other possibly new elements have been extracted from thorianite (M. Ogawa, 1908: C. de B. Evans, 1908).

Analysis I. of thorianite from near Balangoda (W. R. Dunstan and B. M. Jones, Proc. Roy. Soc. 1906, A, 77, 546). II. same locality (Dunstan and G. S. Blak·, *ibid.* 1905, A, 76, 253). III. ditto (Dunstan, Nature, 1904, 69, 510). IV. ditto (E. H. Büchner, Proc. Roy. Soc. 1906, A, 78, 385). V. and VI. from Galle, Southern province (Dunstan and Jones, *l.c.*).

Thorianite contains a higher percentage of thoria than any other known mineral, and it has been employed as a source of thoria for use in incandescent gas mantles. The amount exported from Ceylon in 1905 was about 9 tons, which sold for £1600 to £1700 per ton; since then, however, the price of thoria has fallen considerably.

For local details of occurrence, &c., *see* Administration Reports, Ceylon, Colombo, 1904, &c.; Colonial Reports, Miscell. Ser., Ceylon Mineral Survey, London, 1904, &c.

L. J. S.

THORITE. A mineral consisting essentially of thorium silicate, $ThSiO_4$, crystallising in the tetragonal system and isomorphous with zircon. Analyses show: SiO_2, 12–19; ThO_2, 48–74 (the formula requires 81·5); U_2O_3, 1–10; Ce_2O_3, 0–3; H_2O, 6–10 p.c. The presence of water appears to be due to secondary alteration; and the fact that the mineral is frequently optically isotropic and amorphous indicates that it is not fresh. The colour is yellow to dark brown, and in the orangite variety (*q.v.*) a bright orange-yellow; the lustre is resinous; sp.gr. 4·4–5·4. The mineral occurs as small masses and indistinct crystals in the augite-syenite on the Langesund-fjord and near Arendal, and a few other places in the south of Norway. It is also found, together with thorianite, in the gem-gravels of Ceylon. Small amounts are collected for the preparation of thorium compounds and used principally for the mantles of incandescent gas-lights. L. J. S.

THORIUM. Sym. Th. At.wt. 232·4. This element, which has the highest atomic weight of the metals of the rare earth series, was identified by Berzelius in 1829 as occurring in the form of silicate in the mineral thorite, obtained from the island of Löv-ön (near Brevig, Norway).

Occurrence.—Thoria is present as the main constituent in thorite, orangite, and their alteration products, mackintoshite, auerlite, calciothorite, and freyalite, and in thorianite (Dunstan and Jones, Proc. Roy. Soc. 1905, 76 A, 253: 1906, 77 A, 546; Szilard, Compt. rend. 1907, 145, 463). It occurs in variable amounts (1–18 p.c.) in monazite, and yttrocrasite (Amer. J. Sci. 1906, [iv.] 22, 515).

Extraction and Purification.

1. *Separation from thorite, orangite,* and *thorianite.* These minerals are easily decomposed by the strong mineral acids when silicic acid separates, and the solution containing the metallic constituents is freed from lead, bismuth, &c., by hydrogen sulphide. Thorium is then separated in the form of its octahydrated sulphate $Th(SO_4)_2,8H_2O$, which separates from aqueous solutions below 47°. This salt is redissolved in water, and oxalic acid added to precipitate thorium oxalate, which is then ignited to thoria and the cycle of operations repeated (Krüss and Nilson, Ber. 1887, 20, 1665).

Thorium salts may be separated from those of the cerite metals by dissolving in alkali carbonates or oxalates. But this process brings into solution also small amounts of the ytterbite metals, which, however, do not occur in thorium minerals to any large extent. Solutions of thorium salts readily undergo hydrolytic change when boiled with sodium thiosulphate, thorium hydroxide being precipitated mixed with sulphur; this operation separates thorium from all rare earth metals excepting scandium and zirconium (Bunsen, Pogg. Ann. 1875, 155, 379; Moissan and Étard, Compt. rend. 1896, 122, 573; Urbain, Bull. Soc. chim. 1896, [iii.] 15, 338; Brauner, Chem. Soc. Trans. 1898, 73, 951).

2. *Separation from monazite sand.* Monazite, an orthophosphate of the cerite metals which contains varying proportions of thorium, is very widely diffused in the earth's crust, occurring primarily as an accessory constituent of certain plutonic rocks (granites, diorites, gneisses, &c.). It is, however, chiefly in its secondary form of monazite sand that the mineral is exploited for the gas-mantle industry. The erosive action of rivers and tides on the original monazite containing rocks gives rise to enormous accumulations of monazite sands found in littoral and fluviatile deposits chiefly in Brazil (Bahia and Minas Geraes) and in North and South Carolina. Less extensive strata are found in Australia and the Ural Mountains, and certain deposits on the coast of Travancore have acquired some importance.

In addition to the yellow grains of monazite, the sand contains fragments of magnetite, chromite, titanite, quartz, felspar, hornblende, rutile, brookite, zircon, and small quantities of rare-earth minerals (*e.g.* samarskite, æschynite).

---

[1] Also He, 0·39.

[2] Also ZrO_2, 3·68 (due to enclosed zircon); SiO_2, 1·34; sp.gr. 8·98.

[3] Also ZrO_2, 0·23; SnO_2, 0·05; Sb_2O_4, 0·11; Al_2O_3, 15; etc.

After some preliminary mechanical or magnetic dressing the monazite sand is decomposed by heating with concentrated sulphuric acid, and the product dissolved in cold water, the residue containing the unattacked constituents of the sand, quartz, zircon, titanite, &c. The acid solution is partially neutralised with magnesia, sodium hydroxide or ammonia until precipitation of the phosphates of the rare-earth metals occurs, when thorium phosphate, being the least soluble of this series, is concentrated in the first fractions. The phosphate is dissolved in strong hydrochloric acid and the thorium reprecipitated by oxalic acid.

The sparing solubility of thorium oxalate in solutions containing excess of mineral acid serves also to separate thorium from the commoner metals (iron, manganese, calcium, &c.).

The thorium oxalate in the precipitate when warmed with aqueous sodium carbonate passes into solution together with small quantities of any ytterbite metals present. The cerite metals remain for the chief part undissolved in the form of double carbonates.

The thorium in the carbonate solution is reprecipitated either as oxalate by adding acid or as hydroxide by adding caustic soda. Further purification is effected by converting the oxalate or hydroxide into sulphate and crystallising repeatedly the octahydrated salt (Koppel and Holtkamp, Zeitsch. anorg. Chem. 1910, 67, 266).

A method similar in principle to the foregoing is based on the employment of normal sodium sulphite when salts of thorium (and zirconium) form double sulphites

(*e.g.* $Th_2(OH)_2(SO_3)_3,2Na_2SO_3,22H_2O$)

soluble in excess of aqueous alkali sulphite, whereas the cerite metals remain for the most part undissolved (Chavastelon, Compt. rend. 1900, 130, 781; Grossmann, Zeitsch. anorg. Chem. 1905, 44, 229; Batěk, *ibid.* 45, 87).

Hydrated thorium peroxide is precipitated by hydrogen peroxide from acid solutions of thorium salts, but in presence of cerite metals a certain amount of cerium is co-precipitated. The operation must be repeated several times to effect a complete separation (Wyrouboff and Verneuil, Bull. Soc. chim. 1898, [iii.] 19, 219; Compt. rend. 1898, 127, 412).

A separation of thorium and zirconium from the cerium and yttrium elements is brought about by stirring thoroughly into a dilute solution of the nitrates (containing tervalent cerium) an excess of freshly-prepared lead carbonate. After 12 hours the hydrates of thoria, zirconia, and ferric oxide are completely precipitated, the hydroxides of aluminium, chromium, and uranium are partially deposited, whilst cerium, yttrium, and other rare earth metals remain in solution. The precipitate is redissolved and the thoria present is further purified (Giles, Chem. News, 1905, 92, 130). The sparingly soluble basic acetate (Böhm, Die Darstellung der seltenen Erden, vol. i. 40, 1290), and the chromate (Ber. 1900, 33, 2028) have been recommended for separating thorium from the cerite metals. The acetylacetonate may be employed in purifying small quantities of thoria; the well-dried salt is extracted with chloroform, in which thorium acetylacetonate alone dissolves (Urbain, Bull. Soc. chim. 1896, [iii.] 15, 338, 347; Ann. Chim. Phys. 1900, [vii.] 19, 184). Repeated precipitation of thorium by potassium azide is recommended as a mode of separation and purification (Dennis and Kortright, Amer. Chem. J. 1894, 16, 79; J. Amer. Chem. Soc. 1896, 18, 947).

m-Nitrobenzoic acid precipitates thorium quantitatively as thorium *m*-nitrobenzoate in presence of aniline or from neutral solutions of the rare-earth nitrates derived from monazite, and a repetition of the process affords a complete separation from cerium, lanthanum, neodymium, and praseodymium, but the first of these elements must be in the tervalent condition, otherwise the sparingly soluble yellow ceric *m*-nitrobenzoate is deposited (J. Amer. Chem. Soc. 1904, 26, 780; Zeitsch. angew. Chem. 1905, 18, 92). This method avoids the use of alcohol, which is required in the separation of these metals with fumaric acid.

Certain organic bases have a selective action in the precipitation of the hydroxides of the rare earths; *p*-toluidine separates thorium and zirconium from lanthanum, neodymium, and praseodymium, whilst hexamethylenetetramine and the chloranilines serve to separate thorium from zirconium (Hartwell, J. Amer. Chem. Soc. 1903, 25, 1128).

The resolution of thoria into three chlorides differing in volatility and containing respectively three elements with different atomic weights has not been confirmed (Baskerville, *ibid.* 1904, 26, 922; Ber. 1905, 38, 1444; *cf.* R. J. Meyer and Gumperz, *ibid.* 1905, 38, 817; Eberhard, *ibid.* 38, 826).

Metallic thorium. The isolation of the metal in a pure state is a matter of considerable difficulty owing to its infusibility, and to its power of combining with nitrogen, hydrogen, carbon, silicon, and the metals. The reduction of thoria with magnesium is not complete (Ber. 1891, 24, 873); the action of silicon and aluminium on thoria or on potassium thorium fluoride leads respectively to the formation of a silicide $ThSi_2$, and an alloy $ThAl_3$ (Compt. rend. 1906, 142, 157, 280). Reduction of the chloride or double potassium chloride with sodium at red heat in an iron cylinder gives a product still containing thoria. A rolled specimen of metal obtained in this way melted at 1450° and had sp.gr. 12·14 (Ber. 1883, 16, 153; Compt. rend. 1883, 96, 346; Ann. Chim. Phys. 1906, [viii.] 8, 182; Zeitsch. Elektrochem. 1908, 14, 768). Electrolysis of thorium chloride dissolved in a fused mixture of sodium and potassium chlorides contained in a graphite crucible afforded a product melting at 1700° (*ibid.* 1909, 15, 866). Alloys of thorium are obtained by reducing, with sodium or with carbon and sodium hydroxide, mixtures of thorium salts with those of more fusible metals (Sn, Pb, Sb, Al, or Cu), and thorium fluoride heated with tin or lead gives thorium alloys of these metals (D. R. P. 146503).

Reduction of thoria by amorphous boron leads to the formation of two *thorium borides*, ThB_4, prismatic crystals, sp.gr. 7·5 at 15°, and ThB_6, reddish-violet mass, sp.gr. 6·4 at 15°: the former is soluble and the latter insoluble in concentrated hydrochloric acid (Compt. rend. 1905, 141, 191).

Colloidal thorium is prepared by rubbing 95–96 p.c. thorium with cold dilute hydrochloric acid and washing the mass on a filter until a grey opalescent solution passes through; this liquid is stable to acids, but not to alkalis. On electrification the thorium particles are found to carry a positive charge (Zeitsch. Chem. Ind. Kolloide, 1909, 5, 191).

Thorium hydride ThH_4, produced by direct combination of the metal and hydrogen at red heat, or by absorption of the gas by a heated mixture of thoria and magnesium. It is not decomposed by water, but evolves hydrogen on treatment with hydrochloric acid (Ber. 1891, 24, 873; Compt. rend. 1900, 131, 891; 1901, 132, 36; Ann. Chim. Phys. 1907, [viii.] 10, 130).

Thorium carbide ThC_2, yellow microscopic crystals, sp.gr. 8·96 at 18°, prepared by heating an intimate mixture of thoria and carbon in the electric furnace (900 ampères, 50 volts), is decomposed by cold water evolving acetylene, methane, ethylene, and hydrogen (Compt. rend. 1893, 116, 1227; 1896, 122, 573; Ann. Chim. Phys. 1897, [vii.] 12, 427).

Thorium silicide $ThSi_2$, quadratic plates, sp.gr. 7·96/16°, produced by heating to 1200° a mixture of potassium silico- and thoro-fluorides and aluminium (Chem. Zeit. 1906, 29, 1031; Compt. rend. 1906, 142, 157).

Thorium nitride Th_3N_4, brown powder, obtained by direct union of its components at high temperatures; by heating a mixture of thorium and ammonium chlorides in hydrogen chloride, or by passing ammonia over heated thorium carbide; it is decomposed by water with evolution of ammonia (Compt. rend. 1896, 122, 573; 1900, 131, 837; 1901, 132, 36: Ann. Chim. Phys. 1897, [vii.] 12, 427; 1907, [viii.] 10, 130).

Thorium sulphide ThS_2, dark-brown lamellæ sp.gr. 6·7 at 0°, and **thorium oxysulphide** ThOS, yellow crystalline powder, sp.gr. 8·42 at 0°, are produced by passing hydrogen sulphide over a mixture of thorium chloride and excess of sodium or potassium chloride at red heat (Compt. rend. 1908, 146, 815; *cf.* Zeitsch. anorg. Chem. 1907, 53, 74).

Thorium fluoride ThF_4, white amorphous powder, resulting from the interaction of hydrogen fluoride and thorium chloride or bromide at 354°–400° (Compt. rend. 1908, 146, 973). The *hydrate* $ThF_4,4H_2O$, a gelatinous precipitate, obtained on adding hydrofluoric acid to solutions of thorium salts, changes to a heavy white powder, the insolubility of which in excess of the precipitant serves as a separation of thorium from zirconium (Bull. Soc. chim. 1897, [iii.] 20, 69); *double fluorides* have been prepared approximating to the composition $KTh_2F_9,6H_2O$ and $KThF_5,H_2O$, and not to the typical fourth-group formula $K_2R^{IV}F_6$ (Zeitsch. anorg. Chem. 1903, 35, 424).

Thorium chloride $ThCl_4$ can be prepared by the following methods, but unless oxygen and moisture are carefully excluded, the product is always contaminated with oxychloride: (i.) heating metallic thorium in hydrogen chloride (Ber. 1887, 20, 1665; Zeitsch. physikal. Chem. 1887, 1, 301); (ii.) heating thoria in carbon tetrachloride vapour or in a mixture of carbon monoxide and chloride (Compt. rend. 1901, 132, 36, 1908; 147, 1046; Ann. Chim. Phys. 1907, [viii.] 10, 130); (iii.) heating thoria in chlorine saturated with sulphur chloride (Compt. rend. 1904, 138, 631; *cf.* Ber. 1905, 38, 817); (iv.) decomposing the heated carbide with chlorine (Compt. rend. 1905, 140, 1510). When purified by sublimation *in vacuô* (720°–750°) the chloride is obtained in colourless needles or prisms, sp.gr. 4·59, m.p. 820°.

Thorium oxychloride $ThOCl_2$ is an intermediate product obtained in the foregoing operation (No. ii.); it crystallises from alcohol and absorbs $6H_2O$ from moist air. The *hydrate* $ThCl_4,8H_2O$ is readily soluble in water or alcohol, and the soluble *hydroxy-chlorides* $Th(OH)Cl_3,7H_2O$ and $Th(OH)_2Cl_2,5H_2O$ have been isolated.

Thorium chloride combines with ammonia to form several additive compounds, of which $ThCl_4,4NH_3$ alone is stable above 120° (Compt. rend. 1910, 151, 387). Additive compounds are also formed with organic bases and with alcohols and aldehydes (Zeitsch. anorg. Chem. 1903, 35, 424; Ber. 1904, 37, 3662).

Thorium bromide $ThBr_4$, transparent colourless needles, sp.gr. 5·62, unstable in the light, evolving bromine, boils at 725° and sublimes *in vacuô* at 600°–620° (Compt. rend. 1905, 140, 1510; 1907, 145, 243).

Thorium platinocyanide $Th[Pt(CN)_4]_2,16H_2O$, yellow rhombic prisms from thorium sulphate and barium platinocyanide.

Thorium hydroxide $Th(OH)_4$, heavy white powder, readily soluble in mineral acids or in aqueous alkali carbonates. The hydrosol form of this hydroxide is produced by dialysing solutions of thorium nitrate or by adding thorium nitrate solution gradually to the well-washed hydrosol and boiling the mixture until an opalescent solution is obtained. Thorium hydroxide hydrogel is also converted into the hydrosol form by diluted (N/20) hydrochloric acid, or by solutions of aluminium or ferric chloride (Biltz, Ber. 1902, 35, 4436; 1904, 37, 1100; Müller, *ibid.* 39, 2857; Zeitsch. anorg. Chem. 1908, 57, 314; J. Chim. Phys. 1907, 5, 488, 495).

The so-called *thorium meta-oxide* is a soluble modification of thoria, produced by igniting the oxalate or hydroxide at comparatively low temperatures and evaporating the residue with hydrochloric or nitric acid until a syrup is left, which dissolves in water to a milky solution, appearing yellow by transmitted light (Cleve, Jahrb. Min. 1874, 161; Stevens, Zeitsch. anorg. Chem. 1901, 27, 41; Wyrouboff and Verneuil, *ibid.* 28, 90; Compt. rend. 1898, 127, 863).

Thorium dioxide (*thoria*) ThO_2, white powder, sp.gr. 10·220 at 17°, is obtained by igniting the hydroxide or the thorium salts of volatile acids.

Thorium peroxide is a gelatinous white precipitate, retaining acid and of somewhat uncertain composition, formed by adding hydrogen peroxide to solutions of thorium salts; its peroxide character is manifested by the liberation of iodine from potassium iodide (Compt. rend. 1898, 126, 340; Bull. Soc. chim. 1898, [iii.] 19, 219; Ann. Chim. Phys. 1906, [viii.] 6, 441; Zeitsch. anorg. Chem. 1900, 25, 378; 1902, 31, 359; R. Accad. Sci. Torino. 1911, 46, 195).

Thorium sulphate $Th(SO_4)_2$, obtained in the anhydrous condition by treating thoria with concentrated sulphuric acid, dissolves in ice-cold water to a 25 p.c. solution, which is supersaturated at all temperatures from 0° to 100° and yields between 0° and 43° (or 47° ?) either spontaneously or after seeding, monoclinic prisms of the *nonahydrate* $Th(SO_4)_2,9H_2O$, and above the latter temperature needles of the *tetrahydrate* $Th(SO_4)_2,4H_2O$; these hydrates are isomorphous with the corresponding uranous compounds $U(SO_4)_2,9H_2O$ and $U(SO_4)_2,4H_2O$ (Zeitsch. Krist. 1900, 32, 250; 1901, 34, 307).

The *octahydrate* $Th(SO_4)_2,8H_2O$, prismatic crystals, separates under conditions similar to those which favour the formation of the more stable nonahydrate, and owes its production to the existence of a metastable phase having a very low velocity of transformation (Bull. Soc. chim. 1901, [iii.] 25, 105; Bull. Soc. Min. 1901. 24, 105; Ber. 1887, 20, 1665; 1905, 38, 817).

The *acid sulphate* $ThSO_4(HSO_4)_2$, needles, is obtained by drying *in vacuô* at 130°, the product of the action of concentrated sulphuric acid on a saturated solution of the anhydrous normal sulphate (Zeitsch. anorg. Chem. 1904, 38, 322); a *hydrated acid sulphate* $2Th(SO_4)_2,H_2SO_4,2H_2O$ (Gazz. chim. ital. 1903, 32, ii. 523); and a *basic sulphate* $ThOSO_4,2H_2O$ (Compt. rend. 1883, 96, 1860; 1910, 151, 70; Ber. 1910, 43, 2776) have been described. The following *double sulphates* have been isolated: $K_4Th(SO_4)_4,2H_2O$, sparingly soluble; $K_8Th(SO_4)_6,2H_2O$; the corresponding ammonium salt series;

$Rb_2Th(SO_4)_3,2H_2O$;

$Cs_2Th(SO_4)_3,2H_2O$; $Na_2Th(SO_4)_34$ and $12H_2O$ (Bull. Soc. Min. 1901, 24, 105; Zeitsch. anorg. Chem. 1903, 35, 424; Gazz. chim. ital. 1903, 32, ii. 523).

Thorium nitrate $Th(NO_3)_4$, with 5, 6, and $12H_2O$, the dodecahydrate separating in hygroscopic plates (Cleve, *l.c.*; *cf.* Zeitsch. angew. Chem. 1897, 115; Chem. Soc. Trans. 1898, 73, 951). The commercial product, which is not a definite hydrate, but approximates to $Th(NO_3)_4$ with $4H_2O$, swells up considerably on ignition, leaving a finely divided residue of snow-white thoria. Commercial thorium nitrate should contain from 48 to 50 p.c. of ThO_2; a considerably higher percentage of oxide indicates the presence of yttrium metals.

Thorium nitrate unites with the nitrates of univalent and divalent metals, forming complex nitrates, having respectively the general formulæ $R_2'Th(NO_3)_6$ and $R''Th(NO_3)_6,8H_2O$, which correspond with the double nitrates containing quadrivalent cerium. Similar double nitrates (and sulphates) are formed with organic bases (Zeitsch. anorg. Chem. 1901, 27, 359; 1908, 60, 123).

Complex thorium carbonates. Normal thorium carbonate is not known, but complex carbonates are prepared by adding soluble carbonates to thorium solutions until the precipitate first formed redissolves or by dissolving thorium hydroxide in aqueous alkali bicarbonate, saturated with carbon dioxide; the product is precipitated by alcohol. *Sodium thorium carbonate* $Na_6Th(CO_3)_5,12H_2O$ separates in prismatic crystals; the thallous salt $Tl_6Th(CO_3)_5$ is precipitated as a crystalline powder on adding a soluble thallous salt to a solution of ammonium thorium carbonate (Cleve, *l.c.*; *cf.* Zeitsch. anorg. Chem. 1903, 35, 424).

Thorium formate $Th(HCO_2)_4,3H_2O$ and **thorium acetate** $Th(CH_3{\cdot}CO_2)_4$, crystallising respectively in leaflets and needles, are produced by dissolving thoria in the corresponding acids; interaction between thorium salts and soluble formates and acetates leads to basic salts $Th(OH)_2(HCO_2)_2$ and $Th(OH)_2(CH_3{\cdot}CO_2)_2,H_2O$ (Haber, Monatsh. 1897, 18, 687).

Thorium oxalate $Th(C_2O_4)_2,6H_2O$ is precipitated completely by adding oxalic acid to thorium solutions even in the presence of considerable proportions of mineral acid (Brauner, Chem. Soc. Trans. 1898, 73, 951). Complex oxalates such as $K_4Th(C_2O_4)_4,4H_2O$ and $Na_4Th(C_2O_4)_4,6H_2O$ are produced by dissolving thorium oxalate in concentrated solutions of alkali oxalates (Cleve, *l.c.*; and Brauner, *l.c.*).

Thorium acetylacetonate $Th[CH(CO{\cdot}CH_3)_2]_4$, m.p. 171°, soluble in alcohol or chloroform, is prepared by adding acetylacetone dissolved in aqueous ammonia to 13 p.c. thorium nitrate solution. This salt can be distilled *in vacuô* (Urbain, Bull. Soc. chim. 1896, [iii.] 15, 1338; Biltz, Annalen, 1904, 331, 334; Zeitsch. anorg. Chem. 1904, 40, 218).

Thorium tartrates and **complex tartrates**, *v.* Cleve, *l.c.*; Haber, *l.c.*; Rosenheim, Zeitsch. anorg. Chem. 1903, 35, 424.

Thorium salts of other organic acids, *v.* Morgan, Pharm. J. 1904, [iv.] 19, 472; and Karl, Ber. 1910, 43, 2068.

Thorium oleate has been employed therapeutically in ointment form for carbuncles and other skin troubles (Martindale, Extra Pharmacopœia).

Pharmacological action of thorium, *v.* Sollmann and Brown, Amer. J. Physiol. 1907, 18, 426.

Biological action of thorium. Elemental thorium inhibits the growth of certain microorganisms and algæ without endangering the life of higher organisms (Amphioxus, Zeitsch. Elektrochem. 1911, 17, 816; Arch. Sci. Phys. Nat. 1911, [iv.] 32, 347).

Industrial application of Thoria v. GAS MANTLES. Gas mantles are generally woven in cotton or preferably ramie fibre, but artificial silk has also been employed, and formerly the thorium-cerium solution was added to the dissolved cellulose before it was spun into thread. The present practice, however, is to impregnate the woven stocking just as in the case of ramie or cotton fibre. The rare earth nitrates may be replaced by the corresponding acetates or formates and, with artificial silk, the impregnated stocking is treated with ammonia or some volatile alkali such as hydrazine or tetraethylammonium hydroxide in order to produce within the fibres the hydroxides of thorium and cerium. Hydrogen peroxide may also be employed as the precipitant. In either case, the stockings are washed free from soluble salts (ammonium nitrate, &c.) or acid; the head is hardened with a solution of magnesium, aluminium, zirconium, glucinum or chromium salt, and the mantle 'burnt off' and 'seasoned' as in the case of the ramie fibre.

Although in most instances the optimum effect is attained by mixing the thorium and cerium salts in such proportions that the mixed oxides of the mantle consist of 99·0 p.c. of thoria and 1·0 p.c of ceria, yet owing to the yellow colour of the light produced by this amount of ceria in inverted mantles using high-pressure gas, it is customary in this form of illumination to reduce the proportion of ceria to 0·5 p.c.

A pure thoria mantle gives no emission in the visible region of the spectrum and only a slight radiation of infra-red rays of short wave length. A cerium dioxide mantle gives a maximum radiation at the extreme red end of the visible spectrum, the intensity at first diminishes in the infra-red region and then increases again for heat rays of longer wave length. In this mantle there is, on the whole, a relatively considerable loss of heat by radiation, the temperature remains comparatively low and consequently the emission of light rays is only feeble.

In the Welsbach mantle containing 0·5 p.c. to 1·5 p.c. cerium dioxide, the emission of light is selective and attains its maximum in the blue region of the spectrum. On the other hand, the heat radiation is remarkably small, except for rays of comparatively long wave length. Consequently the temperature attained by the mantle is comparable with that of the flame itself. The cerium dioxide colours the transparent ground mass of thoria so that an intense selective absorption is developed in the visible region of the spectrum and, providing that the amount of colouring oxide is small, this result is attained without any appreciable increase in the loss of heat by radiation and consequently without diminution in the intensity of illumination.

One hundred parts of thoria can hold in solid solution 6·7 parts of cerium dioxide, and as the mantle contains only about 1 p.c. of the latter oxide, it is entirely in the dissolved condition. Owing to this intimate mingling of the two oxides, a very small addition of cerium dioxide suffices to bring about the intense emission of light waves whilst the increase in heat radiation is too slight to act injuriously. If, however, the proportion of cerium is raised, the greater loss of heat by radiation leads to lowering of the mantle temperature and consequent diminution in luminosity. Cerium dioxide itself is stable in the Bunsen flame, but nevertheless the ignited mixed oxides, when treated with hydrochloric acid and potassium iodide solution liberate an amount of iodine corresponding with only a portion of the dioxide originally introduced into the mixture. This result suggests the possibility of some chemical combination between the cerium and thorium oxides which may be the chemical cause of the characteristic physical properties of the Welsbach gas-mantle (*cf.* White and Traver, J. Soc. Chem. Ind. 1902, 21, 1012; Lewes, Chem. News, 1905, 26, 62; Journ. Gas Beleuchtigung, 1903, 46, 787, 974; R. J. Meyer and Anschütz, Ber. 1907, 40, 2639).

Radio-activity of Thorium.

Thorium preparations, in general, exhibit radio-activity, yielding α-rays of similar intensity but greater penetrative power than those of uranium. The β-rays from thorium are about one-tenth as intense as those from uranium, and have less penetrating power. The γ-rays are relatively feeble but very penetrating. It has been stated that the radio-activity of thorium from monazite is due to the uranium present in this mineral, and that minerals free from uranium yield inactive thorium (Baskerville, J. Amer. Chem. Soc. 1904, 26, 1642; Zerban, Ber. 1903, 36, 3911; 1905, 38, 557). On the other hand, minerals free from radium have been found to give helium and thorium emanation (Strutt, Proc. Roy. Soc. 1905A, 76, 88, 312; 1907A, 80, 56; Hahn, Ber. 1905, 38, 3371). After allowing for uranium, a constant ratio between the radio-activity and amount of thorium was found for thorium minerals in which, probably, thorium and radiothorium are in equilibrium. In thorium salts, where the radiothorium is largely removed, this constancy does not exist. Boltwood has not succeeded in obtaining inactive thorium (Amer. J. Sci. 1906, 21, 415, and 433).

Thorium hydroxide precipitated by ammonia from a solution of a thorium salt has no emanating power and only a greatly diminished α-radiation. The filtrate retains the whole of the emanating power, and the minute residue obtained on evaporation and ignition possesses the radio-activity which the precipitate has lost. The emanating power and radio-activity of this product, thorium X, disappear in the course of a month, decaying to half their original value in four days. The precipitated thorium hydroxide recovers the properties just as fast as they disappear from thorium X, and a second treatment of its acid solution by ammonia after one month leads to the separation of another quantity of thorium X having the same activity as the first fraction. Thorium X, a short-lived radioactive product of thorium, produces gaseous thorium emanation, and this in turn gives thorium 'active deposit,' which imparts radioactivity ('induced activity') to solid objects brought into contact with this disintegration product (Rutherford and Soddy, Chem. Soc. Trans. 1902, 81, 321, 837; Phil. Mag. 1902, 4, 370, 569).

Owing to the complicated nature of the disintegration changes the radio-activity of a thorium preparation is a complex function of its age. The sequence of these changes is indicated in the annexed diagram.

Mesothorium 1 is separated from thorianite by adding 26 grms. of barium nitrate to 1·5 litres of a slightly acid solution of 600 grms. of the mineral in nitric acid and by shaking the solution for an hour with excess of sulphuric acid when the sulphate of mesothorium 1 is coprecipitated with barium sulphate. The radioactive precipitate is reduced to sulphide by heating with sugar carbon in a quartz crucible and the product dissolved in hydrochloric acid. The lead is precipitated from this solution by hydrogen sulphide and traces of iron and thorium by ammonia. The radio-active chloride in the filtrate is crystallised out fractionally when mesothorium 1 is concentrated in the least soluble portions (Hahn, Ber. 1907, 40, 1462, 3304).

From monazite sand, mesothorium 1 is isolated by adding 0·1 p.c. of barium carbonate and heating the sand (400 grms.) with 800 grms. of concentrated sulphuric acid. The product is thoroughly mixed with cold water when the sediment contains practically the whole of the mesothorium 1 and radium. These two active components are concentrated from the barium sulphate precipitate by converting this product successively into sulphide and chloride, and fractionating the latter from water when the mesothorium 1 accumulates in the least soluble crystals (Soddy, Eng. Pat. 25504, 1910; Chem. Soc. Trans. 1911, 99, 75).

Mesothorium 1 is chemically identical with radium, and cannot be separated from it by fractional crystallisation of active barium chloride or other salts. On account of this complete similarity of chemical properties all radium compounds separated from uranium minerals containing thorium contain mesothorium 1, and all mesothorium preparations include the radium present in the thorium minerals, about 25 p.c. of radium being present in technically prepared mesothorium 1 (Hahn, Chem. Zeit. 1911, 35, 845).

Mesothorium 1 is rayless, and it disintegrates into mesothorium 2; its period of average life is 7-9 years, the period of half-change being 5·5 years. It behaves like a metal of the alkali earths.

Mesothorium 2 reacts like a metal of the rare-earth series, and accordingly ammonia serves to precipitate it from solutions of mesothorium 1, a trace of zirconium salt being generally added to serve as a nucleus for precipitation (Hahn, Zeitsch. physikal. Chem. 1908, 9, 246; Russell and Soddy, Phil. Mag. 1911, [vi.] 21, 130). Two other disintegration products, radio-thorium and thorium X, are co-precipitated, but if the precipitation is repeated on the solution after one or two days the second precipitate will contain mesothorium 2. relatively free from radio-thorium. Mesothorium 2 has an average life period of 8·9 hours, the half-change period being 6·2 hours; it gives β- and γ-rays; the former are heterogeneous, the absorption coefficient increasing as absorption proceeds; the γ-rays resemble those of uranium X.

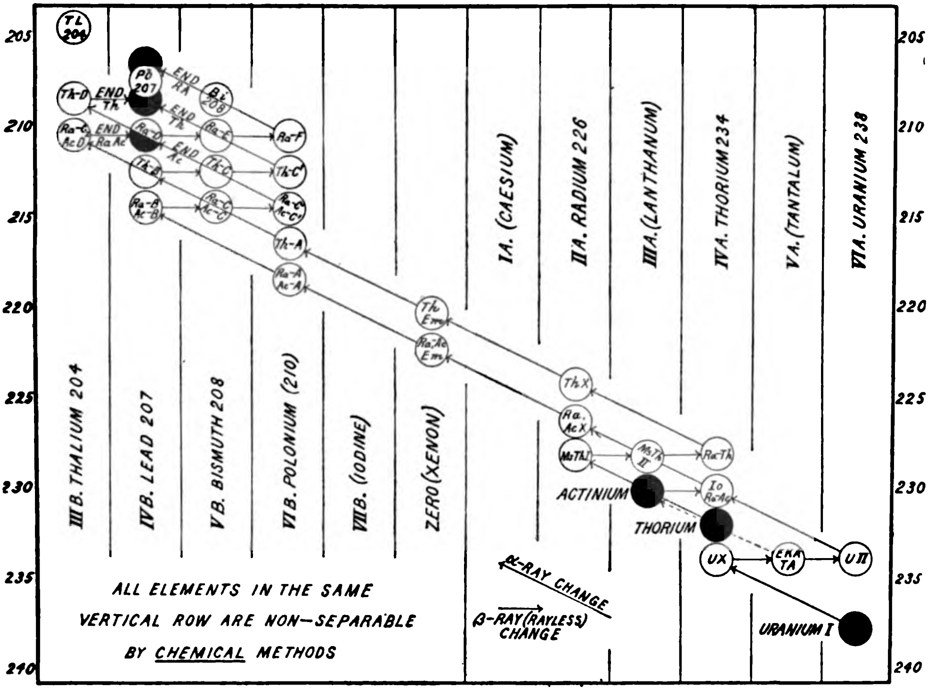

Fig. 1.

Radio-thorium. Period of average life 1063 days (?), period of half-change 737 days (?). Is chemically identical with thorium, and is only distinguished from the latter by preparing it through mesothorium 1 and 2. Mesothorium 1 is readily separated from thorium, and when left to itself produces radio-thorium, which is separated by precipitating a solution of the two disintegration products with ammonia in the presence of a trace of zirconium salt. When first precipitated in this way the radio-thorium will contain mesothorium 2, but this decays completely in the course of 3 days, while the formation of the next disintegration product, thorium X, causes an increase in the radioactivity of the preparation over a period of 3-4 weeks. The emanating power increases with the growth of thorium X, but after a month the total activity and emanating power decay to zero.

Radio-thorium preparations, especially when kept moist, are very suitable for demonstrating the properties of the thorium emanation. When the air in the tube containing a radio-thorium compound is blown between two darkened zinc sulphide screens with films turned inward, a brilliant luminescence is observed, and the decay and reproduction of the emanation can be thus illustrated (*cf.* Hahn, Ber. 1905, 38, 3371; Zeitsch. physikal. Chem. 1905, 51, 717; Phil. Mag. 1906, [vi.] 11, 793; Elster and Geitel, Chem. Zentr. 1906, ii. 302).

Radio-thorium emits α-rays which have a range of 3·9 cm. of air (Leslie, Le Radium, 1911, 8, 356).

Thorium X. Period of average life 5·35 days, period of half-change 3·7 days. Resembles radium, mesothorium 1, and the metals of the alkaline earths and remains in solution when thorium is precipitated with ammonia. The residue left on evaporating the filtrate gives on ignition a small amount of an intensely radioactive product, this activity being due to thorium X. If, however, thorium is precipitated by a carbonate or phosphate, thorium X is also rendered insoluble; the precipitate retains the initial radio-activity of the thorium compound, and when dissolved it exhibits the initial emanating power. The emanating power of a thorium solution is a measure of the amount of thorium X present (Zeitsch. anorg. Chem. 1909, 61, 338; 63, 197).

When fumaric or *m*-nitrobenzoic acid or pyridine is used to precipitate thorium both thorium X and thorium B are left in solution. In this way thorium hydroxide is freed from thorium X and its disintegration products. Four precipitations with *m*-nitrobenzoic acid give thorium hydroxide, having neither β-activity nor emanating power and a minimum of α-activity; the activity of this preparation then increases regularly without the initial decay characteristic of the precipitate obtained by ammonia (Schlundt and Moore, J. Phys. Chem. 1905, 9, 682).

Thorium X is more electro-positive than its successive products and cannot be separated from acid solutions by electrolysis or by the action of metals, only the thorium 'active deposit' being deposited. From alkaline solutions, however, all the active substances may be deposited electrolytically (von Lerch, Monatsh. 1905, 26, 899).

Thorium X exhibits an α-activity, the rays having a range of 5·7 cm. of air; it also emits feebly penetrating β-rays of low velocity, and in this respect differs from thorium and radiothorium (Levin, Phil. Mag. 1906, [vi.] 12, 177).

Thorium emanation, period of average life 76 seconds, period of half-change, 53 seconds, radio-active constant 0·0131 (sec.)$^{-1}$, α-activity, range of α-rays 5·5 cm. of air. This emanation, which differs from radium emanation in its short period and resembles it in showing α-activity, is most conveniently obtained from moist radio-thorium preparations; it is absorbed by charcoal at the ordinary temperature and is condensed on cooling, condensation starting at −120°, and being complete at −155°. The molecular weight determined by effusion is between 200 and 210, the coefficient of diffusion being about 0·1 (Leslie, Compt. rend. 1911, 153, 328). Thorium emanation, like radium emanation (niton) and actinium-emanation, belongs to the family of inert gases and is not absorbed or affected by chemical reagents. The induced radio-activity imparted to solid objects by thorium emanation lasts a few days, whilst that from radium or actinium emanation decays completely in a few hours (Rutherford, Phil. Mag. 1900, [v.] 49, 161).

Solid thorium nitrate and oxide have a lower emanating power than the hydroxide or carbonate, and in the latter case this phase of activity is further reduced by ignition. In these instances the molecules of emanation diffuse so slowly from the solid that the majority disintegrate within the substance and never escape. But when the thorium compounds are dissolved their solutions exhibit the same emanating power.

The amount of thorium present in a mineral may be quickly estimated by passing a steady current of air through the thorium solution and comparing the constant leak in an electroscope produced by the stream of emanation with that brought about by a similar volume of a standard solution of thorium mineral (*cf.* Ramsay, J. Chim. Phys. 1905, [iii.] 617).

Thorium active deposit (thorium A, B, C_1, C_2, D, and E).

	ThA	ThB	ThC_1 & ThC_2	ThD
Period of average life	0·203 sec.	15·3 hrs.	79 mins.	4·5 mins.

Radiation	α-rays	β-rays	2 α-rays	β- & γ-rays
Ranges of α-rays	—	—	5·0 and 8·6 cm. of air	—
Penetration power of β-rays (mm. of Al, half absorption)	—	0·05		0·441
„ „ γ-rays (cm. of lead, half absorption)	—		—	1·5

Thorium A, the first product of thorium emanation, is very short-lived, but its existence is indicated by the appearance of the double scintillations on the zinc sulphide screen produced by the pair of α-particles emitted by the emanation. A distinct although very short time interval separates the two members of the pair (Rutherford and Geiger, Phil. Mag. 1911, [vi.] 22, 201, 621; Zeitsch. physikal. Chem. 1910, 11, 7; Moseley and Fajans, Phil. Mag. 1911, [vi.] 22, 69).

Thorium B, the second product of thorium emanation, is practically rayless except for a feeble β-activity. Consequently, a negatively charged wire exposed for a short time to a powerful source of emanation (*e.g.* radio-thorium) has no very appreciable activity one second after withdrawal, but after a few hours acquires a powerful activity due to thorium C_1 and C_2.

On heating the active wire to red heat thorium B distils off without any appreciable effect on the activity of the wire. The inactive sublimate (thorium B) acquires an activity which, after reaching a maximum in 4 hours, decays with a half period of 10·6 hours (Phil. Mag. 1905, [vi.] 9, 628).

Thorium C is removed from a solution of thorium active deposit by absorption with animal charcoal when thorium B remains dissolved. Thorium C is also deposited alone when the solution is electrolysed or shaken up with metallic nickel. Zinc, however, deposits both thorium B and C, but not thorium X.

Thorium C gives two sets of α-rays having different ranges, these being attributed to the presence in this active product of the two constituents **thorium C_1** and **thorium C_2**; these products have not, however, been separated, and it is not known whether the two sets of rays are due to successive or concurrent changes (Hahn, Phil. Mag. 1906, [vi.] 11, 793; Ber. D. physikal. Ges. 1909, 11, 55).

Thorium D. When the thorium active deposit coating a plate or wire is kept in a vacuum at the ordinary temperature, the powerful α-ray disintegrations of thorium C_1 and C_2, one of which is the strongest known, cause a considerable proportion of thorium D to 'recoil,' *i.e.* to become projected from the plate or wire on to surrounding surfaces of the vacuous space, these receiving surfaces being kept negatively charged.

According to von Lerch's rule the disintegration of radio-active elements is accompanied by a regular increase in the electro-negative character of the successive products. But to this rule thorium D is an exception, as it dissolves more readily in acids than the other products, and is moreover more volatile than its generators, being completely volatilised from an active wire placed for 30 seconds in a Bunsen flame (Sitzungsber. Akad. Wiss. Wien, 1907, 116, [iia], 1443; 1909, 118 [iia], 1575; Zeitsch. physikal. Chem. 1911, 12, 273, 378).

Thorium D, which emits only β- and γ-rays, is the last active member of the series; its decay is regular and complete, and the nature of the ultimate product (*thorium E*) has not been completely elucidated, but this final member of the series is regarded by Soddy as an element indistinguishable from ordinary lead. Thorium D is probably non-separable by chemical methods from thallium, and like this element is coprecipitated with potassium platinichloride (Chem. News, 1913, 107, 97). Barratt has found that thorium C undergoes dual disintegration into *thorium C′*, and thorium D (Proc. Physical Soc. 1912, 24, 112).

The relationship existing between radioactive elements and the ordinary elements of the periodic classification is illustrated by the diagram on p. 481, in which can be seen the connection between the degradation products of thorium and the elements non-separable from these products by ordinary processes (Soddy, *loc. cit.*)

THORN APPLE *v.* DATURA.

THORTVEITITE. A silicate of scandium with yttrium, dysprosium, and erbium

$$(Sc,Y)_2O_3{\cdot}2SiO_2,$$

forming long prismatic (orthorhombic) crystals of a greyish-green colour and somewhat resembling epidote in appearance. It occurs in some quantity in pegmatite near Iveland in Sætersdalen, Norway, and is remarkable in being the only mineral containing scandium (Sc_2O_3 about 37 p.c.) as an essential constituent (J. Schetelig, Centr. Min. 1911, 721). L. J. S.

THSING-HOA-LIAO. A Chinese name for a cobaltiferous aluminium silicate used in the manufacture of porcelain; also applied to a cobaltiferous manganese ore used for producing a blue colour on porcelain.

THUJONE *v.* KETONES.

THULIUM. Sym. Tm. At.wt. 168·5. The erbium sub-group of the yttrium metals contains the three elements, erbium, dysprosium, and thulium; the compounds of the last of which have been hitherto studied only by few workers owing to difficulties of isolation.

Occurrence. Thulium is a very rare element, the best sources being euxenite, sipylite (a columbite from Northern Norway), ytterspar (Norwegian xenotime) and samarskite. It occurs in small quantities in the yttrium earths from other rare minerals.

Separation. Cleve first indicated the existence of the rare earth, *thulia* (Compt. rend. 1879, 89, 478, 521, 708; Thalén, *ibid.* 1880, 91, 376), and Lecoq de Boisbaudran, by decomposing fractionally the nitrates of the yttrium group, discovered thulium fractions between those of erbium and ytterbium (Compt. rend. 1879, 89, 516). A separation of erbium and thulium has been effected by fractional crystallisation of the ethyl-sulphates (Urbain, Ann. Chim. Phys. 1900, [vii.] 19, 184).

The minerals containing thulium are decomposed by hydrochloric or sulphuric acid; the rare earth oxalates precipitated, ignited, and the resulting oxides converted successively into oxalates and sulphates. The latter salts are heated with barium bromate in aqueous solution from which the rare earth bromates are fractionally crystallised. After 15,000 operations the absorption spectrum underwent no change.

Thulium bromate $Tm(BrO_3)_3,9H_2O$, hexagonal prisms, which has been obtained in considerable amount by repeated crystallisation of the more soluble portions of the rare earth bromates, is more soluble than erbium bromate, but less soluble than ytterbium bromate. Fractional crystallisation of the bromates of the yttrium earths gives a fairly rapid separation of thulium from its associates (C. James, Chem. News, 1908, 97, 61; 1911, 104, 73; J. Amer. Chem. Soc. 1910, 32, 517; 1911, 33, 1332).

Thulium salts are pale bluish-green, but their colour is readily masked by small quantities of erbium, the hue changing to yellowish-green, yellow, white, and finally pink as the amount of this impurity increases.

Thulium oxide (*thulia*), Tm_2O_3, a dense white powder with a greenish tinge, is prepared by igniting the oxalate; it is the least basic of the oxides of the erbium subgroup and dissolves slowly in strong acids. It exhibits a reddish incandescence on heating.

Thulium hydroxide is a white precipitate filtering readily even in the cold.

Thulium chloride $TmCl_3,7H_2O$, deliquescent crystals very soluble in alcohol or water.

Thulium sulphate $Tm_2(SO_4)_3,8H_2O$ is precipitated by alcohol from an aqueous solution of thulium chloride and sulphuric acid.

Thulium nitrate $Tm(NO_3)_3,4H_2O$, deliquescent crystals obtained from solution in strong nitric acid.

Thulium oxalate $Tm_2(C_2O_4)_3,6H_2O$, a greenish-white precipitate, soluble in aqueous alkali oxalates to form double oxalates.

Thulium acetylacetonate

$$Tm[CH(CO{\cdot}CH_3)_2]_3,H_2O$$

crystallises from an alcoholic solution of thulium hydroxide in acetylacetone; the absorption spectrum of this compound differs appreciably from that of the inorganic salts, nitrates, chlorides, &c.

Absorption spectrum, v. Cleve, *l.c.* and Forsling, Bit. Sv. Vet. Akad. Handl. 1899, 24, 1, No. 7). G. T. M.

THUYA OCCIDENTALIS (Linn.). In 1858 Rochleder and Kawalier (Wien. akad. Ber. 29, 10) isolated from the green portions of the *Thuya* (*Thuja*) *occidentalis* a glucoside *Thujin*, which, when hydrolysed, gave a yellow colouring matter *thujetin*. It is very probable that this compound is a member of the flavonol group.

Thujin $C_{20}H_{22}O_{12}$. The plant was extracted with alcohol, the extract when cold filtered from wax, and evaporated to a small bulk. The residue was diluted with water, and then with a few drops of lead acetate solution, the precipitated impurities removed, and the clear brown filtrate treated with lead acetate. The yellow lead compound was collected, extracted with dilute acetic acid, and basic lead acetate now added to the solution. The bright yellow precipitate was suspended in water, decomposed with sulphuretted hydrogen, the lead sulphide removed, the filtrate treated with carbon dioxide in order to free it from sulphuretted hydrogen and evaporated *in vacuô* over sulphuric acid. Crystals gradually separated, and these were crystallised repeatedly from dilute alcohol until when treated with ammonia a green coloration was no longer produced.

Thujin forms citron yellow microscopic prisms sparingly soluble in cold water. The alcoholic solution becomes yellow on treatment with alkalis, whereas with ferric chloride a dark green coloration is produced. When thujin is digested in alcoholic solution with dilute hydrochloric or sulphuric acid it is hydrolysed with formation of glucose and *thujigenin*. Thujigenin is apparently an intermediate product, which readily takes up a molecule of water, with formation of thujetin

$$C_{20}H_{22}O_{12}+H_2O=\underset{\text{Thujigenin}}{C_{14}H_{12}O_7}+C_6H_{12}O_6$$

$$\underset{\text{Thujigenin}}{C_{14}H_{12}O_7}+H_2O=\underset{\text{Thujetin}}{C_{14}H_{14}O_8}.$$

Thujetin $C_{14}H_{14}O_8$ forms yellow crystals, and is characterised by the fact that its alcoholic solution is coloured blue-green with ammonia, and green coloured by potassium hydroxide solution.

With lead acetate it gives a deep-red precipitate. When thujetin is digested with boiling baryta water it is converted into *thujetinic acid* $C_{25}H_{22}O_{13}$, which consists of yellow microscopic needles, sparingly soluble in water, readily soluble in alcohol.

Thujigenin $C_{14}H_{12}O_7$ is obtained as fine yellow needles soluble in alcoholic ammonia with a blue-green coloration, and appears to closely resemble thujetin.

The quantity of thujin which is present in the plant is very small; thus, from 240 lbs. Rochleder and Kawalier were successful in isolating a few grams only. Perkin (Chem. Soc. Trans. 1899, 829), who obtained only a trace of thujetin from 500 grms. of the material, considers that this compound may prove to be identical with myricetin. A. G. P.

THYME CAMPHOR v. Camphor.

THYME OIL v. Oils, essential.

THYMINE v. Pyrimidines.

THYMOL v. Camphors; also Phenol and its homologues.

THYMOLOFORM v. Synthetic drugs.

THYROIODINE, THYREOIDIN, THYRADEN, THYRADOL, THYREOIDECTIN v. Synthetic drugs.

TIERS ARGENT v. Aluminium.

TIGER EYE v. Crocidolite.

TIGLIC ACID v. Oils, Fixed, and Fats.

TIGLIC ALDEHYDE, TIGLIC ANHYDRIDE v. *Guaiacum*, art. Resins.

TIL or **TEEL OIL** v. Sesame oil.

TILE ORE v. Cuprite.

TIMA. A medicinal preparation imported from Tampico as a remedy for phthisis. Is prepared as a syrup by boiling the fruit of *Parmenteria edulis* (DC.) with sugar, and mixing the product with almond oil (Arch. Pharm. [iii.] 107, 375).

TIMBO. The name of a narcotic medicine, the root rind of a variety of *Conchocarpus*. The rind appears in the form of tubes or rolls, is bright reddish-brown on the outside and yellowish on the inside. The outer and middle rind break off short, but the inner rind has a long fibrous fracture and the interior colour is whitish. It possesses a weak aromatic taste somewhat like cascarilla bark, but has no special odour. A cross-section shows an interrupted yellow zone near the outer side, whilst the inner rind is faintly streaked in radiating lines. Some of the cells contain crystals of calcium oxalate (Chem. Zeit. 11, 315; J. Soc. Chem. Ind. 6, 560).

TINCAL v. Borax.

TIN MORDANTS v. Dyeing.

TIN. Sym. Sn. At.wt. 119·0. Tin was known and prized in the earliest historic ages, for it is mentioned without comment as one of the common metals in the days of Moses (Numbers xxxi. 22), and was an important commodity in the fair at Tyre; numerous bronze instruments of very early date have also been discovered in Assyria, and, particularly by Layard, in the ruins of Nineveh. Many of these bronzes are now preserved in the British Museum. The tin so employed was obtained by the Phœnicians from Cornwall and the Scilly Isles in this country, and from the mountains of Spain, and there is no evidence of the occurrence of tin in those countries in which, in ancient times, the metal was most largely used. Pliny appears to have been familiar with tin, and states that it occurs in grains, in alluvial soil, from which it is obtained by washing. These grains, he further states, are black, and their metallic character can only be recognised by their great weight. Though tin was regarded by the ancients as one of the baser metals, its cost was greater in the days of Homer and Pliny than at present, for in the days of the latter of these writers an avoirdupois pound of tin cost 8*s*. 7½*d*. sterling, or about six times its present value. The uses of tin among the Romans were similar in many respects to those of the present day. It was chiefly employed in the form of an alloy with copper, on account of the hardness imparted to the alloy by a comparatively small proportion of tin, and some of the very earliest known bronzes agree closely in composition with those used for similar purposes at the present day. Tin was also used with lead by the Romans for the production of solder, and for tinning the inside of copper and brass vessels, in which art the Roman workmen appear to have attained considerable skill. Alloys containing more tin, corresponding somewhat to the modern *speculum metal*, were used by the ancients for mirrors, but the art of tinning iron does not appear to have been discovered until a much later date.

Occurrence of tin. Tin occurs in comparatively few localities, never in the native state, and in but few forms of chemical combination. The most important ore is *tinstone* or *cassiterite*, tin dioxide (SnO_2), which is met with in two principal forms, crystallised and massive. The crystals are of the regular prismatic or tetragonal system, isomorphous with those of rutile, and are frequently well formed and of large size. Tinstone in the usual or massive form is a dark reddish-brown or slaty-coloured very heavy mineral, which occurs in Cornwall in veins usually running nearly east and west, and in which the tin ore is associated with arsenical pyrites, copper sulphide, wolfram, and a great variety of other minerals. Tin usually occurs in plutonic or metamorphic rocks, such as granite, felspar, porphyry, or clay slate, but by the action of denudation on these older rocks grains of tinstone are frequently met with in the neighbouring alluvial deposits, and this variety of ore, which is of special purity and now almost entirely exhausted in this country, is known as 'stream tin.' The metal also occurs in small quantities as *tin pyrites* (SnS_2). The largest quantities of tin are now produced in the island of Banca ('Straits tin'). Smaller though considerable quantities are met with in Britain, Germany, Austria, Siberia, China, South Australia, New South Wales, and Bolivia. Among the newer sources of tin may be mentioned the Waterberg district, to the north of Pretoria, in the Transvaal, the present monthly output of which is valued at about £30,000, and is likely to increase. Promising reports are received in connection with tin mining in Texas. In parts of Nigeria tin occurs distributed over wide areas, but in relatively small proportions. The present world's output of tin is about 115,000 tons per annum.

Production of tin. The metallurgy of tin is in its main features simple, but the mechanical preparation of the ore involves more skill and labour than is the case with any of the other common metals. So much, in fact, is this true that success in the extraction of tin frequently depends more upon the captain of the mine, who superintends the dressing of the ores, than upon the smelter. On account of the high price of tin, and the relatively high density of tinstone, it is found practicable to work ores which in the first place contain comparatively little tin, ores which contain only 0·5 p.c. of tinstone being sometimes profitably worked. The principle adopted in the mechanical separation of tinstone is very simply illustrated in the operation of 'vanning,' which is frequently used in Cornwall and elsewhere as an approximate test of the richness of an ore. A quantity of the crushed material is placed in a miner's shovel of special shape, known as a vanning shovel, water is added, and then by means of a circular motion which is imparted to the shovel by the hands, aided by a peculiar jerk of the wrist, the ore is ultimately almost completely separated from the earthy matter, and can be dried and weighed. On the large scale the ore is first picked and assorted, and then broken by suitable stone breakers and rolls. The roughly-powdered ore is carefully assorted, and then fed into a mill containing a battery of stamps, of which there are many varieties in use. Each stamp weighs 3 cwts. or upwards, the face of the stamp being either steel or chilled cast iron. By means of suitable cams on a revolving wheel the stamp is raised at regular intervals, and allowed to fall upon the ore which is contained in the box or coffer of the stamp. A supply of water flows through the boxes and escapes through perforations, carrying away the finely-crushed ore, while the larger pieces remain in the box to be further crushed by the stamp. The finely-powdered ore now passes to some form of buddle, or to a concentrating table, which more or less completely separates the earthy matter. Probably the simplest form of such apparatus, of which there is an endless variety, is the inclined plane with ridges or 'riffles' placed at right angles to its length. On such a plane the heavier particles naturally remain, the richer fragments being deposited principally at the upper part of the buddle, whilst the earthy matter, with some ore, passes away. But such a simple form of buddle is now seldom used, and a considerable number of improvements have been from time to time adopted. Thus the inclined plane is made movable, and either a jerking or a rocking motion is imparted to it, and this is found to give better results than the fixed form. But buddles of a circular shape have met with considerable favour in late years, one form (Borlase's) being a circular concave buddle fed from the outside and discharging the slimes from the middle; but the variety generally preferred in Cornwall is that of a very flat cone, the water and ore being distributed either by a revolving spout, near the apex of the cone, or by means of a smaller and more acute distributing cone. The waste liquid from the buddle is led into a succession of tanks or pools, where it is allowed to settle in order to recover the finer portion of the ore, which would otherwise be lost, and the slimes thus obtained are worked over again in order to recover the finely-divided tin ores.

In dressing tin ores it is important that they should not be too finely crushed, or the gangue will be removed with greater difficulty. The ore should be, as far as possible, separated into parcels, the fragments in each being of uniform size, and the method of treatment is varied with the fineness of the material; in no case should the ore be crushed more than is necessary to separate the matrix. These facts form the basis of all successful ore dressing.

Reduction of tin. From the point of view of the tin smelter, ores of tin may be divided into two classes, first those of tolerable purity, which may be directly smelted in the furnace, and secondly a less important class of ores, which, from the fact that they contain notable proportions of copper, arsenic, sulphur, or tungsten, require to be further treated, after dressing, before smelting. Ores which contain arsenic or sulphur are roasted at a low temperature, usually in calciners with a bed which is mechanically rotated in a horizontal plane, and which is supplied with mechanical rabbles. The greater part of the arsenic and sulphur is thus removed. The mass is then withdrawn, and, after being exposed for some time to the action of the atmosphere, is washed to remove the oxide of iron and other lighter matters from the heavy oxide of tin. Ores which contain much tungsten are heated with sodium sulphate or carbonate in a reverberatory furnace, by which means soluble sodium tungstate is produced, and can be removed by washing from the unaltered oxide of tin. This process (Oxland's) is not carried on now to any considerable extent. The ore having been purified by one or other of these processes is ready for smelting in the ordinary way. The reduction of the metal from the ore is always accomplished by heating with carbon, which operation may be performed either in a reverberatory furnace, as is the custom in this country, or in small blast furnaces such as are used to a limited extent in Germany. Shaft furnaces also are used in China, Sumatra, Nigeria, and by natives in many other localities.

Tin smelting in England. The furnace employed for the smelting of tin in this country, and in fact pretty generally elsewhere, is a reverberatory, with a fireplace at one end and a stack at the other. At the front is a single working door, while at the back is a tapping hole which is closed during the smelting, but which when the operation is concluded serves to convey the metal into a 'float' or circular iron pot lined with clay. The bed of the furnace is about 18 ft. long by 9 ft. broad, and slopes to the tapping hole. The fireplace is about 2 ft. broad, and the firebridge is of firebrick and some 14 ins. high. The roof is low, and slopes uniformly from the firebridge to the stack.

The charge of ore, which weighs 20–25 cwts., is mixed with rather less than one-fifth of its weight of anthracite powder, and spread uniformly over the furnace bottom. If the ore is refractory, a little fluorspar or lime is added as a flux. The door is then closed and luted up, and the temperature gradually raised for 5–6 hours, when the door is opened, the mass rabbled, and a quantity of powdered anthracite or 'culm' is thrown on the surface of the charge. After heating for about another hour, and a further rabbling, the metal is tapped. Part of the slag produced is thick and is raked out of the furnace, while the remainder is more fluid, flowing out with the metal, and is called 'glass' by the smelter. The slag consists essentially of ferrous silicate, and as it frequently contains a considerable amount of tin it is melted again when the furnace is at liberty.

Small blast furnaces, which were previously used in Cornwall, have survived longer in southern Germany, and are also employed by the natives of India. The waste of metal is much greater than in the reverberatory furnace, whilst the cost of fuel (charcoal) is also greater than in England, but the tin obtained is stated to be of excellent quality.

Refining. The refining process consists of two parts, a preliminary liquation, and the refining proper. The liquation is conducted in a furnace of similar shape to the reverberatory furnace above described, and about 18 tons are operated upon at once. The temperature is carefully regulated so as to just melt the purer tin, which gradually flows away into a separate pot or 'kettle,' while the impurities, consisting of iron, arsenic, sulphur, and traces of many other elements, together with some 20 p.c. of tin, remain in the form of a hard, brittle, white, semi-metallic mass known as *hard-head.* For the composition and properties of hard-head, *see* Levy and Ewen, Trans. Inst. Ming. & Metallurgy, 1908–9, 466. The purer metal which has collected in the kettle (which is heated by a small separate fire) is now refined by plunging billets of green wood under the surface of the melted tin. A quantity of gas is evolved from the wood, and violently agitates the metal, gradually separating a scum which contains the impurities originally present in the crude tin. The same result is sometimes attained by 'tossing' the melted metal in ladles from a height of several feet and allowing it to fall into the kettle; in this way the metal is also exposed to atmospheric influences, and a scum separates as before. The refined metal is sold as *grain, refined,* or *common tin,* according to its quality, though all tin met with in commerce has been more or less refined. For *refined tin* purer ores are employed, the refining is continued longer, and after poling the metal is allowed to stand some time, and only the upper or purer portions are used. The second or ordinary quality, when cast in suitable moulds, is known as *block tin.* A simple test of the commercial quality of tin is to melt the metal at a moderate temperature, and to pour it into an ingot mould. The ingot, if of good quality, should be smooth, bright, and rounded, and should retain this appearance on solidification; if impure it will have more or less sharp edges, and will 'frost' over on solidifying, while very impure metal will be tinged with yellow or purple, according to the amount and nature of the impurities. *Grain tin* is produced by heating blocks of refined tin to a temperature a little below the melting-point of the metal, at which point it becomes very brittle, and is broken either by dropping from a height or by a blow of a hammer. For further particulars of the properties and metallurgy of tin, *see* H. Louis, Metallurgy of Tin, London, 1911.

Brands of tin. In 1911 a committee of the London Metal Exchange drew up a new form of contract for the purchase of tin. This provided for the recognition of two classes of tin: Class A. includes Straits or Australian tin of good merchantable quality, and also refined tin of good merchantable quality, assaying not less than 99·75 p.c. of tin. Class B. includes common tin of merchantable quality, and assaying not less than 99 p.c. of tin. The official brands include the following: Straits, Australian, Banca, Billiton, English, German, and Chinese. In connection with this classification a number of brands and descriptions were assayed, and tabulated analyses prepared (p. 487).

It will thus be seen that some of the best brands of commercial tin are of remarkable chemical purity.

Uses of tin. The manufacture of tin plates absorbs more tin than any other industry, and of this a separate account will be given. Tin is also largely used for alloying with copper to produce

bronze, bell metal, and speculum metal, while in combination with other metals tin produces a number of useful alloys, to be afterwards described, among which may be mentioned pewter, Britannia metal, plumber's (or soft) solder, Queen's metal, type metal, fusible metal, &c. Though tin is comparatively brittle at ordinary temperatures, it becomes very malleable at about 100°, and can then be rolled into thin sheet or foil, for which there is a considerable application, and which was formerly much used, in the form of an amalgam, for the 'silvering' of mirrors. On account of its power of resisting atmospheric influences and the action of vegetable acids, tin is also used for the manufacture of pipes for brewers, distillers, and other purposes. For similar reasons lead pipes are sometimes tin-lined. Pots, pans, kettles, and other culinary utensils are frequently *tinned* inside. The process is very ancient, and extremely simple. The surface of the vessel to be tinned (which may be of copper, brass, or iron) is carefully cleaned and brightened, and a little ammonium chloride (patented for this purpose by John Bootie in 1768) is often rubbed over the surface. Some tin and a little powdered resin is now melted in the vessel, and is wiped over the surface with tow. By this means a skilful workman rapidly produces a uniform coating of tin, which resists considerable wear, and yet weighs, according to the experiments of Bayen, less than a milligramme per square inch of surface. No wonder that Pliny states, with surprise, that copper when tinned does not increase in weight ! Tin salts are also used for tinning brass and copper wire, and as mordants in dyeing.

Alloys of tin. The alloys of tin are of great practical importance, and have naturally attracted considerable attention, although accurate information is still wanted in respect of many of their physical and other properties. For convenience of study the alloys of tin may be divided into two classes, the first in which the properties of the resulting alloy are entirely different from the mean of the constituents, while the second class includes those alloys some of the most important properties of which agree very closely with what might be anticipated from the properties of the constituent metals. The first class is typically represented by the alloys of copper and tin, which include the important alloys known as *bronzes*, *gun metal*, *bell metal*, &c. Tin itself is weak, soft, readily fusible, and of a nearly white colour, while copper is strong, tough, moderately hard, and of a characteristic red colour. On adding tin to copper, however, in gradually increasing proportions a succession of alloys is obtained with properties which are utterly different alike from those of each other and from their constituent metals. Thus an addition of about 5 p.c. of tin to copper produces a tough strong alloy, which still retains a fairly characteristic copper colour, but which is much harder than copper, and is suitable for medals or coinage, but the hardening effect of tin is so great that already the practical limit has been reached for coinage purposes. On adding 5 p.c. more tin we have an alloy which is still harder, so much so that it has to be cast instead of being rolled or drawn, and the alloy possesses a rich yellow colour. With a little more tin an alloy suitable for the hardest bearings is produced, and with still more tin we have the alloy used for small bells, and which is sonorous, but shows considerable brittleness when cold, but which may be worked at a low red heat. With still more tin an alloy suitable for the largest bells is obtained ; brittleness is more marked, and the fracture is dull earthy grey, and it is only when the metal has been worked or burnished that a yellow colour is visible. But on continuing the addition of tin, which is one of the softest of the common metals, the alloys become more and more brittle, until with about 33 p.c. the alloy can easily be pounded in a mortar, and possesses a white colour, with a more or less pronounced blue shade. This alloy is thus utterly different alike from its constituents and from either of the other alloys previously mentioned. As examples of the second class of alloys of tin, in which the properties of the alloy are approximately what would be expected from the characters of the constituents, the combination with zinc or with lead may be taken. Tin and zinc unite in all proportions, and the colour, hardness, ductility, &c., of the alloys are what would be anticipated from a mixture of the two constituents. Tin and lead also unite in all proportions to form a series of alloys, all of which are nearly white in colour, and are soft, malleable, and readily fusible, like the metals themselves. Tin-lead alloys, however, furnish a characteristic illustration of the fact that the melting-point of mixtures or alloys is very commonly lower than the mean calculated from the melting-points of the pure substances. This rule is very generally observed, both in salt solutions, with mixtures of salts, and with mixtures of organic substances (Guthrie, Phil. Mag. [iv.] 49, 1, 206, 266; [v.] 1, 49, 354, 446; 17, 462; 6, 35). Common, or soft, solder is an alloy of tin and lead, the best proportions being very nearly 2 parts of tin to 1 of lead. The melting-point of this alloy, calculated from the melting-points of its constituents (Pb=327°, Sn=228°), would be 261°, but the lowest melting-point in this series of alloys actually observed is 180° (Turner, B'ham. Phil. Soc. [iv.] 318), and the composition of the alloy was very nearly 2 parts of tin to 1 of lead. A number of investigators have examined these alloys of tin and lead, including Küpffer, Pillichody, Laurie (Chem. Soc. Trans. 1889, 678), and more recently Rosenhain and Tucker (Phil. Trans. Series A. 1908, 89), and the results of the determination of the composition of the lowest melting-point alloy vary from about 60 to 65 p.c. of tin (62·93 p.c. tin, Rosenhain and Tucker). There appears to be no indication of a definite alloy of tin and lead in atomic proportions, though, on very slow cooling, there is evidence of the existence of a solid solution, at the lead end of the series. There is also an inversion at 150° with alloys containing 18–63 p.c. of tin. In addition to their use for solders the tin-lead alloys have an important application in the form of *pewter*, the toughest and hardest variety of which contains about 3 parts of tin to 1 of lead. Alloys of tin and antimony belong to the same class as those previously mentioned, and a mixture of 4 parts of tin with 1 of antimony is used for one kind of type metal. Tin also enters into the composition of Britannia metal, the proportions being as follows (Greenwood, Metallurgy, i. 211):—

	Britannia metal			
	For spinning	For rolling	For casting	Queen's metal
Tin . . .	94	90	84	75
Antimony . .	5	7	10	8·5
Copper . .	1	3	4	—
Bismuth . .	—	—	2	8
Lead . .	—	—	—	8·5

A Birmingham manufacturer's mixture for Britannia metals is as follows: tin, 1 cwt.; antimony, 12 lbs.; copper, ½ lb.

Britannia metal has a somewhat considerable application on account of its white colour, and the fact that it takes a good polish and resists the influence of the atmosphere; its low conductivity for heat also renders it very suitable for some purposes. This manufacture was introduced by Jessop and Hancock about 1770.

Type metal varies considerably in composition, consisting essentially of antimony and lead; but for small type tin is commonly added, and in some cases considerable proportions of tin are employed.

The following illustrates the composition of type metal of excellent quality, and suitable for different sizes of type. It will be noted that large type is made of a softer and cheaper mixture.

	Tin	Lead	Antimony
Large type . .	7·5	78	14·5
Medium type .	9·0	73	18
Small „ .	14·5	57	28·5

From 1 to 1·5 p.c. of copper is also added in some cases to improve the wear of the type.

White bearing metals for heavy machinery contain the same constituents as type metal. At least 10 p.c. of antimony is required: with above 20 p.c. the alloy is brittle. The limit of tin, on account of price, is usually about 45 p.c. (Hague, Bearing Metals, South Staffs. Iron & Steel Inst. Jan. 1909; Hiorns, Anti-friction Alloys, Birm. Metallurgical Soc. Feb. 1909). For special purposes larger proportions of tin are employed, as shown in the following analyses (G. Hughes, Non-ferrous Metals in Railway Work, Journ. Inst. of Metals, Sept. 1911)—

	A	B	C
Tin	82·0	11·5	80
Antimony . .	14·0	13·5	10
Copper . . .	4·0	3·0	10
Lead	—	72·0	—

Alloy B is a fairly typical soft bearing metal. A and C are harder, the former being used for bearings, &c., in steam locomotives, and the latter for high-class axle bearings on the pinion and commutator ends of electrical rolling stock.

Tin is also a constituent of the various *fusible alloys*, one of the best known being *Wood's* alloy, which consists of 4 parts of tin with 4 of lead, 8 of bismuth, and a little cadmium; it fuses at 63°.

The tin-lead-bismuth eutectic melts at 94°. It can be prepared by melting together 4 parts of tin, 8 of lead, and 13 of bismuth. The alloy with 4 of tin, 8 of lead, 10 of bismuth, and 4 of cadmium melts at about 71°.

Fusible alloys are used chiefly for taking rapid impressions of objects which would frequently be injured by the use of metal melting at a higher temperature, and also for safety plugs in steam boilers, &c.

Tin-copper alloys. *History.*—Copper is one of the few metals which have been known from prehistoric periods, and, like silver and gold, is in the pure condition too soft and ductile for many useful applications. The ancients, therefore, prepared various hard copper alloys or bronzes, which were used for many purposes to which iron and steel are now applied. The elements added to give hardness were arsenic, iron, or, preferably, when obtainable, tin. A very ancient Egyptian knife-blade (1400 B.C.) examined by Dr. Percy (Metallurgy, i. 504) consisted of copper with 2·29 p.c. of arsenic and 0·43 p.c. of iron; such a material would, of course, form an indifferent cutting tool.

The Hindoos have for many centuries produced a variety of bronze for coins and statues, which was hardened by the presence of iron. Dr. Percy mentions an ancient Indian coin which contained 5·06 p.c. of iron, the remainder being copper (*l.c.*), while in the Birmingham Art Gallery there is one of the earliest known images of Buddha, which is believed to be 2500 years old, and which was found by Daniel Forbes to contain 91·50 p.c. of copper and 7·59 p.c. of iron. With the introduction of tin by the Phoenicians came the use of bronze in Egypt, Assyria, Greece, and all the important countries of the ancient world. Of these bronzes, numerous examples are preserved, and the composition recommended for various purposes was very similar to that which is used at the present day. Thus Pliny states (Thomson, Hist. Chem. i. 57) that the Romans made their pans for boiling from a mixture of 100 lbs. of copper and 3–4 lbs. of tin, while for statues to every 100 lbs. of copper, consisting of one-fourth old copper and three-fourths new metal, 12½ lbs. of tin was added. Brass was not known, or at all events was not in general use, until shortly before the Christian era, and the references to brass which so frequently occur in the Old Testament have to do either with copper or bronze, and not with alloys of copper and zinc. *See* further on the early history of copper and copper alloys, W. Gowland, Presidential Address, Institute of Metals, 1912.

Constitution of copper-tin alloys. Previous to the researches of Matthiessen, it was customary to regard alloys as examples of chemical combination, and most experimenters prepared and studied alloys of definite atomic proportions. An example of this method of working is to be found in the researches of Mallet on the tin-copper alloys (Brit. Assoc. Rep. ix., Construction of Artillery, p. 82). The remarkable change in properties which results when tin and copper are alloyed was used as an argument in favour of the view that definite chemical compounds were produced. The result of more recent investigations, however, tends to show that although in some cases definite atomic combinations actually do occur, still these are comparatively few (*see* C. H. Desch, Intermetallic Compounds, Journ. Institute of Metals, vol. i. 227); while the other alloys, which constitute the vast majority of those in use, are either solid solutions of a metal in an excess of one of the constituent metals, or are simply mixtures of the two or more metals present in the alloy. The equilibrium of the copper-tin series has been studied by Heycock and Neville (Phil. Trans. 202A, 1: Giolitti and Tavanti, Gazz. chim. ital. 1908, 38, ii. 209; Shepherd and Blough, J. Phys. Chem. 1906, 10, 630; Haughton and Turner, Jour. Institute of Metals, 1911, part ii.). For a discussion of the equilibrium diagram, *see* art. **Metallography.** In the tin-copper series there is good evidence of the existence of a definite alloy Cu_3Sn containing 61·64 p.c. of copper, while there is considerable reason to believe that Cu_4Sn, containing 68·18 p.c. of copper, also exists. Thus Calvert and Johnson (Phil. Trans. 1858), in investigating the conductivity for heat of these alloys, found a maximum conductivity corresponding to Cu_3Sn, and a minimum conductivity corresponding to Cu_4Sn. Some very interesting determinations by Riche (Compt. rend. 55, 1862, and more completely Ann. Chim. Phys. [iv.] 30, 361) show two maxima, corresponding to Cu_3Sn and Cu_4Sn. These experiments have also received strong support from the induction balance curve of Roberts-Austen (Phil. Mag. 1879, [ii.] 57), which shows two distinct breaks corresponding to Cu_3Sn and Cu_4Sn. The determination of relative electric conductivity by Lodge (*ibid.* 1879, [ii.] 554) also show a very distinct maximum at Cu_3Sn and a minimum conductivity corresponding to Cu_4Sn. Laurie examined these alloys from the standpoint of the electro-motive force produced in a standard cell, and concluded that there was very definite evidence of the existence of Cu_3Sn, but failed in this way to obtain any proof of the existence of Cu_4Sn (Chem. Soc. Trans. 1888, 109; 1889, 678).

The evidence in favour of Cu_3Sn is therefore exceedingly strong, while that in favour of Cu_4Sn, though not quite so complete, is still good, and at present there is no trustworthy evidence in support of any other atomic combinations. Further evidence on this point will be found in C. H. Desch's paper on Intermetallic Compounds, Journal Institute of Metals, 1, 1909, 227, above cited. These facts, when considered in connection with the known characters of the two alloys in question, give a key to the peculiar characters of the useful tin-copper alloys. The two definite alloys are white, hard, and brittle, and practically all the alloys used in the arts, except speculum metal, contain more copper than $Cu_4Sn = 68·18$ p.c. Cu. Hence the useful bronzes may be regarded as mixtures of one of two definite alloys with an excess of a solid solution of tin in copper, and these tend to separate more or less completely during solidification. This separation is particularly marked with large castings rich in copper, as in *gun metal*, which was in former times largely used for ordnance. Microscopical examination shows clearly that at the copper rich end of the series of alloys the first constituent to separate out on cooling the fluid alloy is a solid solution of tin in copper. This forms a dendritic, or fir-tree like structure, giving cores which increase in tin from the centre outwards. This copper-rich solid solution is called the α constituent, and is relatively soft and ductile; as the proportion of tin increases harder constituents separate out, the first of them being designated by the symbol β. It is harder and more brittle than α.

The production of bronze castings requires special precautions, which cannot be described here. For details, *see* Mallet On the Construction of Artillery, 1856; also Reports of the United States Chief of Ordnance, 1880, 126, 189; 1884, 369. These latter reports contain some important observations with regard to this variety of bronze. It is stated that the best proportion for such purposes is 91 of copper to 9 of tin. This is best cast in a mould or 'chill' of cast iron, and 100 tests of metal so prepared gave an average tensile strength of 21·9 tons per square inch, the maximum being 24·8 tons and the minimum 16·5 tons. It should be mentioned that these values are higher than those usually obtained in this country, where the metal is generally cast in sand moulds.

Composition of principal tin-copper alloys. The following list is based on that given by Holtzapffel (Mechanical Manipulation, i. 270).

Tin, 0–5 p.c. A small quantity of tin is sometimes added to copper for engraver's purposes to give crispness. About 5 p.c. was used by the Romans for pans, and for ancient flexible bronze nails. A similar alloy is now used for bronze coinage and medals, often with a little of the tin replaced by zinc; also for engineers' soft gun metal or 'brasses.'

7 p.c. Slightly harder alloy; suitable for mathematical instruments, &c.

8·5 p.c. Rather harder; fit for wheels to be cut with teeth.

8–12 p.c. Soft bronze statues of the ancients. These alloys are harder than the preceding, and mark the extreme limit for coinage purposes. Also used for brass ordnance, 9 or 10 p.c. of tin being preferred. Medium engineers' 'brasses' contain 10–12 p.c. of tin.

12–14·5 p.c. Hard bronze of the ancients, used for weapons and tools. These proportions are also used for engineers' hard bearings.

16 p.c. Soft musical bells.

18–20 p.c. Chinese gongs and cymbals.

20 p.c. Small house bells; Indian gongs.

22 p.c. Large house bells.

24 p.c. Limit for large church bells.

About 33 p.c. Speculum metal (*v.* Phil. Trans. 1840, 503).

About 66 p.c. 'Temper,' an alloy used for addition to tin and lead to harden pewter.

It has already been mentioned that the addition of a small quantity of tin to copper prevents it rolling well when hot, and the addition of a little more tin destroys its malleability when cold. Bronze is tempered by an exactly opposite process to that used in the case of steel, namely, the alloy is heated to redness and then rapidly cooled in water.

For the majority of purposes bronze is melted in crucibles of fireclay or plumbago, the charge being about 90 lbs. For large castings a reverberatory furnace is often employed, though such work is sometimes performed by means of a large number of crucibles. It is recommended that the copper should be well melted and kept in fusion for some time before the tin is added, if strong castings are required. Founders also prefer to use some new metal in every charge, and not merely to re-melt scrap. The oxidation which takes place during melting removes some 3 or 4 parts of copper to 1 of tin; the result is, therefore, that the alloy, which contains about 9 parts of copper to 1 of tin, tends to get poorer in tin by remelting, and due allowance must be made for this loss, even though it may appear to be slight, as small differences in composition often exert a most important influence in tin-copper alloys.

Bronze bearing metal. According to Dudley (Jour. Franklin Inst. 133, 81, 161; J. Soc. Chem. Ind. 11, 460), the following composition is very suitable for bearings for locomotives and similar purposes: copper, 77; tin, 8; lead, 15. The presence of lead in bearings very much diminishes the loss of metal caused by wear, and also reduces the local heating of the journals. Phosphor bronze and other varieties of bearing metal for similar purposes to the above often contain about 10 p.c. of lead, and the wearing properties of the alloys is chiefly connected with the proportion of copper and tin to lead. The presence of tin is necessary in order to obtain a uniform alloy, as lead and copper alone do not unite well. With too much tin the alloy wears more rapidly and becomes more heated. The presence of phosphorus and arsenic gives solidity to the castings, but with suitable proportions of tin and lead, as above, alloys are obtained which wear even better than standard phosphor bronze with the following composition: copper, 79·7; tin, 10; lead, 9·5; phosphorus, 0·8 p.c.

Phosphor bronze is an alloy containing copper and tin in various proportions, and which also contains a small quantity of phosphorus, introduced in the form of phosphor tin. Occasionally small quantities of zinc or lead are also added. The phosphorus varies from a mere trace, added chiefly to ensure soundness in casting, to about 1·75 p.c. with hard alloys. The results of the analyses and mechanical tests of 99 samples of phosphor bronze, as received by the British Admiralty, have been given by A. Philip, Journ. Inst. of Metals, 1, 164, while the constitution and microstructure have been dealt with by O. F. Hudson and E. F. Law, Journ. Inst. of Metals, iii. 1910, 161. This alloy has met with considerable favour where special strength or power of resisting wear (as with bearings for quick running machinery) is required. Similar alloys containing manganese, which is added in the form of ferro-manganese, have also met with considerable application, and are known as *manganese bronzes. Silicon bronze,* made by the addition of copper silicide, is used for conductivity wire, though many of these so-called bronzes contain very little or no tin. They are usually alloys which closely resemble Muntz metal in composition, and contain about 60 p.c. of copper, 38 p.c. of zinc, and the remainder of specially added elements, such as manganese, and impurities. T. T.

Dry assay of tin ores. Hofman finds that Winkler's method of assaying black tin stone gives results averaging 65·96 p.c., or 1·88 p.c. too low, the figures disagreeing amongst themselves up to over 3 p.c. The process consists of reducing together 5 grms. each of cassiterite and cupric oxide with 15 grms. of black flux, 1·25 grms. of borax, and a little salt as a cover. A similar experiment is conducted without the cassiterite, and the copper obtained in the one case deducted from the alloy in the other gives the amount of tin. The following modifications of this method were tried: increasing the amount of charcoal, using chalk-lined crucibles, omitting the salt and increasing the potassium carbonate, and Rickett's modification of adding argol; but they all gave worse, and in some instances very variable, results.

The iron method—reduction with hæmatite, charcoal, and potassium cyanide or fluorspar—gave unsatisfactory results. The same may be said when a mixture of ferrocyanide and cyanide was used, and also when any of the Cornish methods were employed. So far, with fairly pure cassiterite only two methods have proved satisfactory, viz. the German and the pure cyanide methods. Hofman has attempted to prove which of these two methods gives the best results when the cassiterite is mixed with those minerals likely to be naturally associated with it. The minerals used were quartz, felspar, mica, tourmaline, garnet, and columbite. Mixtures of the purified cassiterite ore with varying proportions of each of these minerals were assayed by both methods, the percentage of tin being calculated on the cassiterite ore present. The charges were so regulated that the flux in the German assay was always equal to three times the quantity of ore *plus* the mineral, and in the cyanide assay to six times the quantity. In the latter case 4 parts of cyanide were mixed with the ore; 1 part was used to coat the crucible bottom, and 1 part as a cover. In all cases the cyanide method gave more concordant, and less prejudicially affected, results than the other. The results of the German assays fluctuated greatly as the amount of mineral present increased. Thus, in the case of quartz and albite the results were lower as the quantity of mineral was increased, the respective figures being, with 37·5 p.c. of each mineral, 60·7 and 60·2 p.c.; the corresponding cyanide figures being 63·90 and 65·30 p.c. (the real percentage of tin was 67·84). The tin buttons, moreover, in the German assay with albite contained iron, while those by the cyanide process were free, the temperature of fusion being too low to cause decomposition of the albite.

With muscovite, tourmaline, garnet, and columbite the results with the German method were very unreliable, being sometimes too high and very ferruginous, and sometimes too low, varying from 82 p.c. with 50 p.c. of garnet to 46 p.c. with 44 p.c. of tourmaline. The cyanide method gave fairly good results in all the above cases, very little iron getting into the buttons, except in the case of garnet, when the result was 69·89 p.c., with 37·5 p.c. of mineral present. With the same quantity of muscovite, tourmaline, and columbite the assays were respectively 63·3, 64·7, and 66·0 p.c. Consequently, where anything like a true result is required the cyanide assay is by far the most to be relied upon, and should be employed in cases of buying and selling, although in concentration works, where comparative results and large numbers of assays are required, the question of cost must be considered, and the cheaper German method might be adopted.

Hofman emphasises the importance of properly preparing the ore for assay, and states that the ordinary method of grinding the whole sample to a uniform size is not suited to the tin ores of the Black Hills, chiefly on account of the preponderance of mica. Hence a preliminary sizing is advantageous. The ore while being pulverised is screened through a series of sieves Nos. 20, 40, 60, and 80, the different-sized screenings being then washed. This method gives purer concentrates, and necessitates less loss of cassiterite, as the material has been washed without excessive grinding, which in the present process reduces the brittle cassiterite to a slime, while some of harder associated minerals are only converted into sand. The subsequent treatment of the concentrates mentioned in the first part of the paper is recommended, as the roasting renders the cassiterite more friable and more readily reducible, the assays in some cases showing a difference of 0·5 p.c. between the raw and roasted ores in favour of the latter (Part ii., H. O. Hofman, Technol. Quarterly, 3, 261–280; J. Soc. Chem. Ind. 9, 1154; *v.* Rennie and Derrick, *ibid.* 1892, 662).

COMPOUNDS OF TIN.

Oxides. A monoxide, *stannous oxide* SnO, and a dioxide, *stannic oxide* SnO_2, each of which gives rise to a distinct series of salts, are known, the former acting as a base and the latter acting as either base or acid. Oxides of the composition Sn_2O_4, $SnO{\cdot}3SnO_2$, $2SnO_3,H_2O,SnO_2$ and others have also been said to exist, but it is probable that, with the exception of SnO_3, they are mixtures of the other two oxides.

Stannous oxide SnO is obtained as an olive-brown anhydrous powder, when stannous oxalate is heated out of contact with the air; or as a white precipitate of the composition $2SnO,H_2O$, with evolution of carbon dioxide, when stannous chloride and an alkaline carbonate or hydroxide are mixed in solution. If the precipitate is washed with air-free water, and the lixiviated product is heated in the absence of air, nearly pure dark grey stannous oxide is obtained (Enequist, Eng. & Mining J. 1895, 219; *see* also Hantzsch, Zeitsch. anorg. Chem. 1902, 30, 289).

It may also be obtained as a bluish-black anhydrous powder by heating a mixture of 4 parts of stannous chloride with 7 of sodium carbonate, and lixiviating the resultant mixture of stannous oxide and sodium chloride (Sandall, J. pr. Chem. [i.] 254). The anhydrous oxide may also be obtained from the hydrated form as follows: (1) as a black powder by heating it out of contact with the air; (2) in minute cubes by digestion with acetic acid at 56°; (3) of a brilliant scarlet colour, which becomes brown on rubbing, by evaporating a dilute solution of ammonium chloride containing stannous chloride in solution until the chloride commences to crystallise (Fremy, Berz. J. 24, 133; 25, 172; Ann. Chim. Phys. [iii.] 12, 460); (4) as small black shining crystals, which, when heated to 258°, decrepitate and swell up, with production of soft olive-green laminæ, by prolonged digestion with a weak solution of caustic potash at the ordinary temperature (Fremy, *l.c.*). A stronger solution dissolves the oxide and ultimately deposits it in crystals, the deposit from a solution of 4 parts of potassium hydroxide in 10 of water containing potassium stannate and tin, the former produced by absorption of atmospheric oxygen. Fremy also describes various red, black, brown, and other forms of this oxide.

Stannous oxide becomes incandescent, and forms stannic oxide, when heated in the air. It is violently oxidised by nitric acid and other oxidising agents. Carbon or hydrogen reduces it to metal at a red heat. It dissolves in acids, with production of stannous salts, and in caustic potash or soda, but not in ammonia. The soda solution is employed in calico printing and dyeing under the name *sodium stannite*, and is prepared as described under *sodium stannate*.

Stannous oxide and tin salts are used as reserves under paranitranaline red and other diazo colours (Bull. Soc. Ind. Mulhouse, 1900, 45).

Stannous oxide is sometimes recommended for use in glass and enamel manufacture, but it is too costly, and the results are not very satisfactory.

A so-called *sesquioxide* Sn_2O_3 is obtained as a slimy grey precipitate by the action of recently-precipitated ferric hydroxide on a solution of stannous chloride (*v.* Fuchs, Kastner's Archiv. für Chemie und Meteorologie, 23, 368; J. pr. Chem. 5, 318; and Berzelius, Pogg. Ann. 28, 443; Berz. J. 13, 110).

This substance is readily soluble in ammonia and in concentrated hydrochloric acid. It does not appear to form definite salts. Its hydrochloric acid solution acts like a mixture of stannous and stannic chlorides. An orange-yellow oxide of the composition $SnO \cdot 3SnO_2$ is obtained by digesting metastannic acid in cold aqueous stannous chloride (Fremy, J. Pharm. [ii.] 1, 344).

Stannic oxide SnO_2 occurs as *cassiterite* or *tinstone*, varieties of which are known as *stream tin*, *wood tin*, *toad's eye*, &c. Daubrée (Ann. Mines, 20, 65) has pointed out that, with the exception of quartz, the minerals most frequently associated with tin ore are fluorine compounds.

Stannic oxide is obtained as an anhydrous white powder of sp.gr. 6·7122 at 4° (Joule and Playfair, Chem. Soc. Trans. 1849, 1, 128) when tin is heated until it burns in the air. The powder is converted into microscopic quadratic crystals resembling the native oxide when heated in a current of hydrogen chloride (Deville, Compt rend. 1861, 53, 161; *see* also Abel, Chem. Soc. Trans. 1858, 119). The oxide may also be obtained in trimetric crystals, and is therefore dimorphous (*v.* Daubrée, Pharm. Zentr. 1849, 821; Levy and Bourgeois, Compt. rend. 94, 1365).

It has also been obtained in oblong and rhombic plates of sp.gr. 7·0096 and approaching the form of anatase (Emich, Monatsh. 1893, 14, 345).

Metallic tin may be heated electrically or otherwise to 1700° out of contact with air, and the resulting tin vapour is then burnt in a current of air or oxygen. The stannic oxide thus produced is said to be more homogeneous and in a better state of subdivision for enamelling than the ordinary oxide (Eng. Pat. 9231, 1900).

Stannic oxide is obtained from its ores or from dross, waste, &c., by heating the ore or waste with or without an admixture of coke, chalk, or dolomite and acting upon the liberated molten tin with hot air or oxygen (Fr. Pats. 392805, 392806, 1908; 370640, 1906; 409157, 409485, 1909; also Eng. Pats. 12910, 1899; 28565, 1908; U.S. Pats. 695939, 1912; 780984, 1905; 880873, 1908; J. Soc. Chem. Ind. 1900, 448; *ibid.* 1905, 197; *ibid.* 1908, 335; *ibid.* 1909, 21; *ibid.* 1910, 352; *see* also *ibid.* 1904, 1239; *ibid.* 1907, 696, 1094).

The dioxide may also be formed by electrolysing a solution of sodium chloride using a tin plate as anode and a platinum plate as cathode (Lorenz, Zeitsch. anorg. Chem. 1896, 12, 436).

Stannic oxide is reduced to metal when heated with hydrogen, carbon monoxide, carbon, potassium, or sodium (Doeltz and Graumann, Metallurgie, 1907, 4, 420). It dissolves in fused potassium disulphate, but separates from the mass when treated with water. When fused with sulphur, stannic sulphide is formed, with evolution of sulphur dioxide.

The anhydrous oxide is insoluble in acids, except in concentrated sulphuric acid, with which it forms a syrup decomposed by dilution, with precipitation of the oxide. It dissolves in aqueous or fused alkalis, with formation of stannates.

Treated with hydrochloric acid in presence of tin both stannous and stannic oxides form stannous chloride, and this is used as a method for the recovery of tin from the waste liquors of the dye house (Vignon, Textile Colourist, 18, 333; J. Soc. Chem. Ind. 1893, 762).

With chloroform stannic oxide chiefly reacts thus:

$$SnO_2+2CHCl_3=SnCl_4+2CO+2HCl$$

(Renz, Ber. 1906, 39, 249).

When heated with hypophosphorous acid over a Bunsen flame for 30 mins., *stannous phosphate* or *pyrophosphate*, is formed; since these are readily soluble in hydrochloric acid, stannic oxide can thus be separated from silica which is not affected by this treatment (Dott, Pharm. J. 1908, 81, 585).

Stannic oxide, in the form of *putty powder*, which is a mixture of tin and lead oxides, or a stannate of lead, is used as a polishing material for glass. To avoid any possibility of danger from the use of this powder it has been recommended to mix 1 part of putty powder with 2 of metastannic acid (Gueroult, Compt. rend. 1892, 115, 757). Stannic oxide is an important factor in the manufacture of glazes and of enamels, the latter assuming an intensely white colour on the addition of a small quantity of the oxide. It is also the best material known for making opaque glaze or glass, and is employed in glaze brick and tile manufacture (Enequist, *l.c.*; Burt, Trans. Amer. Ceramic Soc. 1902, 4, 139).

Tin oxide is also said to be useful for the purification of water (J. Soc. Chem. Ind. 1894, 56).

Perstannic oxide SnO_3. W. Spring (Bull. Soc. chim. [iii.] 1, 180) has obtained a substance of the composition $H_2Sn_2O_7$, probably a hydrate of this oxide, by dialysing the turbid solution obtained by adding hydrated barium peroxide in excess to a solution of stannous chloride in hydrochloric acid, and evaporating the solution of the colloid on the water-bath.

Stannic acids. Two isomeric stannic hydroxides are known, each of which behaves as an acid and exists in various degrees of hydration between the limits H_2SnO_3 and H_4SnO_4. They are both colloidal modifications of hydrated stannic oxide, only differing in the size of their particles, the α-acid consisting of relatively small, the β-acid of relatively large particles. (Mecklenburg, Zeitsch. anorg. Chem. 1909, 64, 368; *see* also Fremy, Ann. Chim. Phys. 1844, [iii.] 12, 466; *ibid.* 1848, 23, 385; Musculus, Compt. rend. 1867, 65, 961; Vignon, *ibid.* 1889, 108, 1049; *ibid.* 109, 372; and others.)

Stannic acid, α- or ortho-stannic acid H_2SnO_3 is obtained by precipitating stannic chloride with ammonia, or by addition of calcium or barium carbonate to a solution of stannic chloride in quantity insufficient to precipitate the whole.

It is also formed by treating an alkali stannate with a mineral acid (Kühl, Pharm. Zeit. 1908, 53, 49) and by electrolysing an alkali chloride, nitrate or sulphate solution, using platinum as cathode and tin as anode (Lorenz, Zeitsch. anorg. Chem. 1896, 12, 436), and by other methods (Engel, Compt. rend. 1897, 125, 651;

Neumann, Monatsh. 12, 518; Coppadoro, Chem. Zeit. 1907, 31, Rep. 336).

Its composition varies with its mode of drying, and it is converted into anhydrous SnO_2 at 630°–655°. It forms a gelatinous substance, or white voluminous, amorphous precipitate, slightly soluble in water and of acid reaction. When dried spontaneously, it forms translucent lumps, resembling gum arabic.

When boiled with phenosafranine in the presence of sodium sulphate, stannic acid forms an intense red lake; metastannic acid under the same conditions only forms a pale rose tint (Vignon, Compt. rend. 1891, 112, 580).

A colloidal stannic acid is known (*v.* Graham, Phil. Trans. 151, 213; Van Bemmelen, Rec. trav. chim. 7, 87; Schneider, Zeitsch. anorg. Chem. 1894, 5, 83; *ibid.* 1900, 23, 111; Lottermoser, J. pr. Chem. 1899, [ii.] 59, 489; Biltz, Ber. 1902, 35, 4431). It can be prepared by the dialysis of an alkali solution of tin chloride or of a hydrochloric acid solution of potassium stannate. Colloidal stannic acid is the most important constituent of purple of Cassius (*v.* GOLD PURPLE).

Stannic acid forms a large and important series of salts, most of which are crystalline. The alkaline stannates are soluble, and may be prepared by dissolving the precipitated oxide in the alkaline hydroxide. The others are mostly insoluble, and are best obtained by double decomposition. The potassium and sodium salts are the only ones of technical importance. The stannates have been investigated by Fremy (Ann. Chim. Phys. 1844, [iii.] 12, 462; 1848, [iii.] 23, 393), Moberg (J. pr. Chem. [i.] 28, 230), Marignac (Ann. de Mines, [iii.] 15, 277), Ordway (Amer. J. Sci. [ii.] 40, 173), Ditte (Compt. rend. 1882, 94, 1114; 1883, 96, 701), and Bellucci and Parravano (Atti. R. Accad. Lincei. 1904, [v.] 13, ii. 324, 339; *ibid.* 1905, 14, i. 457).

According to the last-mentioned authors they are isomorphous with the plumbates and platinates.

Sodium stannate Na_2SnO_3 usually occurs in six-sided tables of the composition $Na_2SnO_3,3H_2O$ (Moberg, Marignac, Ordway, *l.c.*), which are less soluble in hot than in cold water. According to Ordway, 100 parts of water dissolve 67·4 parts at 0°, and 61·3 parts at 20°.

According to Bellucci and Paravanno, the water is present not merely as water of crystallisation but in a more intimate form, namely, as $Na_2Sn(OH)_6$.

Crystals of the above composition are deposited from a hot alkaline solution, but the salt may also be obtained with 8, 9, or 10 molecules of water. The form crystallising with 9 molecules is said to be obtained in oblique rhombic prisms by recrystallising the commercial salt (Jonas, Chem. Zentr. 1865, 607); while, according to Haeffely (Dingl. poly. J. 144, 66), crystals of the composition $Na_2SnO_3,3H_2O$ are deposited from hot concentrated solutions of 1·3 sp.gr., but re-dissolve on cooling to a solution of 1·35 sp.gr., from which crystals containing 8 molecules of water are gradually deposited.

Copper is readily tinned by immersion in a solution of the salt.

Sodium stannate is largely used, under the name of 'preparing salt,' as a mordant in dyeing and calico-printing, the fabric being first passed through a solution of the stannate, and then through weak sulphuric acid, which precipitates the hydrated oxide on the fibres.

For preparing this salt on the large scale, the original processes patented by J. Greenwood, J. Mercer, and J. Barnes (Eng. Pat. 10757, 1845), J. Young (Eng. Pat. 12359, 1848; 12744, 1849), and Haeffely (Eng. Pat. 603, 1854), are still used with some modifications. A number of other processes are mentioned in the list of patents relating to tin salts (*infra*).

The process of Greenwood, Mercer, and Barnes consists in heating 22 lbs. of caustic soda in an iron crucible until evolution of water ceases, and then adding 8 lbs. of sodium nitrate and 4 lbs. of sodium chloride, followed, when the mass is nearly fused, by 10 lbs. of feathered tin, with constant stirring until deflagration ensues. The mixture then becomes white hot and pasty, and is wholly converted into the stannate.

For preparing sodium '*stannite*' a mixture of 4 lbs. of sodium chloride, 1 gallon (13·5 lbs.) of caustic soda, 1 lb. of sodium nitrate, and 4 lbs. of tin is heated in an iron crucible, and the dry powder finally obtained is stirred so long as ammonia is evolved.

Young's processes—most of which are described below—consist mainly in the preparation of the stannate directly from the ore, thus avoiding the cost of obtaining and re-oxidising the metal.

By one process the native or prepared oxide is boiled in an iron pot with a quantity, varying with the tin value of the ore, of 22 p.c. soda lye, the temperature being gradually raised to about 600°F., at which combination takes place. When the operation is completed, which is ascertained by removing a portion and seeing how much dissolves, the mass is cooled in another vessel and is dissolved, filtered, or decanted, and recrystallised or sold in solution.

In another process, the ore is heated to redness with one and a half parts of sodium nitrate in a current of steam with constant stirring. The stannate is produced, with evolution of nitrous fumes and nitric acid. The nitrate may be replaced by 1 part of salt, hydrochloric acid being then obtained as the by-product.

'Stannite' of soda is obtained by heating the metal with its own weight of caustic soda, with constant stirring, or by electrolysing a concentrated solution of sodium hydroxide, using a rotating tin anode and a platinum cathode. The current must not be too strong, and the solution must be protected from oxidation by a stream of hydrogen (Goldschmidt and Eckardt, Zeitsch. physikal. Chem. 1906, 56, 385). The solution of the stannite may be used in dyeing and printing operations as it is, or it may be converted into stannate, with precipitation of tin as a black powder, by boiling.

The stannate may be obtained direct from the metal by heating a mixture of 20 parts of tin, 16 of sodium hydroxide, and 3 of manganese dioxide to redness, with constant agitation and free exposure to the air. The dioxide appears to act as a carrier of oxygen, and is obtained unchanged at the end of the operation.

In another process, calcium stannate is obtained by roasting in a reverberatory furnace a mixture of the ore with slaked lime. The product is treated with sufficient hydrochloric acid to precipitate the tin as oxide, but not to redissolve any of it, and the precipitate is dissolved in boiling soda lye. The salt may also be obtained by boiling barium stannate, obtained similarly to the lime salt, with sodium sulphate, until all the barium is converted into sulphate.

Haeffely's process consists in the preparation of a solution of 'plumbate of soda' by dissolving 54 lbs. of red lead or 70–80 lbs. of litharge in a solution of 45 lbs. of caustic soda of 70°Tw. The solution is diluted, and 16 lbs. of tin is suspended in it while boiling, so that in 4 or 5 hours the lead is obtained as a deposit, which may be readily oxidised for re-use, while sodium stannate remains in solution.

The following process has also been employed (Chem. Zeit. 9, 851):—Ten boilers, arranged in horseshoe form, and each having a central tube, the lower end of which forms a perforated funnel, are almost filled with granulated tin, and six of them are charged with soda lye of 15°Bé. The liquor is drawn off from each, after a suitable amount of boiling, through a siphon passed into the central tube, and is passed from boiler to boiler until of 30°Bé., when it is allowed to settle in a tank. For preparing 'sodium stannate liquor,' enough common salt is dissolved in the solution to reduce the proportion of tin to 5 p.c.; and for producing the solid the liquid is evaporated and calcined, and mixed with enough sodium chloride to reduce the tin to 42 p.c.

A *sodium arsenio-stannate*

$$Na_2O{\cdot}6SnO_2{\cdot}2As_2O_5,5H_2O,$$

occurring in shining needles, is sometimes used instead of the ordinary stannate, and is said to give brighter colours and to be more economical. It is prepared by adding nitric acid to a boiling solution of sodium stannate and sodium arsenate, and treating the resulting precipitate of $2SnO_2{\cdot}As_2O_5,10H_2O$ with excess of soda (*v.* Haeffely, Dingl. poly. J. 140, 290; J. Mercer and W. Blythe, Eng. Pat. 12807, 1849). In the latter process a sodium phosphostannate is also employed for the same purposes. Another sodium arsenio-stannate

$$Na_2SnO_3 5Na_3AsO_4,60H_2O$$

has been obtained by Prandtl (Ber. 1907, 40 2133).

Potassium stannate K_2SnO_3 is obtained similarly to the sodium salt, and is sometimes employed in dyeing and calico-printing. It crystallises from spontaneously evaporated solutions in transparent oblique rhombic prisms of the composition $K_2SnO_3,3H_2O$ (Marignac, Ann. de Mines, [v.] 15, 277; Moberg, J. pr. Chem. [i.] 28, 230; Ordway, Amer. J. Sci. [ii.] 40, 173). It becomes anhydrous when heated to redness.

Potassium stannate is insoluble in alcohol, but dissolves in water to an alkaline solution, 100 parts of water dissolving 106·6 parts at 10° and 110·5 parts at 20° (Ordway, *l.c.*).

Cupric stannate $CuSnO_3$ has been employed as a green pigment. It is prepared for this purpose by precipitating sodium stannate with copper sulphate, or by addition of a solution of 118 parts of tin in *aqua regia* to a solution of 250 parts of copper sulphate, with subsequent addition of sodium hydroxide in excess.

Chromium - tin compounds. A so-called chromium stannate or 'pink colour,' used for producing a blood-red colour in pottery glaze, is prepared by heating a mixture of 10 parts of stannic oxide, 34 parts of calcium carbonate, 5 parts of silica, 1 part of alumina, and 3–4 parts of crystallised potassium chromate for several hours in a closed crucible. The red compound produced gives a fine rose-coloured product when washed with dilute hydrochloric acid.

A substance known as *mineral lake*, possessing a fine lilac colour, is used in colouring paper hangings and for oil painting. It consists of a mixture of chromium oxide and excess of stannic oxide, and can be prepared by igniting together 1 part of the former with 50 of the latter (Leykauf, J. pr. Chem. 1892, 19, 127), or by dissolving potassium chromate in 5 or 6 parts of water, and adding this solution to a solution of stannous chloride until precipitation ceases. The damp, washed precipitate is ground with half its volume of nitre, and dried, and the finely-powdered mixture is thrown in small portions into a crucible heated to redness and containing some potassium nitrate. After pouring off the supernatant fused salt, the pale-yellow residue is washed free from alkali, and is calcined at a strong heat in a luted crucible until it becomes dense and acquires the desired colour.

A series of 'pinks' have been prepared by moistening equal portions of calcium stannate or mixtures of tin dioxide and whiting with varying proportions of a solution of ammonium dichromate. The mixtures are then dried, fired, cooled, and washed with hot water. The products all contain a more or less constant quantity of chromium, and it is probable that they consist of the colouring agent, chromium oxide, resting on a base of stannic oxide (Lethbridge, Trans. Engl. Ceramic Soc. 1903–1904, **9**: *see* also Hull, Trans. Amer. Ceramic Soc. 1902, **4**, 230).

Stannates of many other metals and thiostannates have also been obtained.

Metastannic acid or **β-stannic acid** is obtained as a white insoluble powder, with evolution of nitrous fumes, when tin is treated with strong nitric acid (Engel, Compt. rend. 1897, **124**, 765; *ibid.* 125, 709; Van Leent, Rec. trav. chim. 1898, 17, 86).

It is also obtained by the ready isomerisation of stannic acid, as when a hydrochloric or hydrobromic acid solution of the latter is allowed to stand (Lorenz, Zeitsch. anorg. Chem. 1895, 9, 376).

Its degree of hydration, like that of stannic acid, depends on the process used for drying (*see* Frémy, Weber, &c.).

Metastannic acid is insoluble in nitric acid (*cf.* Jörgensen, Zeitsch. anorg. Chem. 1908, **57**, 353). It swells up in concentrated sulphuric acid, the product being soluble in water and alcohol, but decomposing into the two acids on boiling. Hydrochloric acid converts it into a chloride of metastannic acid, which is soluble in water but not in hydrochloric acid, and which is reprecipitated from solution in the gelatinous form on boiling, or on addition of much hydrochloric acid.

It is insoluble in ammonia, except when

freshly-precipitated from a cold solution of a metastannate by an acid, but dissolves in alkaline hydroxides and carbonates, with formation of mestastannates.

A colloidal metastannic acid is known (*v.* Graham, Phil. Trans. 151, 213; Van Bemmelen, Rec. trav. chim, 7, 87; Liebschutz, Chem. News, 1910, 102, 213).

The meta- acid is said to have a tendering effect on silk fibres (Heermann, Färber Zeit. 1908, 19, 318; Bayerlein, *ibid.* 1908, 18, 241).

The salts of metastannic acid appear to indicate that the acid has the formula

$$5(SnO_2 \cdot H_2O), \textit{ i.e. } H_2Sn_5O_{11},4H_2O,$$

but it is generally considered to have the same composition as stannic acid.

The metastannates are difficultly crystallisable. When strongly heated, they decompose into stannic oxide and the base. *Potassium metastannate* $K_2Sn_5O_{11},4H_2O$ is a strongly alkaline salt obtained by dissolving the acid in potash. It is precipitated from aqueous solution by a neutral alkaline salt or by ammonium chloride. *Sodium metastannate* $Na_2Sn_5O_{11},4H_2O$ is a slightly soluble granular salt obtained like the potassium salt. A hard gummy precipitate of the composition $Na_2Sn_9O_{19},8H_2O$ is obtained by addition of caustic soda to a solution of the above compound of hydrochloric acid and metastannic acid.

Thiometastannates are also known.

Perstannic acid $HSnO_4,2H_2O$ is formed when stannic acid is treated with excess of 30 p.c. hydrogen peroxide and the mixture heated to about 70°. On heating to 100° it yields the acid $H_2Sn_2O_7,3H_2O$. The alkali stannates when similarly treated form the salts corresponding to these acids (Tanatar, Ber. 1905, 38, 1184). When concentrated alkali stannates are electrolysed at low temperature with a low current density they also form perstannates (Coppadoro, Gazz. chim. ital. 1908, 38, i. 489, and *l.c.*).

Salts of tin with oxyacids. These salts, although numerous, are of little technical importance, but a number of solutions containing them are used in dyeing and calico-printing. *Stannous sulphate* $SnSO_4$ is obtained as a crystalline powder by evaporating *in vacuô* a solution of tin or stannous hydroxide in dilute sulphuric acid. *Stannic sulphate* $Sn(SO_4)_2$ is obtained as a white salt, soluble in dilute sulphuric acid but mostly precipitated on dilution, by dissolving the hydroxide in sulphuric acid. According to Ditte (Compt. rend. 1887, 104, 172), a solution of stannic hydroxide in warm dilute sulphuric acid (1–8) deposits, on concentration, first radiating needles, then rhomboidal lamellæ, and finally hexagonal prisms, all colourless and all possessing the composition $Sn(SO_4)_2,2H_2O$. He has obtained the same product by the action of sulphuric acid on metastannic acid. The crystals deliquesce to a clear liquid. The solution is decomposed, on dilution, with precipitation of the hydroxide. A number of double tin sulphates are known (Weinland and Kühl, Ber. 1906, 39, 2951; Zeitsch. anorg. Chem. 1907, 54, 244). *Stannous nitrate* $Sn(NO_3)_2$ is obtained by dissolving tin or stannous hydroxide in very dilute nitric acid (R. Weber, J. pr. Chem. [ii.] 26, 121; Walker, Chem. Soc. Proc. 1893, 114; Engel, *l.c.*).

A basic salt of the composition $2SnO \cdot N_2O_5$ is obtained as a white crystalline precipitate by adding a solution of sodium carbonate to the neutral salt in quantity insufficient for complete precipitation. It may also be obtained by digesting the normal salt with stannous hydroxide. It deflagrates at 100°, or on friction. *Stannic nitrate* $Sn(NO_3)_4$ crystallises in silky tablets from a solution of stannic hydroxide in nitric acid.

It is also formed by dissolving tin in 70 p.c. nitric acid (Montemartini, Gazz. chim. ital. 1892, 22, 384).

The so-called 'nitrate of tin' or 'physic' used by dyers is a mixture of stannous and stannic chlorides (*v. Stannous chloride, infra*). A solution of tin in nitric acid is, however, also used in dyeing (*v.* Crookes, Handb. of Dyeing and Calico Printing, 1874, 527).

Stannous sulphide SnS is obtained as a tough, crystalline, bluish-grey fusible mass by heating tin with sulphur, or in crystalline scales by fusing the sulphide so obtained with stannous chloride and treating the product with dilute hydrochloric acid. The crystalline sulphide may also be obtained by heating the amorphous form in the electric furnace (Mourlot, Compt. rend. 1897, 124, 768). It is obtained as a brown powder, which blackens on drying, by precipitating stannous chloride with sulphuretted hydrogen.

Stannous sulphide is insoluble in normal ammonium sulphide, but dissolves in the yellow sulphide and in alkaline polysulphides (*v.* Ditte, Compt. rend. 1882, 94, 1419), and, with evolution of sulphuretted hydrogen and formation of stannous chloride, in hot hydrochloric acid. Hydrogen chloride acts similarly on the warmed, but not on the cold, sulphide (Ditte, *ibid.* 1883, 97, 42).

Stannous sulphide is sometimes soluble, at other times insoluble, in sodium hydroxide, the cause of this variation being unknown (Perkin, J. Soc. Chem. Ind. 1901, 425).

Pure stannous sulphide has m.p. 880° (Pélabon, Compt. rend. 1906, 142, 1147). It is slightly radioactive (Campbell, Proc. Cambridge Philos. Soc. 1906, 13, 282).

Stannic sulphide SnS_2 cannot be prepared by simply heating tin and sulphur together, because the heat generated is sufficient to reduce the disulphide to monosulphide, but it may be so obtained when sufficient ammonium chloride or other volatile substance is present to moderate the action. Woulfe (Phil. Trans. 1771, 61, 114; also Gmelin's Handbook, 5, 79) describes a number of methods of preparing this compound, which is used as a bronze powder for bronzing articles of gypsum, wood, &c.

Various mixtures of tin chloride and sulphur, or tin, sulphur, and ammonium chloride, or tin amalgam or tin sulphide with sulphur and ammonium chloride, are heated in retorts or covered crucibles, at first gently for a few hours, then more strongly, but not quite to redness. On cooling the greater portion of the sulphide is at the bottom, but the purer and finer crystals are found sublimed at the top.

Crystalline stannic sulphide, sp.gr. 4·425, is often known as 'Mosaic gold,' *aurum mosaicum*, or *musivum.* For a reddish shade, 50 grms. of 50 p.c. tin amalgam, 25 of crystallised stannous chloride, 35 of ammonium chloride, and 35 of sulphur are finely powdered together and ignited gradually in a glass retort covered with asbestos, in the flame of a large blow-pipe, which is moved about periodically. During the operation the colour of the mass should be dark brown. If it becomes black owing to the formation of stannous sulphide, the flame should be lowered. For yellowish shades, 50 grms. of crystallised stannous chloride and 25 grms. of flowers of sulphur are employed. The yield is 57 p.c. of the theoretical (Langutt, Zeitsch. angew. Chem. 1897, 557). *V.* GOLD, MOSAIC.

When heated, stannic sulphide sublimes, with partial decomposition into sulphur and stannous sulphide. It dissolves readily in alkalis, but not in acids, except *aqua regia.* It fuses in a current of chlorine, and absorbs 6 molecules of the gas, forming a yellow crystalline compound of the composition $SnCl_4,2SCl_4$ (Rose, Pogg. Ann. 42, 517). When heated with iodine in a current of carbon dioxide it gives a brown, crystalline, fusible mass of the composition SnS_2I_4 (Schneider, J. pr. Chem. [i.] 79, 419).

The dirty-yellow precipitate obtained by passage of sulphuretted hydrogen through a solution of a stannic salt consists of a mixture of stannic sulphide and stannic hydroxide; this dissolves in alkaline sulphides, with formation of thiostannates (Kühn, Annalen, 1852, 84, 110), and also in alkalis and hydrochloric acid. Ditte (Compt. rend 1882, 95, 641) describes several double sulphides or thiostannates and also seleniothio-stannates.

Hydrogen chloride or bromide convert the sulphide into the corresponding halide (Kelley and Smith, Amer. Chem. J. 1896, 18, 1096).

When stannic sulphide is allowed to remain in contact with ammonia, filtered, and the filtrate acidified, a white mass of an amorphous stannic sulphide is formed. It dissolves readily in ammonia to an orange-red solution, and becomes yellow on drying (Schmidt, Ber. 1894, 27, 2739; Chem. Zentr. 1907, i. 397; Materne, *ibid.* 1906, ii. 557; Lang and Carson, J. Soc. Chem. Ind. 1902, 1018). When dried in air it loses a little sulphur and becomes dark brown, hard, and brittle. This sulphide behaves like a colloidal sulphide. Colloidal stannic sulphide has been obtained (Spring, Ber. 1883, 16, 1142; Schneider, Zeitsch. anorg. Chem. 1894, 5, 83; *see* also Biltz, Chem. Zentr. 1904, i. 1040).

Tin sesquisulphide Sn_2S_3 is obtained by gentle ignition of 3 parts of stannous sulphide and 1 of sulphur in a retort. It forms a yellowish-grey mass of metallic lustre (Antony and Niccoli, Gazz. chim. ital. 1892, 22, ii. 408).

Stannous selenide SnSe is obtained with incandescence when selenium is heated with tin, as a light-grey lustrous body of crystalline fracture, not reducible by hydrogen. It is obtained as a dark-brown precipitate, which becomes nearly black on drying, by passing seleniuretted hydrogen into stannous chloride solution. It dissolves in alkalis and akaline sulphides (*v.* Uelsmann, Annalen, 1860, 116, 124; Pélabon, *l.c.*).

Stannic selenide $SnSe_2$ is obtained by passing seleniuretted hydrogen into stannic chloride solution as a yellowish-red precipitate which dries to a brown powder, soluble in caustic alkalis and alkaline sulphides, and forming stannous selenide when heated in hydrogen.

According to Little (Annalen, 1859, 112, 213), is obtained as a tin-white, lustrous, easily-fusible mass, unaffected by hydrochloric acid, but readily decomposed by nitric acid, by heating tin in selenium vapour. Ditte (Compt. rend. 1882, 95, 641; *ibid.* 1887, 104, 174) describes some double selenides corresponding with the thiostannates (*v. Stannic sulphide*).

A telluride is also known.

Stannous chloride $SnCl_2$ is obtained in the anhydrous condition by heating tin in hydrogen chloride, or by heating a mixture of equal weights of 'feathered' (*i.e.* granulated) tin or filings and mercuric chloride; and in monoclinic prisms of the composition $SnCl_2,2H_2O$ (O. Henry, J. Pharm. 12, 134) by evaporating a solution of tin in hydrochloric acid.

Stannous or stannic chloride may be obtained as desired by the following process: Stannous chloride, formed by the action of a solution containing chlorine on tin, is subjected to the action of a gaseous or fluid mixture containing free chlorine, hydrochloric acid, and air or oxygen (Young, J. Amer. Chem. Soc. 1901, 23, 119, 450). Stannic chloride is thus formed which when made to react with tin reforms stannous chloride (U.S. Pats. 810454, 810455, 810456, 810897, 1906; D. R. P. 184494). For other methods, *see* D. R. PP. 176456, 176457, 181876, 188018).

The crystals melt at 40°, and at 100° lose most of their water, together with a little hydrochloric acid. When dried *in vacuô*, or over sulphuric acid, they become anhydrous.

The anhydrous chloride fuses at 249·3° to an oil which boils at 617°–628° (Carnelley and Carleton Williams, Chem. Soc. Trans. 1879, 563). or, according to Biltz and V. Meyer (Ber. 1888, 21, 22), at 606·1°. The anhydrous chloride is sometimes called 'butter of tin,' although that term is usually applied to the hydrated tetrachloride. Stannous chloride is soluble in water and alcohol. On dilution, the aqueous solution becomes turbid, from precipitation, with separation of hydrochloric acid, of a basic chloride $2SnO,HCl,H_2O$, which is also formed when the clear solution is exposed to the air. Mallet (Chem. Soc. Trans. 1879, 524) has observed a gelatinous deposit of the composition $SnO_2{\cdot}HCl$, to which he has applied the term *chlor-stannic acid*, in a solution of stannous chloride after long standing. Donath (Rep. Anal. Chem. 7, 77) considers that this compound is produced, together with stannic hydroxide, by the action of light on aqueous stannous chloride.

R. Engel (Compt. rend. 1888, 106, 1398) has obtained a compound of the composition

$$SnCl_2,HCl,3H_2O,$$

which he calls *chlorostannic acid*, by passing chlorine over the hydrate $SnCl_2,2H_2O$. The crystals fuse to a clear liquid having the above composition, and depositing, when cooled to −40°, slender silky needles which melt at about −27°. According to Ditte (*ibid.* 1883, 97, 42), however, the liquid contains a chloride of the composition $SnCl_2,H_2O$, which is also formed by the action of concentrated hydrochloric acid on the chloride $SnCl_2,2H_2O$.

When stannous chloride is electrolysed crystalline tin can be obtained (Saposhnikoff, J. Russ. Phys. Chem. Soc. 1905, 37, 153).

Stannous chloride forms crystalline double chlorides with the alkalis (*v.* Benas, Chem. Zentr. 1884, 957, forming salts of the composition $SnCl_2{\cdot}KCl,H_2O$ and $SnCl_2{\cdot}2KCl,H_2O$). It absorbs dry ammonia, with formation of a compound of the composition $SnCl_2{\cdot}NH_3$, and also $SnCl_2{\cdot}2NH_3$ (Naumann, Ber. 1910, 43, 313).

Stannous chloride is soluble in alcohol and in ether, the latter solution gives a brownish-red ring when added to hydrochloric acid containing 1/50 mgrm. of arsenious acid (Jong, Zeitsch. anorg. Chem. 1902, 41, 596).

Like other stannous salts, stannous chloride is a strong reducing agent and is employed as such, both for the reduction of organic and inorganic compounds. It is also used in the analysis of a number of substances (Henriet, Compt. rend. 1901, 132, 966; Weil, *ibid.* 1902, 134, 115).

A small quantity of stannous chloride is said to increase the yield of alcohol in fermentation processes; it also accelerates the revivification of the yeast sown in must, and cultures taken from the yeast so formed retain a similar property for a certain length of time (Gimel, Compt. rend. 1908, 147, 1324).

Stannous chloride and other stannous salts are largely used in dyeing and calico-printing under the name 'tin salts' or 'tin crystals' (Dreher, Färber-Zeit. 7, 145; Reisz, *ibid.* 221, 222; Binder, Bull. Soc. Ind. Mulhouse, 1900, 92; Paterson, J. Soc. Dyers Col. 1906, 22, 188; Coberti, J. Soc. Chem. Ind. 1899, 829).

Stannic chloride $SnCl_4$ was first prepared by Libavius in 1605, who obtained it by distilling a mixture of tin or its amalgam with excess of mercuric chloride; he termed the product *Spiritus argenti vivi sublimati.* It may also be prepared by the action of chlorine (Lorenz, Zeitsch. anorg. Chem. 1895, 10, 44; Beckmann and Geib, *ibid.* 1906, 51, 96); or phosphorus pentachloride on tin (Goldschmidt, Chem. Zentr. 1881, 489); or by the action of chloroform on stannic oxide (Renz, Ber. 1906, 39, 249). Technically, it is generally prepared by the action of chlorine or hydrochloric acid on tin-plate waste or tin waste residues from dye works and a large number of patents have been registered for this purpose (*see* Fr. Pats. 371067, 1906; 392615, 401125, 405851, 406300, 1909; Heermann, Färber Zeit. 1907, 18, 34; U. S. Pats. 884756, 877261, 877248, 1908; 976990, 958986, 1910; D. R. P. 222838; J. Soc. Chem. Ind. 1907, 253; *ibid.* 1908, 160; *ibid.* 1909, 21, 1087; *ibid.* 1910, 424, 1105; *see* also U. S. Pats. 883140, 883141, 1908; Fr. Pats. 386594, 388089, 1908).

The chloride distils over as a colourless mobile liquid, boiling at 113·89° at 760 mm. pressure (Thorpe, Chem. Soc. Trans. 1880, 37, 331), and solidifying at —33° to small white crystals (Besson, Compt. rend. 1889, 109, 940).

The liquid has sp.gr. 2·2788 at 0°/4° (Thorpe, *loc. cit.*), and, owing to its high refractive index, presents a very brilliant appearance.

When exposed to the air, it emits dense white fumes, and is finally converted into a crystalline hydrate $SnCl_4.5H_2O$ (Lewy, Compt. rend. 1845, 21, 369), which is also obtained, with evolution of heat, by mixing stannic chloride with one-third its weight of water. This hydrate is sometimes known as 'butter of tin,' or, by the dyers, as 'oxymuriate of tin.' Hydrates of the composition $SnCl_4.3H_2O$ and $SnCl_4.8H_2O$ are also known. For the sp.gr. of various solutions of this salt, *see* Heerman (Chem. Zeit. 1907, 31, 680).

On hydrolysis, it first forms the intermediate compound $SnCl_3OH$, and then stannic acid; by alcoholysis it gives the compound $SnCl_3OEt$ (Pfeiffer, Ber. 1905, 38, 2466; von Biron, J. Russ. Phys. Chem. Soc. 1906, 37, 963).

Stannic chloride forms crystalline double chlorides, sometimes called *chloro-stannates* or *stannichlorides* with the alkaline chlorides (Bellucci and Parravano, Atti. R. Accad. Lincei. 1904, v. 13, ii. 307; von Biron, J. Russ. Phys. Chem. Soc. 1904, 36, 489, 933; *ibid.* 1905, 37, 963, 994, 1036; Weinland and Bames, Zeitsch. anorg. Chem. 1909, 62, 250); thus, $SnCl_4{\cdot}2KCl$ and $SnCl_4{\cdot}2NH_4Cl$, the latter forming the 'pink salt' formerly much used by dyers.

Stannic chloride dissolves phosphorus and iodine, and mixes with bromine and carbon disulphide. It converts mercury into calomel, and is itself decomposed by nitric acid, with precipitation of metastannic acid. Among the substances produced by direct combination with other compounds may be mentioned $SnCl_4{\cdot}2NH_3$, a soluble volatile solid (Rose, Pogg. Ann. 16, 63); $3SnCl_4{\cdot}2PH_3$, a yellow fuming solid (Rose, *ibid.* 24, 159); $SnCl_4{\cdot}N_2O_3$, a yellow amorphous mass; $SnCl_4{\cdot}SO_3$ a white solid (Rose, *ibid.* 44, 320); $SnCl_4{\cdot}PCl_5$ and $SnCl_4{\cdot}POCl_3$ (Casselmann, Annalen, 1852, 83, 257); $SnCl_4 2(C_2H_5)_2O$, a white crystalline compound (Coldridge, Phil. Mag. [v.] 29, 383, 480). A yellow crystalline substance $SnCl_4{\cdot}2SCl_4$, fusing below 30°, is obtained by the action of chlorine on stannic sulphide (Rose, Pogg. Ann. 42, 517).

When a cooled solution of stannic chloride in chloroform is treated with nitric peroxide, the compound $3SnCl_4{\cdot}4NOCl$ is formed (Thomas, Compt. rend. 1896, 122, 32), whilst if such a solution is treated with nitrogen sulphide dissolved in chloroform, red crystals of the substance $SnCl_4{\cdot}2N_4S_4$ are deposited (Davis, Chem. Soc. Trans. 1906, 1576).

Stannic chloride absorbs large quantities of chlorine at low temperatures, with considerable increase in volume and lowering of the melting-point (Besson, Compt. rend. 1889, 109, 940).

Stannic chloride is used in dyeing as a mordant, and silk is weighted with it before dyeing (Froenkel and Fasal, J. Soc. Chem. Ind. 1898, 148; *ibid.* 1904, 899). Its use for this purpose is said to have been discovered by the Dutch chemist, Drebbel, in 1630, who found that cochineal gives a permanent brilliant red dye in the presence of dilute stannic chloride.

A patent was taken out in England as early as 1748 by O. Pawl (Specification No. 630, 1748) for the use of tin dissolved in *aquafortis*, with addition of ammonium chloride, for dyeing scarlet.

The older methods of preparing tin salts for this purpose, whereby tin is dissolved in excess of hydrochloric acid, and the solution is oxidised by means of chlorates, have the disadvantage of producing a very impure product. The mordanting and weighting is due only to the stannic chloride and the impurities tend to weaken the fibres, to make the latter more sensitive to light, and to bring about the gradual deterioration in the strength of the material. To avoid this, Sperry has devised a special apparatus whereby pure anhydrous stannic chloride may be prepared by the treatment of impure tin bearing materials with ordinary commercial chlorine (J. Soc. Chem. Ind. 1908, 312, 404, 628, 749, 978; Eng. Pat. 389188; U. S. Pats. 882354, 887538, 885391. For Fig. and description of apparatus, *see* J. Soc. Chem. Ind. 1908, 313). From the pure stannic chloride thus prepared all the compounds of tin needed by dyers may be obtained in pure condition.

A solution consisting of stannic and stannous chloride, obtained by dissolving tin in *aqua regia*, is used in the preparation of fuchsine under the name 'nitrate of tin' or 'physic' (*see* above).

It is now more usual, however, to employ the crystalline pentahydrate $SnCl_4,5H_2O$.

A solution consisting of stannic chloride, containing more or less stannous chloride, and used in dyeing under the name 'oxychloride of tin' or 'pink cutting liquid,' is prepared by adding 1 part of stannous chloride to 1½ parts of nitric acid of sp.gr. 1·31 in portions, with constant stirring, to prevent boiling over from the violence of the action; or by dissolving 337 parts of stannous chloride in 300 parts of hydrochloric acid (20°Tw.), with the aid of a minimum of water, and adding gradually 58 parts of potassium chlorate.

In small quantities stannic chloride may be added to the sizing mass for cotton warps in order to prevent the too rapid decomposition of the size (Textile Colorist, 1893, 15, 7).

For the detection of tin in mordanted cloth, *see* Paterson (J. Soc. Dyers Col. 1906, 22, 189); Silbermann (Bull. Soc. chim. Mulhouse, 1906, 76, 357).

A rapid and delicate method for detecting sodium chloride in commercial stannic chloride, consists in precipitating the former with 99·5 p.c. alcohol saturated with hydrogen chloride (Heermann, Chem. Zeit. 1907, 31, 27).

Stannous bromide $SnBr_2$ is obtained in solution by dissolving tin in hydrobromic acid (Balard, Ann. Chim. Phys. 1826, [ii.] 32, 337). It may be obtained as an anhydrous, pale-yellow, crystalline mass by heating tin in hydrobromic acid vapour and re-distilling the product (Freyer and Meyer, Zeitsch. anorg. Chem. 1892, 2, 1).

According to Rayman and Preis (Annalen, 1884, 223, 323), it melts at 215·5° to a pale-yellow oily liquid, of sp.gr. 5·117 at 17°. According to Carnelley and Carleton Williams (Chem. Soc. Trans. 1879, 564), it melts at 259°, and boils at 617°–634°.

A hydrate $SnBr_2,H_2O$ separates in needles or thin plates from the greenish solution of tin in warm concentrated hydrobromic acid. It loses its water in dry air, or when heated to 70°–80°. It dissolves in a little water, but is decomposed by excess, with precipitation of a gelatinous precipitate (*v.* Benas, Chem. Zentr. 1884, 957). A hydrate $SnBr_2,2H_2O$, crystallising in large monoclinic tables, is also obtained from the solution of tin in hydrobromic acid (Benas, *l.c.*).

Benas, Rayman and Preis have also described compounds of stannous bromide with potassium and ammonium bromides.

Stannic bromide $SnBr_4$ was discovered in 1826 by Balard (Ann. Chim. Phys. [ii.] 32, 337). It is obtained by adding bromine drop by drop to strips of tin, the temperature being kept between 35° and 59° (Lorenz, Zeitsch. anorg. Chem. 1895, 9, 366); or preferably, on account of the violence of the action with pure bromine, by gradually adding the tin to a solution of bromine in carbon disulphide, or by passing the vapour of bromine over heated tin (Carnelley and O'Shea, Chem. Soc. Trans. 1878, 55).

Stannic bromide forms a white iridescent deliquescent mass, which, by distillation, is obtained in small, well-formed, highly lustrous crystals, melting at 30° and boiling at 210° (uncorr.) (Carnelley and O'Shea, *l.c.*), or at 203° (corr.) (Rayman and Preis, Chem. Zentr. 1882, 773), and having a sp.gr. of 3·349 at 3·5° (Rayman and Preis, *l.c.*).

It fumes in the air, and dissolves readily in water. The solution deposits stannic hydroxide on heating or after standing. A hydrate $SnBr_4,4H_2O$ is obtained in colourless transparent, fuming crystals, by exposing the anhydrous bromide to moist air, or by dissolving in a little water and evaporating over sulphuric acid. Oxybromides $Sn_2Br_6O,12H_2O$ and $SnBr_8O_2,10H_2O$, obtained from stannic bromide, and a compound $SnBr_4{\cdot}2NH_3$, obtained by absorption of ammonia by the warmed bromide, are also known (Rayman and Preis, *l.c.*).

Stannic bromide unites with ether to form a deliquescent crystalline body $SnBr_4(C_2H_5)_2O$ (Niklès, Compt. rend. 1861, 52, 869). By evaporating solutions of the mixed bromides, Raymond and Preis (*l.c.*) have obtained the following double bromides or stannibromides: $2NaBr{\cdot}SnBr_4,6H_2O$, in pale-yellow, soluble crystals; $CaBr_2{\cdot}SnBr_4,6H_2O$, in slender deliquescent needles; $MgBr_2{\cdot}SnBr_4,10H_2O$, in pale-yellow, deliquescent tables; $MnBr_2{\cdot}SnBr_4,6H_2O$, in large, pale-yellow, deliquescent crystals; $FeBr_2{\cdot}SnBr_4,6H_2O$, in greenish, granular crystals; $NiBr_2{\cdot}SnBr_4,8H_2O$, in apple-green, granular, deliquescent crystals; and

$$CoBr_2{\cdot}SnBr_4,10H_2O,$$

in yellowish-red, deliquescent tablets (*see also* Leteur, Compt. rend. 1891, 113, 540).

Stannous iodide SnI_2 is obtained by dissolving tin in concentrated hydriodic acid. At the ordinary pressure solution is extremely slow, but it proceeds more rapidly in a sealed tube at 120°–150° (Wöhler and Dünhaupt, Annalen, 1853, 86, 374). It may also be obtained in yellowish-red needles, slightly soluble in water, and readily soluble in solutions of alkaline chlorides and iodides, and in hydrochloric acid, by addition of potassium iodide in slight excess to a concentrated solution of stannous chloride (Warden, Pharm. J. 1897, 58, 61). The aqueous solution is decomposed by much water, with separation of hydriodic acid and a yellow, insoluble body the composition of which varies with the amount of water present (Personne, Compt. rend. 1862, 54, 216).

Stannous iodide melts at 316° (Carnelley and Carleton Williams, Chem. Soc. Trans. 1879, 564) and volatilises at a red heat. It absorbs dry ammonia, with formation of a white body having the composition $2NH_3{\cdot}SnI_2$ (Rammelsberg, Pogg. Ann. 48, 169; Ephraim and Schmidt, Ber. 1909, 42, 3856). It unites with other metallic iodides, with hydrogen iodide (Young, J. Amer. Chem. Soc. 1897, 19, 851), and with stannous chloride.

Stannic iodide SnI_4 is obtained in yellowish-red octahedra by heating tin filings, preferably moistened with carbon disulphide, with iodine to a temperature above 50°.

It has sp.gr. 4·696 at 11° (Bödeker, Die

Beziehung zwischen Dichte und Zusammensetung, &c., Leipzig, 1860), m.p. 146° and b.p. 295° (Personne, J. 1862, 172), m.p. 143°, b.p. 341° corr.) (Emich. Monatsh. 1904, 25, 907). It sublimes at 180°.

It dissolves in carbon disulphide, ether, alcohol, chloroform, and benzene. Water decomposes it into stannic hydroxide and hydriodic acid.

By the action of ammonia on stannic iodide, dissolved in carbon disulphide, a white substance $SnI_4.8NH_3$, insoluble in water, is formed (Ephraim and Schmidt, *l.c.*).

Stannous fluoride SnF_2 is obtained in small, opaque, white, monoclinic tables of sweetish astringent taste, by evaporating a solution of stannous hydroxide in hydrofluoric acid.

Stannic fluoride SnF_4 is obtained in aqueous olution by dissolving the hydrated dioxide in hydrofluoric acid; or as a hygroscopic, white crystalline substance by the action of anhydrous hydrofluoric acid on stannic chloride (Ruff and Plato, Ber. 1904, 37, 673). It has sp.gr. 4·78 at 19°, b.p. 705°, but sublimes below this emperature. It combines with other fluorides orming a characteristic series of crystalline double salts, the *stannifluorides*, which are isomorphous with the corresponding fluorides of titanium, germanium, zirconium, and silicon Marignac, J. 1859, 110; Emich, Monatsh. 1904, 25, 907; Ruff and Albert, Ber. 1905, 38, 55; Hall and Smith, Chem. Zentr. 1905, ii. 1162).

A number of mixed halogen compounds, such as $SnCl_3Br$, $SnCl_2I_2$, $SnBr_3I$, &c., have been described (Besson, Compt. rend. 1897, 124, 383; Lenormand, J. Pharm. Chim. 1898, [vi.] 8, 249; *ibid.* 1899, 10, 114). According to Auger (Compt. rend. 1909, 149, 860), most of these compounds are only mixtures, thus, $2SnBr_2I_2=SnBr_4+SnI_4$, &c.

Phosphides. Tin combines directly with phosphorus, forming a series of phosphides, which are used for the production of phosphor-bronze (Emmerling, Ber. 1879, 12, 155; Natanson and Vortmann, *ibid.* 1877, 10, 1460; Künzel, Dingl. poly. J. 1888, 270, 166; D. R. P. 103966; Stead, J. Soc. Chem. Ind. 1897, 206).

Tin phosphide Sn_4P_3 has a silver-white colour, crystallises in spangles, sp.gr. 5·18, and begins to dissociate at 480°.

The phosphide SnP is also a crystalline substance, sp.gr. 4·10. It has a metallic appearance, begins to dissociate into phosphorus and Sn_4P_3 at 415°, and is attacked violently by fuming nitric acid (Jolibois, Compt. Rend. 1909, 48, 636). Other phosphides have also been decribed.

An unstable *tin carbonate* Sn_2CO_3 is also known (Deville, Ann. Chim. Phys. 1852, [iii.] 35, 4, 48; *see* also Moissan, Compt. rend. 1897, 125, 840).

Organic Compounds of Tin.

Stannous acetate, *oxalate*, *citrate*, and *tartrate* are employed in dyeing and calico-printing, being generally prepared by addition of an alkaline salt of the acid to a solution of stannous chloride, or by dissolving the precipitated hydroxide in the acid. Liechti and Schwitzer (Mittheilungen des Tech. Gew. Museums, 1886, 41) have indicated the value of some of these as mordants (Platsch, Zeitsch. anorg. Chem. 1899, 20, 308; Rosenheim and Aron, *ibid.* 1904, 39, 171; Paterson, *l.c.*; Henderson, Orr, and Whitehead, Chem. Soc. Trans. 1899, 555).

The ancient Egyptians are believed to have used basic tin citrates (prepared by the action of lemon juice or citric acid on tin), as a mordant, in dyeing the tapestries discovered in the tombs of Antinoa (Gilliéron, Bull. Soc. Mulhouse, 1907, 77, 148). Basic tin citrate forms a very efficient mordant for yellow dyes on wool, giving pure intense colours.

Stannous formate is prepared by dissolving precipitated stannous hydroxide in dilute formic acid. It forms white anhydrous crystals, which decompose above 100° (Goldschmidt, Chem. Zeit. 1907, 31, 608).

Tin forms a number of alkyl derivatives of the type SnR_4, $SnR^1R^2R_2{}^3$, &c. (Letts and Collie, Chem. Soc. Proc. 1886, 166; Pope and Peachy, *ibid.* 1903, 290; Polis, Ber. 1889, 22, 2915; Pfeiffer and Schnurmann, *ibid.* 1904, 37, 319; Werner, Zeitsch. anorg. Chem. 1898, 17, 99; Pfeiffer, *ibid.* 1910, 68, 102).

Methyl stannonic acid or **methyl stannoxylic acid** $MeSnO{\cdot}OH$ is formed when a mixture of methyl iodide, stannous chloride, and potassium hydroxide is allowed to stand for a day or two and the alkali is then removed by passing carbon dioxide into it. It can also be obtained pure by treating methyl stannic bromide or iodide with ammonia. It is an odourless white powder, insoluble in water and organic solvents, but soluble in mineral and some organic acids, and in alkali hydroxides. With hydrobromic acid it yields *methyl stannic bromide* or methyl stannibromoform $SnMeBr_3$, m.p. 53°, which has also been obtained by other methods. The corresponding *iodide* or iodoform, $MeSnI_3$, m.p. 86°, and the compounds $SnMe_2Br_2$; $SnMe_2O$; $SnMeS{\cdot}SH$ and methyl stannichloroform, m.p. 105°–107°, b.p. 179°–180°, have also been prepared (Pfeiffer and Lenhardt, Ber. 1903, 36, 1054, 3027; Pope and Peachy, Proc. Roy. Soc. 1903, 72, 7; Chem. Soc. Proc. 1900, 42, 116; Pfeiffer, Ber. 1904, 37, 4618; Shukoff, Ber. 1905, 38, 2691).

The tin halogen compounds form a number of double compounds with aliphatic and aromatic amines (Cook, Amer. Chem. J. 1899, 22, 435; Richardson and Adams, *ibid.* 446; Slagle, *ibid.* 1898, 20, 633).

Pyridine stanni-iodide $(C_5H_5N)_2H_2SnI_6$ is formed when an alcoholic solution of pyridine hydriodide is added to stannic iodide dissolved in alcoholic hydrogen iodide. It forms bluish-black glistening needles. The analogous *quinoline* salt $(C_9H_7N)_2H_2SnI_6$ forms black needles. Both these compounds decompose gradually, liberating iodine (Rosenheim and Aron, Zeitsch. anorg. Chem. 1904, 39, 170). Similar chlorides, bromides and alkyl derivatives have also been prepared (Pfeiffer, Annalen, 1910, 376, 310; *see* also Hayes, J. Amer. Chem. Soc. 1902, 24, 360).

A number of other organic compounds of tin have also been prepared (Fischer, Monatsh. 5, 426; Werner and Pfeiffer, *l.c.*; Thiele and Dimroth, Annalen, 1899, 305, 102; Pfeiffer and Lenhardt, *l.c.*; Dilthey, Ber. 1903, 36, 925; Rosenheim and Levy, *ibid.* 1904, 37, 3662; Rosenheim and Schnabel, *ibid.* 1905, 38, 2777; Weinland and Bames, *l.c.*; Pfeiffer, Annalen, 1910, 376, 285).

TIN PLATES. *History.*—Although the art of tinning brass and copper was well known to the Romans (*v. supra*), the production of sheet iron coated with tin, or 'tin plate,' is of a considerably later period. The art was probably of German origin, and existed in Bohemia prior to 1620. About this time the manufacture was introduced into Saxony, and speedily developed into a thriving industry. Unsuccessful attempts, with which M. Réaumur was connected, were made to introduce the manufacture into France. About 1670 an English company was formed to start a tin-plate works in this country, and Mr. Yarranton was sent to Germany to learn the art. Works were started at Pontypool, and met with some success, but were stopped, owing to the grant of a patent for the manufacture to E. Hemming in 1691. Works were, however, once more started in 1720 at Pontypool, and these were gradually followed by others, particularly in South Wales, which gradually became the most important seat of the manufacture in the world. In the earlier processes of manufacture the plates were hammered by hand from iron made in the charcoal hearth, while the surface was cleaned from scale by immersion for several days in sour barley-water, instead of for a few minutes in dilute sulphuric acid, as at present.

In 1728, the *rolling* of sheets was introduced by Hanbury, of Pontypool, while sulphuric acid was substituted for barley-water in 1806. The rolling of tin plates as they leave the tin pot, which saves metal and improves the surface, was introduced by Morewood (who took out many patents for coating metals) in 1866, since which time a great variety of machines have been introduced for use in the tinning process.

Pickling machines have superseded hand labour, while iron made in the old-fashioned open-hearth refinery (or puddling furnace for second qualities) has been generally replaced by steel. Siemens' steel was used about 1875, Bessemer steel about 1880, and basic steel was introduced a few years later (*v.* P. W. Flower, Origin and Progress of the Manufacture of Tin Plates, J. Iron and Steel. Inst. 1886; C. Vogel, Stahl und Eisen, 29, 1097).

The M'Kinley Tariff, which came into force on July 1, 1891, led to a rapid development of the tin-plate industry in the United States, and a corresponding depression in South Wales. Other markets for Welsh tin plates were, however, gradually found, so that the industry has more than made up for the ground lost.

Production of tin plate. The metal used for rolling into sheets was formerly, as above stated, wrought iron of special quality, which was made in refineries using only charcoal. At present very mild steel is employed, Siemens' steel being in most demand for this purpose. The bars are cut into suitable lengths, and each length is heated to redness, and then passed through 'chilled' rolls until its length is about doubled; the plate is then folded across the middle, re-heated, and again rolled. The reheating, folding over, and rolling is repeated until a sheet of the proper thickness is obtained, sometimes as many as thirty-two thicknesses being rolled together as one piece in this way. The sheets are then cut to size with shears and separated, when they should part readily if the operation thus far has been successfully conducted. The 'rough black plates' so produced should be free from streaks or 'spilly' places and should be uniformly coated over with a black scale of oxide. This is now removed by 'pickling' in warm dilute sulphuric acid for about 20 mins., and by subsequent washing and rubbing with sand and water. The sheets are next annealed in wrought-iron boxes, which are usually about 2 ft. square, but vary in size; the upper part is in the form of a bell for ready removal, and to prevent the entry of air the joint is stopped by being covered with sand. The annealing requires about 10 hours, and is conducted in a large furnace maintained at a cherry-red heat. The pots are then withdrawn and allowed to cool, after which the sheets are cold-rolled, to improve the surface and give the smoothness and uniformity which is necessary to produce a good tin plate. The cold-rolling renders the plates somewhat hard, and they are therefore annealed once more, usually in cast-iron pots, as it is not necessary in the second annealing to use so high a temperature or as long a time as in the first case. The sheets are now finally pickled in weaker sulphuric acid than was used in the previous pickling, and after being again rubbed with sand are immersed in water preparatory to tinning.

The tinning apparatus, or 'stow,' varies somewhat with the size and quality of the plates; with very large plates the bath of tin is contained in a basin-shaped pot, while for large sizes and ordinary qualities the plates are manipulated entirely by machinery during the tinning process.

The form of apparatus which was general in S. Wales until nearly the end of the nineteenth century, and which is still occasionally employed for purposes where a specially good tin plate is required to withstand atmospheric and similar influences, consists of five baths or pots, called respectively (1) the grease pot, (2) the tin-man's pot, (3) the washing pot, (4) the dipping pot, (5) the grease pot. Formerly two other pots were used, but these have been rendered unnecessary by the introduction of rolls. The grease pot contains melted grease, such as tallow or palm oil, and in this the sheets are dipped until all moisture has been removed and they are uniformly coated with grease. They are next dipped into the tin pot, which contains melted tin covered with a layer of grease, the latter being now usually replaced by a bath of zinc chloride or 'killed spirits.' The sheet now receives its first coating of tin, which, however, is not perfect, and to complete the tinning the sheet is dipped into the first compartment of the washing-pot, where it remains until a uniform coating is produced. The plate is now taken out and rapidly examined by the workman, who wipes over the surface with a brush, and to remove the marks of the brush rapidly dips the plate into the second compartment of the same pot, which contains the best tin, and then transfers it to the grease pot, where it passes through a pair of rolls, which squeeze off the excess of tin and improve the surface. Formerly the plate remained for about 10 mins. in the grease pot, during which time the excess of tin drained off. The plate was afterwards transferred to the 'cold pot,' after which the lower part was inserted in the 'list' pot, which contains a little tin at a comparatively high temperature, and which rapidly removes the thick edge of tin which had accumulated at the bottom of the plate. The plates, after coating with tin, are then cleaned from grease, usually by rubbing with bran and finishing with the woolly skin of a sheep; they are afterwards separately examined for defects, and, after classification, are packed in the familiar flat wooden boxes and branded for market (*v.* E. Trubshaw, J. Iron and Steel Inst. 1883, i. 252).

For a description of the process of manufacture of tin plates in Germany, which does not materially differ from that above described, *v.* Dingl. poly. J. 250, 231.

In modern tin-plate works mild steel bars are reheated and rolled into 'black plates' by passing successively through two pairs of rolls for 'roughing' and 'finishing' respectively. In the United States sometimes only one pair of rolls is used; or two pairs of finishing rolls may be served by one pair of roughing rolls. The plates, after being separated, are pickled in diluted sulphuric or hydrochloric acid with the aid of pickling machines; they are then annealed under cover in iron or steel boxes, cold rolled, re-annealed at a lower temperature and again pickled, this time in weaker acid. The plates are then swilled in water and introduced, without drying, into the tinning machine. Of such machines there are various modifications. A typical form consists of two divisions connected with each other at the lower part of the pot which contains molten tin. The tin in the first division is coated with a tinning flux of zinc chloride, while that in the second division is covered with hot grease. The plate passes through the flux into and through the tin, emerging through the grease, and passing through rolls which remove the surplus tin, and give a smooth, bright, and even surface. For further details and drawings, *see* G. B. Hammond, The Manufacture of Tin Plates, J. Iron and Steel Inst. 1897, 2, 24.

The occurrence of blisters in the thin sheets of steel used in the manufacture of tin plates is not infrequently a cause of considerable trouble. The origin of these has been studied by E. F. Law (J. Iron and Steel Inst. 1906, 1, 134) who concludes that oxidised steel will give rise to blistered sheets, and the defect is more likely to arise with Bessemer, than with open hearth steel. Brittleness in sheets may arise from excess of sulphur or phosphorus. In metal of good chemical purity a peculiar form of weakness, sometimes called "rectangular brittleness," may result from annealing at an improper temperature, or for too long a time. T. T.

TIN PYRITES *v.* Stannite.

TIN SALTS or **TIN CRYSTALS.** *Stannous chloride v. Tin salts and oxides*, art. Tin.

TIN STONE. *Native oxide of tin v.* Cassiterite.

TINTOMETER *v.* Colorimeter.

TIN WHITE COBALT. *Smaltine, Cobalt arsenide v.* Cobalt.

TITANIC IRON-ORE *v.* Ilmenite.

TITANITE *v.* Titanium.

TITANIUM. Sym. Ti. At. wt. 48·1.

Titanium is not found in the free state, but occurs as oxide in three minerals of different crystalline form: *rutile, anatase*, and *brookite*. It is found as *titaniferous iron ore* or *ilmenite* $(FeTi)_2O_3$, and in smaller quantities as *sphene* or *titanite* $CaTiSiO_5$, *perofskite* $(CaFe)TiO_3$, *schorlomite* $Ca(TiFe)SiO_5$, and *keilhauite* $CaY(TiAlFe)SiO_5$. It occurs in magnetic iron ores, and is thus frequently found in slags and pig iron; and in other minerals, in soils, clays, certain mineral waters, and in the sun's atmosphere (Barnes, J. Soc. Chem. Ind. 1896, 421; Rieke, *ibid.* 1908, 901; Becker, Zeitsch. Kryst. Min. 1903, 38, 317; Hall and Smith, Chem. Zentr. 1905, ii. 1161). The presence of titanium oxide in clays considerably reduces their refractibility. Titanium is said to be diffused throughout all primitive granite rocks (Dieulafait).

It has also been found in human and in ox flesh and bone (Baskerville, J. Amer. Chem. Soc. 1899, 21, 1099); in the ash of many plants (Wait, *ibid.* 1896, 18, 402; Lippmann, Ber. 1897, 30, 3037); and in many peats (Baskerville, *l.c.* 402). It is more abundant in nature than has hitherto been supposed, but it is only within the last few years that the metal and many of its compounds have become important industrially.

Titanium can be extracted from its oxide by electrolysing a solution of the latter in dry halogen salts of the alkaline earth metals heated to moderate redness. After cooling, the titanium is separated from the electrolyte by lixiviation with water and with dilute hydrochloric acid (Fr. Pat. 344099, 1904; J. Soc. Chem. Ind. 1904, 1098; *cf.* also Moissan, Eng. Pat. 2073, 1895; Sternberg and Deutsch, Eng. Pat. 13117, 1893; Borschers, U. S. Pat. 930344, 1909; J. Soc. Chem. Ind. 1909, 986). In a somewhat impure form it can be obtained by the reduction of potassium titanium fluoride with sodium (Weiss and Kaiser, Zeitsch. anorg. Chem. 1910, 65, 345). Very pure titanium has been obtained in moderately large quantities by heating pure titanium tetrachloride with about half its weight of sodium in a steel bomb to a low red heat (Hunter, J. Amer. Chem. Soc. 1910, 32, 330).

Titanium has the appearance of polished steel. It is hard and brittle in the cold, but can be readily forged when raised to a low red heat. It has sp.gr. 4·50 and melts at 1800°–1850° (Hunter); (*see* also Moissan, Compt. rend. 1906, 142, 673).

Titanium burns in oxygen and in the halogens, dissolves readily in sulphuric or hot concentrated hydrochloric acid, more slowly in nitric acid, and decomposes steam at 700°–800°.

Titanium readily forms alloys with various metals; some of those with iron having been employed for the manufacture of pencils for arc lights (Ladoff, J. Ind. Eng. Chem. 1909, 711).

Filaments of metallic titanium having a high melting-point and high resistance, and as used for incandescent electric lamps, are manufactured by treating titanic oxide with ammonia in the cold. The product is heated in a vacuum to 1200°, and is then mixed with an organic binding material such as a solution of casein in ammonia. The mixture is formed into threads and then heated in an electric furnace to 1200°. Finally the filament is subjected to the action of a high tension electric current in a vacuum (Trenzen, Eng. Pat. 14852, 1908; J. Soc. Chem. Ind. 1909, 877).

Titanium is used in metallurgy, its addition to steel increasing greatly the transverse strength and elasticity of the steel (Ladoff, *l.c.* 642; Venator, Stahl und Eisen, 1910, 30, 650).

A protective coating on iron and steel is said to be formed by mixing a titanium ore with 10–50 p.c. of asphalt, and if the product is to be used as a paint, adding turpentine. These coatings can also be formed by heating the metal to be treated with a layer of titanic mineral mixed with carbonaceous material in a furnace for several hours (Johnson, Eng. Pat. 15500, 1893; J. Soc. Chem. Ind. 1893, 1046).

Compounds of titanium. Titanium forms four oxides. The *monoxide* TiO forms black prisms, obtained by heating the dioxide in the electric furnace, or with magnesium powder (Winckler, Ber. 1890, 23, 2658; Moissan, Compt. rend. 1892, 115, 1034; J. Soc. Chem. Ind. 1909, 982). The *sesquioxide* Ti_2O_3 (Moissan, Compt. rend. 1895, 120, 290; Braun, Min. Mag. 1892, ii. 37) is obtained by strongly igniting the dioxide in hydrogen and allowing the product to cool in this gas. In sulphuric acid it forms a violet solution, this being the characteristic colour of all the solutions of trivalent titanium compounds. The corresponding *hydroxide* is obtained by digesting a solution of titanic acid in hydrochloric acid with metallic copper at 20°–40°, or by treating the trichloride with alkalis. The sesquioxide and the corresponding salts are readily oxidised to the dioxide or the trioxide and their salts (Manchot and Richter, Ber. 1906, 39, 320, 488).

Titanium dioxide TiO_2 is the most important of the four oxides. It is trimorphous, occurring as the three distinct minerals mentioned above. It can be obtained by the decomposition of aqueous titanium chloride by ammonia or by fusing rutile with three times its weight of potassium carbonate.

Titanium oxide can be prepared by mixing crushed ilmenite or other titanium ore with carbon and heating to about 1800°. The resulting mass is crushed and the iron is removed by magnetic separation and treatment with acid (U. S. Pat. 921686, 1909; J. Soc. Chem. Ind. 1909, 657).

Amorphous titanium dioxide is a white, tasteless powder which becomes lemon yellow when gently heated, and brown when ignited strongly. It has a sp.gr. 3·89–4·25. It is insoluble in water and dilute acids, resembles silicon dioxide closely in chemical properties, and when fused with alkalis or alkali carbonates forms the titanates.

Titanium oxide is used as a mordant, and in at least two cases it has an advantage over alumina; thus alizarin yellow produces with titanium as bright but a much faster colour than with alumina, whilst the scarlet obtained from alizarin orange on a titanium mordant is the fastest scarlet that can be obtained on wool.

For this purpose the titanium mordant must be freed from iron, and this can be done by dissolving freshly precipitated titanium hydroxide, containing iron, in tartaric acid, making alkaline with ammonia and precipitating the iron by the addition of the requisite amount of ammonium sulphide. The filtered solution is then warmed until most of the free ammonia has been expelled (Barnes, J. Soc. Chem. Ind. 1899, 15).

According to Sabatier and Maille (Compt. rend. 1910, 150, 823) the dioxide forms a very efficient catalyst in the esterification of acetic acid.

Like silicic acid, titanic acid forms a number of hydrates known as ortho- and meta-titanic acids (Wagner, Ber. 1888, 21, 960; Pfordten, Annalen, 1887, 237, 213; Tamann, Zeitsch. anorg. Chem. 1905, 43, 370: Bornemann and Schirmeister, Chem. Zentr. 1910, ii. 1870). Many titanates are known.

Titanium peroxide TiO_3 (Classen, Ber. 1888, 21, 370) resembles hydrogen peroxide very closely in its reactions in solution. Faber (Zeitsch. anal. Chem. 1907, 46, 277) has prepared the hexavalent acetate and phosphate

$$Ti(OH)_4PO_4,$$

both of which are stable at low temperatures, but, particularly the acetate, are explosive on heating. Hypertitanates of potassium and sodium have also been prepared (Melikoff and Pissarjewsky, Ber. 1898, 31, 678).

Halogen compounds. **Titanium tetrachloride** $TiCl_4$ can be obtained readily by passing dry chlorine over a mixture of the dioxide with carbon; by passing the vapour of chloroform over titanium dioxide (Renz, Ber. 1906, 39, 249), and by heating the latter with sulphur monochloride (Hall, J. Amer. Chem. Soc. 1904, 26, 1235; Bourion, Ann. Chim. Phys. 1910, [viii.] 20, 547; *ibid.* 21, 49).

Titanium tetrachloride is best prepared from industrial ferro-titanium by treating the latter with hydrochloric acid to remove most of the iron. It is then levigated to remove titanic anhydride, and after drying the mass is introduced into a porcelain tube, heated to dull redness, and subjected to the action of a current of dry chlorine. The ferric chloride is separated by filtration, and the filtrate is fractionally distilled when the pure substance is obtained. It boils at about 136°, is colourless, and does not fume in air (Vigouroux and Arrivaut, Compt. rend. 1907, 144, 485).

The tetrachloride can also be prepared from rutile by igniting the latter with aluminium and then heating the mixture in a current of chlorine (Ellis, Chem. News, 1907, 95, 122).

It is a mobile, transparent, colourless liquid of sp.gr. 1·7604 at 0°/4° (Thorpe) which solidifies at −23° and boils at 136·4° under 760 mm. pressure (Thorpe). It is decomposed by an excess of water yielding titanic acid and combines with ammonia, forming a number of solid addition compounds (Rosenheim and Schütte, Zeitsch. anorg. Chem. 1901, 26, 239; Stähler and Wirthwein, Ber. 1905, 38, 2618). When the latter are extracted with liquid ammonia, dark yellow *titanamide* $Ti(NH_2)_4$ is formed. Titanium tetrachloride, like stannic chloride, yields a large number of crystalline compounds with other chlorides (Rosenheim and Schütte, *l.c.*; Ruff and Ipsen, Ber. 1903, 36, 1777).

Titanium trichloride $TiCl_3$ is formed when a mixture of titanium tetrachloride vapour with hydrogen is passed through a red-hot tube (Georges and Stähler, Ber. 1909, 42, 3200), and can be prepared by electrolysing a solution of the tetrachloride and then evaporating the solution to the sp.gr. 1·5 at 60°–70° (Spence, U. S. Pat. 723217, 1903; J. Soc. Chem. Ind. 1903, 495, 628; D. R. P. 154542). As prepared by the latter process, it forms violet crystals of the composition $TiCl_3,6H_2O$, which decompose into the tetra- and di-chloride on heating, the latter also being formed when the trichloride is heated in hydrogen (Georges and Stähler, *l.c.*). The trichloride is a powerful reducing agent. It liberates sulphur from sulphurous acids, many metals, such as gold, silver, mercury, and copper from solutions of their salts, and reduces nitric acid and nitrates to ammonia. It reduces ferric salts quantitatively to the ferrous condition, organic nitro compounds to amines, and can be employed in the analysis of many dyes (Knecht, Ber. 1903, 36, 166; Knecht and Hibbert, *ibid.* 1549; *ibid.* 1905, 38, 3318; 1907, 40, 3819). This reducing property has also been made use of in cloth printing (D. R. P. 138503; Frdl. 1902–4, 477). Titanium trichloride forms double compounds with the chlorides of rubidium and caesium (Stähler, Ber. 1904, 37, 4405), and also with nitrogen sulphide (Davis, Chem. Soc. Trans. 1906, 1576).

Titanium dichloride $TiCl_2$, prepared as above, is a hygroscopic light-brown powder.

Titanium tetrabromide (Ruff and Ipsen, *l.c.*), and *tribromide* (Stähler, *l.c.*), the *triiodide* (Stähler, *l.c.*), *tetra-iodide* and the *diiodide* (Defacqz and Copaux, Compt. rend. 1908, 147, 65), the *tetra-* and *tri-fluorides* (Ruff and Ipsen, *l.c.*; Ruff, Plato and Graf, Ber. 1904, 37, 673), and a number of *alkali titanofluorides* (Marchetti, Zeitsch. anorg. Chem. 1895, 10, 66; Piccini, *ibid.* 438; Ebler and Schott, J. pr. Chem. 1910, [ii.] 81, 552) have been prepared.

Titanium forms three *sulphides* TiS_2, Ti_2S_3, and TiS (Müller, Chem. Zentr. 1910, ii. 1195), and also a chlorosulphide.

Titanium sesquisulphate $Ti_2(SO_4)_3,8H_2O$ is obtained when the metal is dissolved in dilute sulphuric acid. It is decomposed by heat and forms alums and double salts with the alkali sulphates.

The electrolytic reduction of many organic compounds is greatly facilitated by the addition of a small quantity of a titanium salt, such as the sulphate (D. R. P. 168273; Frdl. 1905-7, 115). Titanous sulphate is also recommended for detecting copper in dyed fabrics (Knecht, J. Soc. Dyers, 1904, 20, 97).

Titanous sodium sulphate $Ti_2Na_2(SO_4)_4,5H_2O$ is obtained by electrolysing a solution containing titanic sulphate, sodium sulphate, and sulphuric acid. The electrolysis is carried out with a low-current density in a lead-lined vessel, the solution being finally evaporated to a sp.gr. of 1·145, when the salt crystallises out.

It is a powerful reducing agent, and can be applied in the preparation of other titanous salts (Peter Spence and Sons, D. R. P. 149602, 1904).

Titanium disulphate $Ti(SO_4)_2,3H_2O$ forms double salts with the sulphates of the alkalis and alkaline earths (Weinland and Kühl Zeitsch. anorg. Chem. 1907, 54, 253). A number of basic sulphates (Blondell, Bull. Soc. chim. 1899, [iii.] 21, 262; Roseheim and Schütte, *l.c.*) and titanosulphuric acid (Reichard, Chem. Zeit. 1904, 28, 16) have also been prepared.

Titanium forms a number of nitrides and also a chloro- and bromo-nitride (Ruff and Eiser, Ber. 1908, 41, 2250; J. Soc. Chem. Ind. 1908, 809; Ruff, Ber. 1909, 42, 900). The mononitride Ti_2N_2 is a bronze yellow mass of sp.gr. 5·18, and is hard enough to cut rubies and diamonds (Moissan, Compt. rend. 1895, 120, 290).

According to Shukoff, however (J. Russ. Phys. Chem. Soc. 1910, 42, 40), titanium only forms solid solutions with nitrogen, but no definite compounds.

Titanium also forms a *carbide* (Shimer, Chem. News, 1887, 55, 156; Moissan, *l.c.*; and Compt. rend. 1897, 125, 839); a *cyanonitride* $Ti(CN)_2{\cdot}3Ti_3N_2$ (Wohler, Annalen, 1850, 73; *ibid.* 34, 74, 212; Franck, Chem. Zeit. 1897, 21, 520; J. Soc. Chem. Ind. 1908, 809); and a *silicide* $TiSi_2$ (Hönigsmid, Compt. rend. 1906, 143, 224; J. Soc. Chem. Ind. 1909, 249).

Soluble double pyrophosphates of titanium and alkali are prepared by mixing together alkali pyrophosphates and basic titanium sulphate (Barnes and Spence, Eng. Pat. 6329, 1906; J. Soc. Chem. Ind. 1907, 93).

Titanium phosphide TiP forms a brittle mass with a metallic lustre. It burns when heated in air, is a conductor of electricity, is insoluble in dilute and in concentrated alkalis and acids (Gewecke, Annalen, 1908, 361, 79).

Titanic acid forms crystalline *thiocyanates* of the type $K_3TiO(SCN)_4H_2O$ and double salts with pyridine $(C_5N_5H)_2H_2TiO(SCN)_4$, and quinoline (Rosenheim and Cohn, Zeitsch. anorg. Chem. 1901, 28, 167).

Double fluorides of titanium with some alkaloids are described by Schaeffer (J. Amer. Chem. Soc. 1908, 30, 1862).

Complex azo- salts of titanium have been prepared by Mazzucchelli and Pantanelli (Gazz. chim. ital. 1910, 40, i. 666). Other titanium organic compounds are described by Dilthey (Ber. 1904, 37, 588; Annalen, 1906, 344, 300), Rosenheim and Schnabel (Ber. 1905, 38, 2777), Grossmann (Chem. Zeit. 1906, 30, 907), Muzzucchelli (Atti. R. Acad. Lincei, 1907, [v.] 16, ii. 265), Fenton (Chem. Soc. Trans. 1908, 1064).

The possibility of using titanium compounds in dyeing processes was first demonstrated by Barnes in 1877, but has only recently been applied by manufacturers. The salts sued are: the sulphate, chlorides, fluoride, oxalate, tartrate, lactates, and the double alkali derivatives of these salts. The salts for this purpose are obtained by the following process:—

The ore is melted with sodium hydroxide and the mass is lixiviated with water; the residue is then washed free from alkali, dissolved in hydrochloric acid, and the solution is treated with alkali to precipitate titanium as hydroxide. The product is freed from iron by the addition of sodium sulphide, washing the precipitate and treating it with sulphurous acid. It is then converted into titanium oxalate by treatment with ammonium oxalate and oxalic acid (Erben, Chem. Zeit. 1906, 30, 145; *cf.* also Dreher, Eng. Pat. 1835, 1903; J. Soc. Chem. Ind. 1904, 18; Spence, *ibid.* 1900, 246).

The *lactates* are conveniently prepared by dissolving titanic acid in hydrochloric acid and pouring the solution obtained into a warm solution of an alkali or alkaline earth lactate (Dreher, Färber Zeit. 1902, 13, 293; D. R. P. 149577; Frdl. 1902–4, 43; J. Soc. Chem. Ind. 1902, 988, 1245; 1903, 908).

The soluble salts of titanium, such as the oxalate, are very efficient fixing agents for the tannates of the basic colours, the results obtained being as good as, and in many cases better than, those obtained with antimony. For this purpose it is unnecessary to purify the titanium salts from iron (Barnes, J. Soc. Chem. Ind. 1899, 15).

Titanium tannate washed free from sulphate and chlorides, and dissolved in warm aqueous oxalic or tartaric acid, is an excellent dye for cotton, the shade varying with the sp.gr. of the solution. The solution of titanium tannate can also be employed as a further fixing and modifying bath after dyeing, the colours becoming faster and more yellow after such treatment. It also serves as an excellent fixing agent for the Janus colours which have been dyed substantively. Very good colours are also obtained with methylene blue, rhodamine, and aniline black (Barnes, *l.c.*; Kearns and Barnes, Eng. Pat. 8589; J. Soc. Chem. Ind. 1899, 491; Erban, Chem. Zeit. 1906, 30, 145).

A solution containing a titanium salt gives, with tannic acid, an orange precipitate; with gallic and pyrogallic acids, orange or brownish-yellow solutions; and with salicylic acid a pale-yellow coloration: a yellow to deep orange colour is also produced by hydrogen peroxide; these colours are imparted to wool when the latter is steeped in the hot solutions (Barnes, J. Soc. Chem. Ind. 1896, 420; 1897, 238; Eng. Pat. 5712).

The oxalate, tartrate, titanium potassium oxalate, titanium-tanno-oxalate, titanium sodium sulphate and titanous chloride can be used with good results in dyeing and mordanting silk. The titanium mordants are also useful in the chrome developing colours, and in the after treatment of silk previously dyed with anthracene yellow or brown or alizarin colours. For this purpose titanium potassium oxalate or titanium sodium sulphate are best used (Hurst, J. Soc. Dyers, 1903, 19, 105; Barnes, *l.c.*).

Titanium salts unite with the tannin matter of leather to form on the fibre a yellowish-brown titanium tannate, which is very fast to light and to the action of soap. On account of its cheapness, potassium titanium oxalate is the most applicable. It is exceedingly soluble in hot water and can be applied to tanned leather either in the dye-bath or with a brush. The mode of application and the previous and subsequent treatment of the leather depend on the quality of the latter, whilst the shade of colour obtained, which varies from bright yellow to a reddish-brown, depends on the nature of the tannage and on the amount of titanium salt used. The basic colours especially give much fuller and richer shades with titanium than without (Lamb, J. Soc. Chem. Ind. 1901, 1111; U. S. Pat. 722857, 1903; Dreher, J. Soc. Chem. Ind. 1902, 771; 1903, 294; 1904, 71; Eng. Pats. 9556, 1901; 27597, 1902; Stiasnky, J. Soc. Chem. Ind. 1902, 1329; Erben, *l.c.*).

According to Barnes (*l.c.*) titanium tannate can also be used effectively as a pigment in water-colour drawings, the colour depending upon the conditions of preparation of the pigment and varying from brick-red to almost pure yellow. Titanium salts are also said to be employed in the manufacture of artificial teeth and in colouring porcelain (Ladoff, *l.c.*; Barnes, J. Soc. Chem. Ind. 1896, 421). Z. K.

TITANIUM GREEN. Titanium ferrocyanide, prepared by adding potassium ferrocyanide to a solution of hydrated titanic oxide in hydrochloric acid, has been suggested as a substitute for Schweinfurth green and other arsenical pigments (Elsner, Dingl. poly. J. 905, 130; Gentele, *ibid.* 140, 238).

TITRATION *v.* ANALYSIS.

TIZA. A local South American name for ulexite (*q.v.*).

TOAD'S EYE. *Native oxide of tin v. Tin salts and oxides*, art. TIN.

TOBACCO. The botanical order of the *Solanaceae* includes many well-known plants which are extensively cultivated because certain portions of them are of great utility to the human race. The tuber of the potato and the fruit of the tomato are food substances of great value and of almost universal consumption. Other genera of the order, however, afford instances of cultivation simply for the production of foliage; the dried leaves of the thorn-apple (*Datura Stramonium* [Linn.]) are sometimes smoked as a remedy for asthma. The most important plants of this class, however, belong to the genus *Nicotiana*, and their dried leaves are known as tobacco. The etymology of the word 'tobacco' is somewhat obscure; the geographical origin assigned to it by tracing it either from Tobago, an island in the West Indies, or from Tabasco, an island in the Gulf of Mexico, is probably incorrect. When the Spaniards first visited San Domingo they found that the natives used a peculiar contrivance for inhaling the smoke of burning tobacco leaves. This instrument was called a 'tabaco,' and was shaped like a Y with the arms so close together that they could be inserted up the nostrils, and it is highly probable that the word tobacco thus originated.

Upwards of 40 species of the genus *Nicotiana* have been described, but many of them are simply modifications resulting from the influence of soil and climate on the chief species. *Nicotiana Tabacum* (Linn.), the most important member of the genus, is a fine plant, indigenous to America, where it grows from 6 to 9 ft. high. The stem is slightly viscous, and the leaves, which are oblong or lanceolate in shape, are attached alternately, and surround the stem in the form of a spiral (of which the ninth leaf overhangs the first, the tenth the second, and so on). The distance between the leaves is usually about 2 ins. Characteristic soft downy glandular hairs cover the stem and the under surface of the leaves, and these are of great service in the identification of tobacco by the microscope. The flowers have funnel-shaped corollas, about 2 ins. long, of a rose or pinkish colour, and are produced in large terminal clusters: the seed pods have two valves, and the seeds are very small and numerous. Modifications in the type have resulted in the production of several varieties of this species, differing chiefly in the size of their leaves. The two principal groups now recognised are *Nicotiana Tabacum*, var. *macrophylla*, or 'Maryland tobacco,' comprising stalked and stalkless forms, and *Nicotiana Tabacum*, var. *angustifolia*, or 'Virginia tobacco.' The finest growths of Cuba, Manila, and Turkey (including Latakia), are now attributed to a form of the stalked Maryland tobacco. Under the name of Shiraz tobacco, *N. persica*, a very fine variety, is cultivated in Persia; but the plant is probably a form of *N. Tabacum*, obtained by cultivation of seed derived from a Brazilian variety. Of the remaining species, *Nicotiana rustica* (Linn.) is the most important. It is of hardier constitution and dwarfer habit than the preceding species, and the flowers are also of a lighter colour. It is cultivated largely in Germany, Hungary, and in the East Indies, and includes the common Hungarian and Turkish varieties.

The use of tobacco for smoking purposes is supposed to have originated among the North American Indians. When America was first discovered, and afterwards when fresh portions of the continent were explored, the practice was found to be prevalent among all the native tribes, and its introduction into Europe very soon followed. The plant was first cultivated in Spain early in the sixteenth century, and was introduced into France and Italy about the year 1560. It attained considerable fame as a medicinal herb, and was at first regarded with universal favour. Sir Walter Raleigh is generally credited with having introduced its cultivation into the British Isles in the year 1586, but plants are said to have been brought to England by Sir John Hawkins in the year 1565. The habit of smoking soon became general, but this use of the plant met with a considerable amount of opposition, not only in England, but also throughout Europe. Nearly the whole of the early literature on the subject was written in an antagonistic strain. Kings' counterblasts, Popes' anathemas, Sultans' decrees and even violent punishments failed to check the growing habit, and plantations sprang up, not only in the New England States, but also all over the United Kingdom. In the year 1604 the tax on the imported article was raised from 2*d*. per lb. to 6*s*. 10*d*. per lb., and English planters were forbidden to produce more than one hundredweight of the leaf. Shortly afterwards the pre-emption of tobacco was made a royal monopoly, and the King enjoined the plucking up of all tobacco found growing in England and Ireland. In the years 1652, 1660, and 1663, Acts were passed prohibiting the cultivation of tobacco in England and Ireland, and these Acts were extended to Scotland in the year 1782. The prohibition as regards Ireland was removed in the year 1779, but was subsequently reimposed in the year 1831. Notwithstanding these measures, the cultivation of tobacco in England did not really cease until the year 1782, when some planters in the vale of York were imprisoned and fined in the sum of £30,000.

Culture. The tobacco plant, though essentially tropical, can, with suitable modifications in the cultural details, be grown successfully in temperate climates. It is cultivated for commercial purposes chiefly in the United States, Cuba, Mexico, Brazil, Paraguay, the Dutch Indies and North Borneo, Australia, India, China, Burmah, the Philippines, Persia, the Transvaal, Rhodesia, the Levant, Greece, Hungary, Germany, Russia, France, and Holland, and is now being grown on a small scale in the United Kingdom. Cigar leaf is grown in Cuba, the East Indies, North and South America, Rhodesia, and Germany; tobacco for pipe smoking in the United States, the Levant, Germany, the Transvaal, Nyassaland, Australia, China, Java, &c.; tobacco for cigarettes in the United States, the Levant, Greece, &c. In the United States, several types of leaf are grown, of which the principal are the Seed leaf and Florida varieties of Cuba and Sumatra tobacço for cigars; White Burley; the Heavy Shipping or dark tobacco of Kentucky, Virginia, and Maryland; the Yellow tobacco of Carolina and Virginia; and the Perique of Louisiana. A spangled type of yellow tobacco is grown also in Ohio. Seed leaf requires a strong, highly-manured soil, to promote a rapid growth, so that the plants may be harvested when expansion of the leaves ceases, and the process of granulation and secretion of the gummy substances begins. White Burley flourishes in a highly fertile disintegrated limestone, while heavy shipping tobacco thrives best on ferruginous clayey soils. Yellow tobaccos need a sandy, porous, sterile soil, to which just sufficient fertilisers (superphosphate, potash, and nitrogenous) have been added to promote summer growth; in the autumn the plant's declining vitality causes the leaves to turn more and more yellow until the tint desired is reached, which is afterwards fixed in the curing process. Perique is grown on the low-lying lands, black with humus, in the swampy districts of Louisiana. Climate has a great influence on the flavour, but the texture of the leaf depends largely on the nature of the soil in which the plant grows. The northern varieties, for example, planted in the Southern States gradually change in character; the plants ripen earlier and the leaves assume a lighter colour and diminish in size but increase in thickness and sweetness.

The seed is sown in February, March, or April, in seed beds, composed of a light friable soil prepared some time beforehand, and a brush heap is burned on the ground prior to sowing to destroy harboured insects. The young plants are raised either in hot beds, or in cold frames protected by plant-muslin, according to the locality. In the three months from April to June, when the plants are about 6 ins. high, they are transplanted into well ploughed soil, thrown up in ridges; and if the weather is dry, they are watered in. A space of from 1½ to 3 ft. is allowed between each plant in the rows, which are made from 3 to 4 ft. apart. The constant removal of suckers from the plants ('suckering'), frequent harrowing of the soil, and destruction of weeds and insect pests are necessary. In Turkey and other Eastern countries, where small leaves are desired, and the buds and flowers are also used, 'topping' is not practised, but the larger growths of the United States, &c., usually require this treatment when the first bloom begins to show. Ten to a dozen leaves in the case of heavy shipping tobacco, and 16 to 18 leaves in the other varieties, are allowed to remain on the stem, and the increase in their leaf surface they thus show may be as much as 50 p.c., when compared with leaves of normal size. Seed leaf requires from 2 to 3 weeks after this operation to ripen, yellow leaf and Burley take a month, and heavy shipping tobacco 2 or 3 weeks longer. An abnormal amount of organic matter accumulates in the cells of ripe tobacco leaf, owing to the 'topping' and 'suckering' of the plant. The continuous accumulation of nicotine, oxidising enzymes and acids which takes place in the cells finally causes the chlorophyll granules to acquire a yellowish colour. The change from the normal deep green tint of the leaf is very noticeable to the experienced eye, and indicates that the time for harvesting has arrived. The constituents of the cells having fulfilled their functions are at this stage going back to the stem to be transferred thence to the upper leaves, to be used for other purposes in the economy of the plant. Compared with the young leaf, the ripe leaf has a density half as high again, and contains about 2¼ times as much matter soluble in boiling water. White Burley and seed leaf are air cured in houses that can be ventilated at will: this operation requires from 6 to 8 weeks. An alternating change from the moist to the dry condition of the leaves takes place according to atmospheric conditions as the curing proceeds. Yellow leaf is cured by artificial heat, distributed by flues in air-tight barns. The temperature is maintained at 80° to 90°F. for 18 to 36 hours for the leaf to acquire the proper colour, and the heat is then raised by 5° to 10° at a time, about every 2 hours, to 115° to 120°F., and maintained at this point until the leaf is properly cured. The curing of the stalks is then effected by raising the temperature hourly by 5° to 10° to about 160° to 175°F. The whole operation takes about three days. Heavy shipping tobacco is hung on scaffolds or in the barns for some days to become yellow, and the curing is completed by open log-fires, kindled directly under the tobacco and gradually increased in size. In India, Ceylon, and other Eastern countries, sun-curing is sufficient; but in places where resort to artificial heat is necessary, it is essential that the increase of heat should be at first very gradual, as the object is not so much to dry the leaf as to fix as far as possible its qualities as regards colour, strength, elasticity and flavour. A fresh leaf subjected to a high initial temperature retains its green colour, whereas by slow drying the tint produced will vary from shades of yellow to brown. The proper fixing of the colour of the leaf is of great financial importance to the curer. The leaves, except those of the yellow varieties which are harvested as they ripen, are not usually removed from the stems prior to curing. Perique tobacco undergoes a special process of curing. After the leaves in the drying-houses have acquired a brown tint they are twisted into rolls containing about 30 leaves; these rolls are packed into boxes holding about 50 lbs. and heavy pressure is applied; the rolls are then slightly opened out and exposed to the air to aerate the exuded juices and, when these are re-absorbed, again subjected to pressure. This operation is repeated daily for about 10 days, and at longer intervals for some 3 months, with the result that the tobacco acquires a glossy black colour, and a rich characteristic spirituous odour. In Florida, cigar leaf is now grown from Cuba and Sumatra seed, but success was only achieved by making considerable changes in the ordinary methods of cultivation. The plants are placed closer together, about 14 ins. apart; the Cuban varieties are topped high, but the Sumatra kinds are allowed to bloom. Each plant yields from 18 to 30 suitable leaves which are primed off as they ripen. The discovery that plants shaded by trees were far superior to those grown in the open fields, led to the adoption of artificial shading, which has also been tried with success in Cuba, Porto Rico, and Connecticut.

Preparation for the market, which involves the grading, fermentation, and ageing of the tobacco, is usually managed by the packers and not by the farmers. Various enzymes occur in ripe tobacco leaf, which are capable of causing the oxidation of the cell-contents, and favourable conditions during the curing process promote their further development. They manifest increased activity during the fermentation, and the development of the aroma which takes place at this stage is believed to be due to the chemical changes resulting from their action. The high temperature necessary for the curing of bright yellow leaf destroys the enzymes, and this class of tobacco is therefore deficient in aroma. There are three methods of fermentation; the sweating in bulk, the natural sweat after packing in cases, and the forced sweat in case; but the first is generally used, as it can be more easily controlled. The natural sweat of seed-leaf is conducted in large wooden cases, each holding about 300 lbs. of leaf; a space of about half an inch is allowed between the boards, through which the air enters and the moisture escapes. In the autumn the leaves are pressed tightly into the boxes, which are then stored in the warehouse in tiers until the sweat occurring in the following summer is finished. The temperature is maintained fairly uniform, and the loss of weight during the process amounts to from 10 to 14 p.c. White Burley and heavy shipping tobacco are allowed to sweat in bulk for a short time before being prized, or forced into hogsheads by pressure; the hogsheads are large enough to hold from 1200 to 1600 lbs. of tobacco leaf.

Yellow tobaccos are also bulked down for a month or two to fix the colour, and are afterwards packed loosely. Cuba, Sumatra, and other cigar tobaccos are carefully graded according to colour, &c., and are fermented in large bulks varying from 3000 lbs. for the light varieties to 15,000 lbs. for the dark varieties of leaf. The fermentation is allowed to proceed for from 6 to 8 days, and the heaps are then re-made, the outside portions being placed in the centre. The operations are conducted in rooms heated by steam pipes to about 165°F., but if the temperature of the heaps is allowed to rise much above 140°F. the enzymes themselves are liable to undergo oxidation and no good effects result.

Home-grown tobacco. In the year 1886, owing to the agricultural depression in this country, efforts were made to remove the restrictions then existing on the home cultivation of tobacco, and permission was obtained to try experimental growings in several selected localities. These experiments were repeated in the following year, and were sufficiently satisfactory to justify the opinion that tobacco could be grown successfully as a farm crop in the British Isles. Experiments under the auspices of the Department of Agriculture in Dublin were started in Ireland in the year 1900. In the year 1904, the cultivation was commenced on a commercial scale, and in the year 1907 the statutory restrictions were repealed. The Department continues to furnish all possible assistance to the tobacco growers, and from the reports it has published it appears that a total area of about 200 statute acres was devoted to the cultivation of tobacco in the year 1912, as compared with 20 acres in the year 1904. The areas under cultivation were situated in the following counties: King's County, Louth, Meath, Kilkenny, Wexford, Tipperary, and Limerick. The influence of the cool, moist climate favours the production of large thin leaves which are somewhat deficient in gum, resins and aroma; but these defects have to some extent been overcome by prolonging the ripening season, during which the leaf gains in body. Yellow Pryor and selected blue Pryor have so far proved most successful for pipe-tobaccos, and Turkish, Pryor, and hybrid varieties have given the best results for cigarette tobacco. Reasonable hopes are also entertained of producing a satisfactory yellow tobacco. The requisites for success are deep cultivation, a fine soil, and fields protected from cold winds by high hedges or other means. As regards manures, the initial growth is found to be more rapid when farmyard manure is supplemented by artificial manures. The largest yield is obtained on uplands, when manures containing a large proportion of phosphates are used; potash is more effective for moorlands. Nitrogen and phosphates have a tendency to produce a coarse leaf; with potash a smooth leaf is obtained, and the burning qualities are improved, but the growth is somewhat retarded. In consequence of the minute size of the seed, about 300,000 to the ounce, the plant is forced to rely unusually early on external nourishment. The seeds are sown in glass-covered hot-beds some time between the middle of March and the middle of April, and the plants are transplanted at the latest by June 1st. The usual cultural details are followed: insect pests, on the whole, are not so troublesome as they are abroad, but the cool, moist climate greatly increases the tendency to produce suckers. 'Topping' of all the varieties, except Turkish, is usually practised. Ripening is hastened by the 'topping' and 'suckering' operations, but the usual indications, change of colour, curling of the edges of the leaf, &c., are not so manifest under Irish climatic conditions. Harvesting lasts from about the end of July to mid-October, according to whether the leaves are primed off as they ripen, or whether the whole plant is harvested with the leaves still attached to the stem. The practice of allowing the plants to wilt in the open air on scaffolds, which are capable of being protected from heavy rains, has been found very valuable. Air-curing, supplemented by suitable artificial heat at critical periods, has proved to be the best method for most classes of tobacco. The subsequent preparation of the leaf for the market involves the usual operations of grading or sorting, fermentation in bulk, and ageing, after the tobacco is packed. A statute acre of land yields on the average about 1000 lbs. of tobacco at a cost of from £20 to £60.

The enactments against the growth of tobacco in Scotland and England were repealed by the Finance Act of the year 1909–1910.

Provision is now made for the remission of the duty on such home-grown tobacco as is used for the preparation of tobacco extract for insecticidal purposes. An approved denaturant must, however, be added to the extract before it is allowed to pass out of revenue control.

Composition. The tobacco plant contains a large number of substances common to the vegetable kingdom, among which may be mentioned cellulose, starch, albuminoids, glucosides, resins, chlorophyll, and many organic acids. On the character and proportion of these organic substances depend largely the uses to which the several varieties of tobacco are put. The freshly-cut green leaves contain from 80 to 90 p.c. of moisture: the normal percentage in the leaf when ready for the market is about 14 p.c., but in the finer grades of cigar and other leaf 20 p.c. is not uncommonly found. The amount of nicotine, the characteristic constituent of tobacco, varies from about 1 to 10 p.c.: thick-leaved varieties contain more than those with thin leaves, and the top leaves of a plant are richer in nicotine than those at the base of the stem. Schloesing has shown that the amount present in the leaves increases as growth proceeds: from leaves of the same kind collected on May 25, August 27, and September 25, he obtained 0·79, 2·27, and 4·32 p.c. of nicotine respectively. The dark, heavy tobaccos contain considerably more nicotine than the light coloured varieties. The use of large quantities of nitrogenous manures also favours the production of an increased quantity of nicotine. Java leaf contains from 1 to 2 p.c., Havannah, Maryland, Manila and Turkish from 2 to 4 p.c., Virginia and Kentucky up to 7 p.c., while some heavy French varieties contain as much as 10 p.c. of nicotine. The organic acids present in tobacco are chiefly malic, citric, oxalic, and pectic; acetic acid is sometimes found in fermented leaves. Some proportion of these acids exists in combination as acid salts and gives an acid reaction to the cell-sap. The malates, owing to their hygroscopic properties, are said by Behrens to exercise a considerable influence on the 'life' of the leaf by preserving its elasticity and softness. The changes in the colour of the leaf which occur during the curing process are concomitant with considerable chemical changes in the composition, brought about partly by the etiolation of the chlorophyll granules, and the subsequent oxidation of the sap contents of the dead cells. The acidity of the leaf, the soluble albuminoids, and the starch also through the action of the diastase, markedly diminish. Further changes of a complex character occur in the sweating process. The nicotine which exists in the leaf in combination with various organic acids is partially liberated, and part of it and of the amino bodies and albuminoids also, are eliminated. The nitric acid, ammonia, and the starch-content are little affected, but excessive fermentation favours the production of ammonium salts. Many attempts have been made to isolate and identify the bodies which impart the aroma to tobacco, but they have so far proved unsuccessful. At one time the source of the aroma was believed to be the so-called tobacco-camphor, or nicotianin, a crystalline volatile substance obtained by the steam distillation of fermented tobacco; but experiments have shown that it is not always associated with nicotine in tobacco leaf, as was supposed. The theory of Suchsland, that the distinctive aromas which characterise the different types of tobacco are due to the action of specific bacteria during the sweating process, has not been substantiated by other observers. The quality of the aroma is liable to be deteriorated by imperfect curing or a high fat content in the leaf. The formation of the aromatic bodies, however, is believed to be closely connected with the considerable reduction in the nicotine-content of the leaf which takes place during the fermentation process. It is a well-known fact that a high nicotine-content in a cigar is often associated with a poor aroma. The aromatic matters of tobacco are soluble in water, and more or less so in alcohol, and are readily dissipated by heat. The odour developed in smoking a cigar may be due partly to the mere volatilisation of the aromatic products of the sweating process and partly to the destruction of certain constituents. Nicotine, ammonia, carbon monoxide, pyridine, trimethylamine, butyric acid, and traces of nicotianin, hydrogen cyanide, formaldehyde and hydrogen sulphide, in addition to water and carbon dioxide, have been found in tobacco smoke. Kissling recovered from the smoke of two different samples of burning tobacco, each containing originally 3·75 p.c. of nicotine, 27·8 and 52·0 p.c. of the nicotine, while the quantity in the unconsumed portions of the tobacco increased to 4·5 and 5·9 p.c. respectively.

The following table of the analyses of certain kinds of tobacco serves to show the wide differences in the composition of various typical varieties. It is compiled from the results of analysis of many kinds of tobacco, which were made in the Inland Revenue Laboratory under the direction of Dr. James Bell.

The amount of ash found in tobacco varies greatly, and when calculated on the dry leaf ranges from about 10 p.c. to as much as 25 p.c., or even more. The lowest amount is found in the light varieties used for making cigarettes, and the greatest amount in leaf intended for making cigars. The ash of tobacco invariably contains potash, lime, magnesia, iron-oxide, alumina, soda; carbonic, silicic, sulphuric and phosphoric acids, and chlorine. The potash, which exists in the tobacco mainly in combination with the organic acids, may be present to the extent of fully 30 p.c. of the total amount of the ash. The amount of lime present is generally lower than that of potash: magnesia and silica rank next, while the amounts of soda, alumina and iron-oxide are relatively small. Lithia and manganous oxide are occasionally present in very small quantities. The combined chlorine varies from a mere trace to as much as 15 p.c. of the total amount of the ash.

The table (p. 509) shows the percentage composition of the ash of the several kinds of tobacco enumerated in the preceding table.

The leaves of tobacco contain more magnesia and silicic acid, and less alkali, phosphoric acid and chlorine than the stalks. The nitrates are confined almost entirely to the stalks and stems of the young plant, and decrease in amount as the plant comes to maturity: analyses of cigar-stalks from Missouri and Connecticut showed from 0·5 to 0·75 p.c. of nitrates, as against 0·15 p.c. found in cigarette leaf. Home-grown tobacco contains as a rule a considerably higher percentage of ash than is present in similar varieties grown abroad: this is probably accounted for by the use of excessive or unsuitable manures, especially when large quantities of chlorine are present, as the tobacco plant is very voracious and will take up almost anything from the soil. Good burning qualities in tobacco are associated with a high percentage of ash, rich in lime and potash, in proper combination: chlorine, except in the presence of much potash and lime, has a decidedly retarding effect on the combustion, but silicic, phosphoric and sulphuric acids have not a detrimental effect. Albuminoids hinder, but cellulose

promotes the good burning qualities of tobacco; while nicotine appears to be an unimportant factor. The comparative burning qualities, estimated by the time of glowing of the kindled leaf, vary from about four seconds in yellow varieties to as much as 175 seconds in Pennsylvania cigar-leaf.

Tobacco is analysed as regards organic and inorganic constituents by the usual methods described in text-books dealing with agricultural and quantitative chemical analysis. Special processes applicable to tobacco are described in the report on the culture and curing of tobacco in connection with the 10th United States Census of 1880. The percentage of moisture is liable to be under-estimated if the drying-oven is not maintained at a temperature of 100° and the ash also, unless it is re-carbonated by the addition of strong solution of ammonium carbonate, and subsequently dried before ascertaining the weight. A convenient method for the estimation of nicotine in tobacco is that of Kissling, which is as follows: Take 20 grms. of tobacco, finely powdered and dried at a temperature not exceeding 60°, and grind it up in a mortar with 100 c.c. of alcoholic solution of soda (6 grms. of NaOH dissolved in 40 c.c. of water and then made up to 100 c.c. with absolute alcohol). Transfer the mass to a Soxhlet extraction apparatus and extract for 3 hours with ether. Remove as much of the ether as possible by careful distillation, mix the residue with 50 c.c. of a 4 p.c. solution of soda, and distil in a current of steam. The flask containing the nicotine extract should be connected with the condensing apparatus by means of a tube having a safety bulb, and the distillation conducted rapidly and in such a manner that when 200 c.c. of the distillate have been collected not more than 15 c.c. of liquid remain in the distilling flask. Titrate the distillate with decinormal H_2SO_4, using litmus or lacmoid paper as an indicator. By using a series of test papers and noting the burette-reading against each, the exact point of neutralisation can readily be ascertained when the papers are dry.

Manufacture. In several European countries, among which may be mentioned France, Spain, Italy, Austria-Hungary, and Turkey, the manufacture of tobacco is a State monopoly, and in Spain the cultivation of tobacco is strictly prohibited. In Germany, Holland, and other European countries the manufacture is in private hands. In the United Kingdom, tobacco is subjected to a heavy import duty, and certain legal restrictions are imposed, which, however, chiefly affect the manufacturers of the commoner kinds of tobacco. The only substances allowed to be used in the manufacture are water, acetic acid, essential oils, and olive oil—the latter in the spinning of roll tobacco. The finished article must not contain more than 32 p.c. of moisture, and if it is roll tobacco, not more than 4 p.c. of olive oil. The leaves of plants other than tobacco may not be employed, nor any preservative used except acetic acid. Essential oils for flavouring purposes may be added to snuff, and the addition is allowed of the carbonates, chlorides and sulphates of sodium and potassium, ammonium carbonate, and of 1 p.c. of lime in the form of lime-water. The snuff, when dried, however, must not contain more than 26 p.c. of alkaline salts nor more than 13 p.c. of the oxides of lime and magnesia, inclusive of the amounts naturally present in tobacco. More latitude is allowed in the manufacture of tobacco in bonded factories: the addition of foreign leaves is not permitted, but any suitable sweetening or flavouring matter may be used. Sugar, honey, liquorice, glycerin, gum, salt, and logwood are the ingredients most commonly used for this purpose in the manufacture of this kind of tobacco, which is known as Cake- or Cut-Cavendish, and is manufactured chiefly for exportation. If intended for home consumption, this tobacco is required to be enclosed in a specially designed Customs' wrapper to distinguish it from the ordinary article, and it is subjected to a higher rate of duty. The sale of cigarettes containing sweetening matter is not permitted, and no flavouring materials may be used in cigars.

Tobacco leaf is imported into this country either entire or with a portion of the mid-rib removed, in which case it is called 'strips': as a slightly higher rate of duty is charged on the latter, a much larger proportion of the entire leaf is now imported. Nearly 90 p.c. of the raw material imported comes from America; 5 p.c. comes from the Dutch Indies, and about 1 p.c. is obtained from the British colonies, of which North Borneo produces a large proportion. The principal kinds of tobacco used are Virginia, Kentucky, Western, Burley, Ohio, Perique, Havannah, Japan, Java, China, Sumatra, Borneo, Turkish, Latakia, and German. The more tender varieties, such as Turkish, are packed carefully in bales leaf upon leaf, but hogsheads are the usual packages employed, in which the leaves are packed either in layers or in bunches of ten to a dozen leaves, bound round with another leaf and known as 'hands.' Commercial tobacco is classified as a rule under five heads—common, middling, good, fine, and selected; but each manufacturer has his own particular method of assortment. Price, colour, texture, burning qualities, aroma, and body or drinking power, that is, ability to absorb and retain moisture without becoming too wet, are all factors which influence manufacturers in selecting tobacco.

Imported leaf, although apparently dry, usually contains from 10 to 20 p.c. of moisture, but 14 p.c. may be regarded as a fair average. There are two rates of duty on imported leaf tobacco depending on the amount of moisture present: the duty on leaf containing 10 p.c. or more of moisture is *5d.* per lb. lower than the duty charged on leaf containing less than 10 p.c. of moisture. The manufacturer of the cheaper kinds of tobacco endeavours therefore to secure leaf containing moisture as little in excess of 10 p.c. as possible, and so to obtain a larger profit from the greater amount of water he can add in the process of manufacture. In cigarette, cigar, and other varieties of leaf requiring careful handling, a higher initial percentage of moisture is desirable, and these varieties of leaf sometimes contain as much as 20 p.c. of moisture.

The principal kinds of manufactured tobacco are cut, twist or roll, and cake tobacco; cigars, cigarettes, and snuff. Many kinds of leaf are blended for manufacturing cut tobacco, and in the commoner kinds a considerable quantity of leaf other than American is employed. These other kinds are known as 'substitutes,' and their introduction dates back to the time of the civil war in the United States of North America, which caused a temporary shortage in the supplies of Virginia leaf tobacco. Many of these 'substitutes' have the distinct advantage of being able to retain a large quantity of moisture without appearing to be unduly moist.

The first process in manufacturing tobacco is the 'liquoring' stage: the old crude method of employing a watering-pot has now been superseded by the use of steam appliances which ensure a more even distribution of the moisture. When 'strips' are not employed, the mid-rib of the leaf which absorbs more moisture than the lamina is then removed—this operation is called 'stripping.' A mechanically actuated knife is employed to cut the tobacco into shreds: 'shags' and such like tobaccos undergo the further process of 'panning,' which consists in thoroughly mixing up the cut tobacco on copper trays heated to a suitable temperature; the tobacco is then set aside to cool on racks. The moisture in the common kinds averages about 30 p.c., but the better kinds of smoking mixtures contain from 15 to 25 p.c. The distinctive flavours of these tobaccos are due either to the presence of Latakia, Perique, &c., in the blend of leaves used or to the addition of essential oils, such as oil of cassia, geranium, cloves, bergamot, and winter-green. Acetic acid is employed as a preservative. For 'twist' tobacco the darker varieties of American leaf, such as Kentucky, Western, Clarksville, &c., are chiefly employed, but a fair quantity of Irish-grown leaf is now used in this class of tobacco. 'Twist' tobacco is made either by hand or on a spinning-wheel: the damp strips or 'fillers' are formed into ropes, the thickness of which depends on the denomination of 'twist' intended to be manufactured, and these ropes are enclosed in a covering wrapper of leaf. The tobacco, at this stage, is known as 'brown twist,' for which a considerable demand exists, chiefly in the North of England. If the tobacco is intended for 'black twist' the rope of tobacco is made up into 'rolls,' consisting of several concentric layers superimposed one on the other. The rolls, after being enclosed in oiled cloths, and tightly bound up with rope, are then baked in steam-heated hydraulic presses until the tobacco assumes a rich black colour, and develops its full aroma; they are then removed to a cold press until cool and fully matured. In order to prevent the coils from sticking to one another in the rolls, olive oil is applied to the tobacco during the 'spinning' and 'rolling' or 'making up' processes, but the amount of oil used is regulated so as to ensure that the finished tobacco does not contain more than 4 p.c. of oil. Acetic acid and essential oils are also employed. Special names are given to different forms of 'twist,' *e.g.* the terms ladies' twist, or Alloa twist, Liverpool roll, pigtail and bogie, have reference to the thickness of the rope; Negrohead indicates a plaited variety; nailrod is in the form of sticks, and target is a thick twist coiled up in a single layer. 'Cake' tobacco is prepared either by pressing 'spun' tobacco or by moulding the damp strips under pressure and then adding an outer covering of leaf. 'Flakes' and 'Cut Cavendish' are obtained by cutting these cakes.

The leaf employed for the manufacture of high-class cigars has to meet many requirements, and blends of different varieties are therefore employed. The component parts of a cigar are the 'filler,' the 'bunch wrapper,' shaped like a balloon gore, and cut from a fairly good strip, and the 'outer wrapper.' The outer wrapper of a cigar should be made from a tough leaf with small veins, of a light and uniform colour and should not possess a pronounced flavour, as it comes in contact with the lips and tongue in smoking; the filler must, however, possess a good aroma, emit an agreeable odour on burning, and have good burning qualities. The finest leaf for cigars comes from Cuba, but Sumatra, North Borneo, Java, &c., supply a considerable quantity of the leaf used for cigar-making in this country. The leaves are moistened with water, opened out carefully, deprived of the midrib, smoothed out and sorted; the perfect leaves are cut in halves and are used as wrappers. The 'filler,' consisting of fragments or cuttings of leaf, or sometimes of cut tobacco, is placed on the 'bunch wrapper,' near one end, and the bunch wrapper is then carefully wound round the filler. Over the 'bunch wrapper' the cigar-maker then winds spirally the 'outer wrapper,' which is a long rectangular strip of leaf; the winding is commenced at the open end and finished off at the pointed, or mouth, end. The cigars are then gauged and cut to the proper length, dried and packed. Great dexterity is necessary in making cigars, especially in manipulating and keeping the cigars to shape, size, and weight, as well as in evenly packing. Uniformity in the commoner kinds is secured by the practice of pressing the cigars in moulds before applying the outer wrapper. The moisture in the finished cigar is reduced to about 10 to 15 p.c. by storage in a drying-room.

The manufacture of cigarettes was introduced into this country by a Greek in the year 1860, and originally Turkish varieties of tobacco only were employed, but now a considerable quantity of bright American leaf is also used. This branch of the tobacco industry is highly specialised, as the character and the aroma of a cigarette depend on the suitable blending of the various kinds of tobacco employed. The tobacco used for cigarettes is comparatively dry, the moisture added is just sufficient to permit of the leaf being satisfactorily cut by the machines. The finer varieties of cigarettes are invariably made by hand, either by rolling up the tobacco in the paper, or by filling it into paper tubes closed at one end. In the latter method, charging cylinders slightly smaller in diameter are used, and the tobacco is transferred therefrom to the tubes by means of a rod; the closed ends of the paper tubes are subsequently cut off. A great impetus has been given to the production of cigarettes by the employment of cigarette-making machines, which can turn out as many as 24,000 cigarettes per hour. The moisture in cigarettes varies according to the time they are stored in the drying-room, but it usually ranges from 12 to 18 p.c.; if the tobacco is made too dry it is liable to be shaken out of the wrapper; and on the other hand, if the tobacco is left too damp, the cigarette will not burn well. Mouthpieces are often fitted to cigarettes made from Turkish tobacco, on account of its superior burning quality. Cigarettes vary considerably in weight; an ounce may contain from 12 to 40 cigarettes, but 20 to 30 is about the average. Sweetening matter is not allowed to be used in making cigarettes, but the paper wrappers of the 'pectoral' kinds sometimes contain a small quantity of saccharin.

Snuff is sold in two forms, dry and moist, the former is made from the stalk or midrib of the leaf, but the latter contains a variable proportion of the lamina. The difference in the quality is dependent on the flavour, the pungency, and the scent. The dry varieties—the Welsh, Scotch, High Toast, and Irish kinds—are, as a rule, more finely ground than the moist varieties. The moisture ranges from about 20 p.c. in Scotch snuffs, to as little as 5 p.c. in Irish snuff. 'Rappees' include such well-known varieties as Latakia, Macuba, and Prince's mixture, and contain from 30 to 50 p.c. of moisture. The tobacco stalks used for snuff-making are cut into small pieces, moistened with water or sometimes with lime-water, and allowed to ferment, the fermentation period frequently lasting for several months. The material, in the case of Scotch snuff, is then ground to the required degree of fineness, dried down, flavoured, and sifted. The stalks for Irish and Welsh snuff, before being ground, are gently roasted, by which means the characteristic odour of these varieties is produced. For moist snuffs the material is ground wet in a special kind of mortar, and is then allowed to ferment until the required depth of colour is produced. Certain kinds of alkaline salts are mixed with the snuff-flour to increase its pungency, but, as already mentioned, the quantity and the kinds which may be employed are defined by statute. Essential oils, ground orris-root and ground Tonquin beans are used for flavouring purposes. Adulteration of snuff is now rarely practised, but such substances as the oxides of iron, red lead, lead chromates, &c., have been used as colouring materials, and chalk, magnesia, borax, sand, and excessive quantities of alkaline salts have been employed to increase the weight.

Prior to the passing of the Pure Tobacco Act of the year 1842, the adulteration of tobacco with sugar, treacle, honey, gum, &c., and such foreign vegetable matters as rhubarb, coltsfoot, &c., was very general; but in consequence of the heavy penalties imposed by that Act and the vigilance of the Revenue Authorities these practices have almost ceased. The enactments relating to the amounts of moisture and oil in tobacco are also strictly enforced. Such substances as malt combings, moss-litter, &c., are occasionally offered as substitutes for tobacco, but the offenders rarely escape detection and punishment. Manufactured tobacco contains frequently considerable quantities of sand, and manufacturers are sometimes suspected of using it as an adulterant. The leaf, however, frequently comes into their possession still retaining a large proportion of the sand which is deposited upon it from the soil by the action of the wind and rain during growth. A portion of this sand only is detached from the leaf during the manufacturing operations, which accounts for the presence of sand in the finished article.

In the manufacture of tobacco, a considerable quantity of waste material is produced, siftings, sweepings, &c., and in addition the quantity of stalks obtained by stripping the midrib from the imported leaf is far in excess of that required for conversion into commercial snuff. Repayment of the duty, called 'drawback,' is made by the Revenue Authorities on this refuse of tobacco when it is deposited in an approved warehouse to be abandoned to the Crown, or in a bonded factory to be utilised in the manufacture of nicotine or the preparation of 'sheep-dip,' hop-powder, insecticides, &c.

Statistics. The amount of tobacco leaf imported into the United Kingdom and the consumption of manufactured tobacco have steadily increased. The imports in the year 1851 amounted to about 28,000,000 lbs. and the consumption was just over 1 lb. per head of the population; in the year 1911, the amount imported was nearly 91,500,000 lbs. and the consumption was slightly in excess of 2 lbs. per head of the population. The manufacture of tobacco is now one of the most important of the minor industries, and according to the returns made in connection with the recent Census of Production, the number of persons employed in tobacco factories in the year 1907 was 37,456. The net value of the raw material was £17,988,000 and, including 11,816,000 lbs. of manufactured tobacco exported, the output amounted to 108,292,000 lbs., representing a money value of £23,799,000. The weight of the different kinds was as follows: of cut and roll tobacco, 69,880,000 lbs.; of cigarettes, 29,904,000 lbs.; of cigars, 3,696,000 lbs.; of sweetened cavendish, 3,136,000 lbs.; and of snuff, 1,568,000 lbs. The degree of the popularity of the principal kinds of tobacco may be ascertained from these figures; the percentages are: of pipe tobacco 67·5 p.c., of cigarettes 29·0 p.c., and of cigars 3·5 p.c. respectively.

Tobacco occupies an important position as a source of revenue in the fiscal systems of most civilised countries. In the tariff of the United Kingdom the rate of duty at the present time is 3*s.* 8*d.* per lb. for normal leaf tobacco, and the net amount of duty paid into the Exchequer in the financial year 1911-12 exceeded seventeen and a quarter million pounds sterling.

D. A. G.

TOBACCO-SEED OIL. Tobacco seeds yield on pressing about 30 p.c. of a greenish-yellow, mild, and odourless oil, sp.gr. 0·923 at 15°, solidifying at −25°, which quickly dries when exposed to the air.

TODDALIA ACULEATA (Pers.). This Indian plant, belonging to the *Rutaceae*, is a rambling shrub found in the sub-tropical Himalayas, in the Khasia mountains, and throughout the Western Peninsula and Ceylon.

The root bark is used in Madras as a yellow dyestuff, and it is also highly spoken of by various writers as one of the most valuable Indian medical products, possessing tonic, stimulant, and antipyretic properties. It was introduced into European medicine in 1771, and at one time enjoyed some celebrity under the name of 'Lopez Root,' but it has long since fallen into disuse.

The colouring matter it contains is berberine (Perkin and Hummel, Chem. Soc. Trans. 67, 413).

A. G. P.

TOLENE *v. Tolu*, art. BALSAMS.

TOLIDENE (*Orthotolidene*) *v.* DIPHENYL.

TOLU *v.* BALSAMS.

TOLUENE. *Toluol, Methylbenzene* C_7H_8 or $C_6H_5{\cdot}CH_3$. First discovered by Pelletier and Walter in 1837 (Ann. Chim. Phys. [ii.] 67, 278) among the by-products in the manufacture of illuminating gas from the resin of *Pinus maritima*, and named by them *retinaphtha*. Mansfield found it in coal-tar, Cahours and Völkel in wood-spirit and wood-tar, and De la Rue and H. Müller in Rangoon tar. It is also found in American light petroleum (Young, Chem. Soc. Trans. 1898, 906); in the products of distillation of a large number of substances (Ritthausen, J. pr. Chem. 1854, 61, 74; Bunte, J. Gasbeleucht, 1892, 35, 571, amongst others) and in a number of naturally occurring substances (Poni, Chem. Zentr. 1901, i. 61, and others). Fittig and Tollens prepared it by the action of sodium on a mixture of bromobenzene and methyl iodide in ethereal solution, and thus proved that it was methylbenzene.

It may also be prepared by the action of methyl chloride on benzene in presence of aluminium chloride (Friedel and Crafts, Ann. Chim. Phys. 1884, [vi.] 1, 459) and by other methods (Gardeur, Chem. Zentr. 1898, i. 438; Fromm and Achert, Ber. 1903, 36, 534; Werner and Zilkens, *ibid.* 2116; Mai, *ibid.* 1902, 35, 162; and many others).

The toluene of commerce is obtained from coal-tar by rectification of the fraction boiling between 100° and 120° (Coupier, Dingl. poly. J. 1866, 181, 386; Leuckart, J. pr. Chem. 1890, [ii.] 41, 301).

Toluene may be purified by treatment with sulphuric acid (Friswell, Chem. News, 1893, 68, 27); it may be freed from thiotoluene by treatment with aluminium chloride (Fr. Pat. 240111, 1894; D. R. P. 79505). It is said to be obtained absolutely pure by converting it into the well crystallised potassium toluene-*p*-sulphonate which is subsequently decomposed (Miller, Chem. Soc. Trans. 1892, 1025; *see* also Kelbe, Ber. 1886, 19, 93; Kraemer and Böttcher, *ibid.* 1887, 20, 601).

Properties. Toluene is a colourless liquid, b.p. 111°, m.p. −97° to −99° (Archibald and McIntosh, J. Amer. Chem. Soc. 1904, 26, 305), sp.gr. 0·8812 at 4°/4°; 0·8723 at 15°/15°; 0·8649 at 25°/25°; 0·8237 at 100°/100°. In its solvent powers it closely resembles benzene.

Oxidising agents, such as chromic acid or dilute nitric acid, convert it into benzoic acid; but by treatment, first with chromyl chloride and afterwards with water, it yields benzaldehyde. Similar products are obtained when it is oxidised electrolytically in alcoholic solution and in the presence of sulphuric acid (Puls, Chem. Zeit. 1901, 25, 263). When the vapour of toluene is passed through a red-hot tube, benzene, anthracene, phenanthrene, dibenzyl, and other hydrocarbons are formed (Berthelot, Bull. Soc. chim. 7, 218; Graebe, Ber. 1874, 7, 48). By passing a mixture of the vapours of toluene and benzene through a red-hot tube, Carnelley obtained a highly complex mixture of hydrocarbons (Chem. Soc. Trans. 1880, 702).

Treated with litharge at a dull red heat, it forms stilbene, diphenyl anthracene, and a liquid hydrocarbon. At 335° only the methyl group is oxidised (Vincent, Compt. rend. 1890, 110, 907); the rate at which the side chain is oxidised depends on the nature and position of substituted groups in the nucleus (Cohen and Miller, Chem. Soc. Trans. 1904, 174; Cohen and Hodsman, *ibid.* 1907, 970).

When air charged with toluene vapour is passed over finely divided platinum or manganese dioxide, the temperature rises until the metals become incandescent and the toluene is completely oxidised to carbon dioxide and water. In the presence of iron, nickel or copper oxides, at temperatures between 150°–300°, it is converted to benzaldehyde, but with carbon at 370°, benzoic acid is formed (Woog, Compt. rend. 1907, 145, 124). Substitution may take place either in the nucleus or in the methyl group of toluene. In the former case a mixture of *p*- and *o*- compounds is chiefly formed.

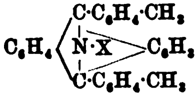
Toluene is employed in the manufacture of nitrotoluene and toluidine, benzyl chloride, benzal chloride, and benzotrichloride, benzaldehyde, benzoic acid, and cinnamic acid. It is also used in the manufacture of dyestuffs, synthetic drugs and perfumes. Formerly toluene formed an essential ingredient of the benzene employed as the starting-point in the manufacture of fuchsin, but at the present day it is usual to start with pure benzene and pure toluene.

Commercial toluene should give only a pale-brown coloration with concentrated sulphuric acid. But pure toluene should give no coloration with sulphuric acid and should not decolorise a N/10 solution of bromine. When shaken with nitric acid (sp.gr. 1·44), the acid should be coloured red but not become viscid or greenish. On distillation a crude toluene should furnish at least 90 p.c. under 120°; and the 'pure toluene' of commerce should distil between 110°–113°—the greater part between 111°–112° (Schultz, Chem. des Steinkohlentheers).

Unless coal-tar toluene has been purified by shaking it with concentrated sulphuric acid, it always contains 2- and 3-methylthiophens (thiotolens).

Toluene reacts with acetylene tetrabromide, methylene chloride or chloroform in presence of aluminium chloride, forming, when the products are well stirred during the reaction, 1 : 6- and 2 : 7-dimethyl anthracenes, m.p. 244·5° and 240° respectively, together with a little β-methylanthracene, benzene, xylene and other homologues (Lavaux, Compt. rend. 1905, 141, 204; *ibid.* 1908, 146, 345).

Like benzene and dimethylaniline, toluene reacts with tetramethyldiaminodiphenylhydroxyanthranol forming a colourless additive compound which yields highly coloured salts and reacts with one molecule of phenylhydrazine or hydroxylamine eliminating two molecules of water and forming the compound



(where X=OH or C_6H_5NH) (Haller and Guyot, Compt. rend. 1903, 137, 606).

Toluene reacts with ethyl diazoacetate at 118° forming ethyl 4-methylnorcaradienecarboxylate, b.p. 122°–126°/15 mm. pressure (Buchner and Feldmann, Ber. 1903, 36, 3509).

Toluene also condenses with benzaldehyde in presence of concentrated sulphuric acid forming di-tolylmethane (Kliegl, Ber. 1905, 38, 84).

Toluene condenses with diphenic anhydride forming fluorene derivates (Pick, Monatsh. 1904, 25, 979).

HALOGEN DERIVATIVES OF TOLUENE.

In the chlorination or bromination of toluene, substitution may, as already mentioned, take place either in the nucleus or in the methyl group. The former is the case when the halogen acts on toluene in presence of iodine or other substances capable of acting as carriers of halogen; the latter, when the halogen alone acts on toluene heated to boiling or exposed to direct sunlight, the influence of light being greater than that of heat in inducing substitution in the side-chain (Cohen, Dawson, Blockley and Woodmansey, Chem. Soc. Trans. 1910, 1623; Bancroft, J. Phys. Chem. 1908, 12, 240). Only the chlorine derivatives belonging to the latter class are of technical importance. Unlike other halogen carriers, sulphur is said to facilitate side-chain substitution (Beck, Ber. 1892, 25, 2445). The latter is also facilitated by the dilution of the halogen (*see* also Cohen and Dakin, Chem. Soc. Trans. 1906, 1455; Holleman and Polak, Rec. trav. chim. 1908, 27, 435).

Benzyl chloride $C_6H_5{\cdot}CH_2Cl$. First obtained by Cannizzaro by the action of hydrochloric acid on benzyl alcohol $C_6H_5{\cdot}CH_2{\cdot}OH$. Manufactured by passing chlorine into toluene contained in acid-proof earthenware vessels and heated to boiling by means of a leaden steam-spiral. The operation is interrupted when the toluene shows the theoretical increase of weight (37·5 p.c.). The vapours are condensed by a reflux worm, and the escaping hydrogen chloride passed into water. The product is shaken with weak alkali and then rectified, by which means it is freed from unaltered toluene and higher chlorinated products. Very good yields are also said to be obtained by allowing sulphuryl chloride to act on excess of toluene in the dark at a temperature a little below 130° (D. R. P. 139552).

For certain other laboratory methods of preparation see Grassi-Cristaldi and Maselli Gazz. chim. ital. [ii.] 28, 498; Solonina, Chem. Zentr. 1898, ii. 887; Schramm, Ber. 1885, 18, 608).

Benzyl chloride is a colourless liquid boiling at 176°–179°; m.p. −43·2° to −48° (Haase, Ber. 1893, 26, 1053); sp.gr. 1·1135 at 4°/4°, 1·1040 at 15°/15°, 1·0967 at 25°/25° (Perkin). Has a somewhat pungent smell; the vapour is very irritating to the eyes. Insoluble in water, but by heating with water to 100°–110°, or by boiling with water for 24 hours with a reflux condenser, it is converted into benzyl alcohol (Niederist, Annalen, 1879, 196, 353); and the same transformation is still more readily effected by boiling benzyl chloride with the calculated quantity of potassium carbonate dissolved in from 8 to 10 parts of water (Meunier, Bull. Soc. chim [ii.] 38, 159; *see* also Vandevelde, Chem. Zentr. 1898, i. 438; Busch and Weiss, Ber. 1900, 33, 2702). Oxidising agents convert it first into benzaldehyde, afterwards into benzoic acid. When subjected to an electric current, hydrochloric acid is evolved and stilbene is formed (Loeb, Zeitsch. Elektrochem. 1903, 9, 903). By heating with a small quantity of copper it yields dibenzyl $C_6H_5{\cdot}CH_2{\cdot}CH_2{\cdot}C_6H_5$. With alcoholic ammonia it gives a mixture of benzylamine $C_6H_5{\cdot}CH_2{\cdot}NH_2$, dibenzylamine

$$(C_6H_5{\cdot}CH_2)_2NH,$$

and tribenzylamine $(C_6H_5{\cdot}CH_2)_3N$ (Cannizzaro, Annalen, 1865, 134, 128; *ibid.* Suppl. 4, 24, 80; Dhommée, Compt. rend. 1901, 133, 636). With aniline it forms benzylaniline

$$C_6H_5{\cdot}CH_2{\cdot}NH{\cdot}C_6H_5.$$

When treated with a metallic salicylate at 130°–140° it yields *benzyl salicylate*, an odourless liquid, b.p. 208°/26 mm., which is said to be useful for external application in medicine (Eng. Pat. of 25735, 1899).

Benzyl chloride is used in the preparation of benzaldehyde and benzoic acid, and also for introducing the benzyl group into basic colouring matters so as to produce varieties of shade.

Commercial benzyl chloride generally contains moisture, benzal chloride ($C_6H_5{\cdot}CHCl_2$), benzotrichloride ($C_6H_5{\cdot}CCl_3$), chlortoluenes, and even unchanged toluene. It should show the correct boiling-point and specific gravity. In order to ascertain whether the whole of the chlorine is contained in the methyl group, a weighed quantity of the substance should be boiled for some minutes with a hot saturated alcoholic solution of silver nitrate, using a reflux condenser; the silver chloride, which will represent only the chlorine from the side-chain, is then collected and weighed (Schulze, Ber. 1884, 17, 1675). Benzotrichloride may be detected by the green colouring-matter (malachite green) which is formed when the substance is heated with dimethylaniline and zinc chloride (Döbner).

Benzal chloride. *Benzylidene chloride*

$$C_6H_5{\cdot}CHCl_2.$$

First obtained by Cahours (Ann. Chim. Phys. 1848, [iii.] 23, 329) by the action of phosphorus pentachloride on benzaldehyde $C_6H_5{\cdot}CHO$. Manufactured by chlorinating boiling toluene in direct sunlight.

Colourless, powerfully refractive liquid, boiling at 206°; m.p. −16·1°; sp.gr. 1·2557 at 14°. Water, alkalis, or concentrated sulphuric acid, convert it into benzaldehyde. When heated with sodium acetate it yields cinnamic acid.

Benzal chloride is employed in the manufacture of benzaldehyde, benzoic acid, and cinnamic acid.

The commercial product is always impure. It may be tested by its boiling-point, and by determining the percentage of chlorine.

Benzotrichloride. *Phenylchloroform*

$$C_6H_5{\cdot}CCl_3.$$

First obtained by Schischkoff and Rösing (Compt. rend. 1858, 46, 367) by the action of phosphorus pentachloride on benzoyl chloride $C_6H_5{\cdot}COCl$. Manufactured by chlorinating boiling toluene in direct sunlight until the weight of the product no longer increases.

Colourless, powerfully refractive liquid, boiling at 213°–214°; m.p. −21·2°; sp.gr. 1·380 at 14°. Heated with water at 150°, it yields benzoic and hydrochloric acids. Sodium ethoxide converts it into ethyl orthobenzoate $C_6H_5{\cdot}C(OC_2H_5)_3$. Heated with dimethylaniline and zinc chloride, it yields malachite green. Methyldiphenylamine, diethylaniline, and diamylaniline give similar green colouring matters, differing in shade from malachite green.

Benzotrichloride was formerly employed in the manufacture of malachite green, but owing to the difficulty of obtaining benzotrichloride in a state of purity this process has been abandoned.

Commercial benzotrichloride is tested by examining its boiling-point. It generally contains compounds chlorinated in the nucleus.

Fluorine derivatives of toluene have been obtained by the action of antimony fluoride on benzotrichloride (Swarts, Chem. Zentr. 1898, ii. 26; Holleman, Rec. trav. chim. 1906, ii. 25, 330).

Literature regarding other halogen toluenes and their nitro and other derivatives (Jackson and Smith, Amer. Chem. J. 1904, 32, 168; Hilpert, *ibid.* 1908, 40, 150; Blanksma, Rec. trav. chim. 1904, 23, 125; Chem. Weekblad. 1909, 6, 728; Reverdin, Bull. Soc. Chim. 1904, [iii.] 31, 63; Mascarelli, Atti. R. Accad. Lincei, 1905, [v.] 14, ii. 199; Artmann, Monatsh. 1905, 26, 1091; Zincke and Buff, Annalen, 1908, 361, 218; Willgerodt and Simonis, Ber. 1906, 269; Caldwell and Werner, Chem. Soc. Trans. 1907, 248; Ponzio and Charrier, Atti. R. Accad. Sci. Torino, 1908, 43, 475; Ponzio, Gazz. chim. ital. 1908, 38, ii. 417; Zincke and Frohneberg, Ber. 1910, 43, 857). Cyano toluenes, *see* Borsche and Böcker, Ber. 1903, 36, 4357.

Nitro derivatives; for preparation *v.* **BENZENE AND ITS HOMOLOGUES.**

When toluene is nitrated with nitric acid of sp.gr. 1·475, the quantity of *o-*, *m-* or *p-* mononitro derivative obtained depends on the temperature, solvent and other conditions (Holleman, Proc. K. Akad. Wetensch. Amsterdam, 1908, 11, 248; Bruner and Vorbrodt, Chem. Zentr. 1909, i. 1807; *v.* also Kohn, Monatsh. 1910, 31, 745; Fischer, Zeitsch. Elektrochem. 1910, 16, 161). The first increases slightly with a rise in temperature; the last decreases, whilst the *m-* product also increases, but is always present only in small quantity.

When freshly distilled *o*-nitrotoluene is rapidly cooled to −20° it solidifies sometimes to the labile *α*-modification, m.p. −10·56°, sometimes to the stable *β*-modification, m.p. −4·14°. The latter may also be prepared by cooling the liquid to −50° or −60° when the *α* form separates at first but rapidly changes to the *β* form. Superheating of the vapour during distillation also favours the formation of the latter modification (Ostromisslensky, Zeitsch. Physikal. Chem. 1907, 57, 341).

o-Nitrotoluene reduced by heating with iron or zinc and sodium hydroxide at 100°, yields *o-azoxytoluene*; when, however, acid is added to the product, toluene-*o*-azobenzoic acid separates as orange-red needles with a blue lustre, m.p. 148°, which is reduced by zinc dust and soda to toluene-*o*-hydrazobenzoic acid, m.p. 136°. This when warmed with concentrated hydrochloric acid yields, on addition of sodium hydroxide, diaminomethyldiphenylcarboxylic acid

$$NH_2{\cdot}C_6H_3(CH_3)C_6H_3(NH_2)CO_2H$$

m.p. 183° (decomp.) D. R. P. 145063; *cf.* Löb and Schmitt, Zeitsch. Elektrochem. 1904, 10, 756).

m- and *p*-Nitrotoluenes mixed with carbon tetrachloride react with chromyl dichloride in the same solvent, yielding the corresponding nitrobenzaldehyde and a small quantity of nitrobenzoic acid. The *o*-nitro compound, similarly treated, yields a mixture of chlorinated nitro compounds, the vapours of which attack the eyes severely. The three chlorotoluenes, when similarly treated, yield the corresponding adehydes (Law and Perkin, Chem. Soc. Trans. 1908, 1635).

p- and *o*-Nitrotoluenes and their derivatives, when treated with potash, yield red nitroso dibenzyl and blue nitroso stilbene compounds (Davies and Horsfall, Chem. Soc. Trans. 1907, 2070; Green and Baddiley, *ibid.* 1908, 1721. Ring substituted *p*-nitrotoluenes are converted by an alcoholic solution of sodium disulphide into the corresponding *p*-aminobenzaldehydes and *p*-toluidines (Blanksma, Chem. Weekblad, 1909, 6, 899).

For other information on the nitrotoluenes and some of their derivatives, *v.* Cohen and Dakin, Chem. Soc. Proc. 1901, 214; Glasmann, Ber. 1903, 36, 4260; Bamberger and Hübner, *ibid.* 3803, 3822; South, Bull. Soc. Chim. 1904, [iii.] 31, 133; Cohen and Marshall, Chem. Soc. Trans. 1904, 527; Walker and Spencer, *ibid.* 1108; Siegfried, Zeitsch. Physiol. Chem. 1904, 43, 68; Zincke, Annalen, 1905, 339, 218; Raikow and Urkewitsch, Chem. Zeit. 1906, 30, 295; Brand and Zöller, Ber. 1907, 40, 3324; Reissert, *ibid.* 4209; Hofer and Jakob, *ibid.* 1908, 41, 3187; Reverdin, *ibid.* 1909, 42, 1523; D. R. PP. 150313, 182217, 182218.

Amino toluenes, see TOLUIDINE.

Sulphonic derivatives of toluene are obtained by treating toluene with sulphuric acid. If the fuming acid is used and the temperature of the reaction is kept at the boiling-point of toluene, the main product is the *p*- acid, but if the temperature is not allowed to rise above 100° and ordinary concentrated acid is employed, 40–50 p.c. of the *o*- sulphonic acid is obtained (D. R. P. 35211, 137935; Eng. Pat. 10810, 1897; Norton and Otten, Amer. Chem. J. 1888, 10, 140; Bourgeois, Chem. Zentr. 1900, i. 253; Reverdin, Ber. 1909, 42, 1523).

They may be separated from one another by taking advantage of the difference in solubility of the potassium salts, or by conversion into their corresponding sulpho-chlorides or sulphonamides (*v.* SACCHARIN).

The *o*- acid crystallises in octahedra whilst the *p*- acid is obtained as a syrup which condenses with tetramethyldiaminobenzhydrol in the presence of sulphuric acid, forming the leuco base of a sulpho acid of the malachite green series which on oxidation gives a bluish-green dye (D. R. P. 87176). Both acids give metallic and other salts.

o-Toluene sulphonyl chloride may be obtained by treating the corresponding sulphonic acid with chlorosulphonic acid. After standing for several hours the mixture is poured into ice-cold water (Eng. Pat. 2304 of 1905; D. R. P. 154493; *see* also Eng. Pat. 6581 of 1897; 4525 of 1900; 11077, 11078 of 1898; 16299 of 1903; Fr. Pat. 312797 of 1901).

The *o*- and *p*-sulphonic chlorides may also be prepared conveniently by treating toluene with fuming sulphuric acid containing about 60 p.c. of the anhydride and previously saturated with dry hydrogen chloride (Eng. Pat. 1877 of 1903).

2 : 6-*Di*- and 2 : 3 : 6-*tri-chlorotoluene* 4-*sulphonyl chlorides* have been prepared by treating *p*-toluenesulphonyl chloride with antimony pentachloride at 70°–75°, then treating the mass with alkali and separating the chlorides by fractional distillation (D. R. P. 210856).

For other derivatives of toluene sulphonic compounds, *see* Chattaway, Chem. Soc. Trans. 1904, 1184; Reverdin and Dresel, Ber. 1904, 37, 4452; Willstätter and Pfannenstiehl, *ibid.* 1905, 38, 2244; Ullmann and Nádai, *ibid.* 1908, 41, 1870; Hilditch and Smiles, *ibid.* 4113; Ullmann and Werner, Annalen, 1903, 327, 120; D. R. P. 150366, 146946; Fr. Pat. 328170 of 1902; Morgan and Pickard, Chem. Soc. Trans. 1910, 56.

2-*Amino*-p-*tolyltoluene*-p-*sulphonate*

$$C_7H_7{\cdot}SO_2{\cdot}O{\cdot}C_7H_6{\cdot}NH_2$$

lustrous prisms, m.p. 78°, is obtained by reducing the corresponding nitro compound. It is employed in the manufacture of colouring matters (D. R. P. 201377).

Stable violet-blue dyes have also been obtained from p-*toluenesulphon*-p-*nitroanilide* (D. R. P. 224499).

p-*Toluene sulphinic acid*, m.p. 86°–87°, may be obtained by the action of sulphur dioxide and aluminium chloride on toluene or its halogen derivatives at low temperature (Knoevenagel and Kenner, Ber. 1908, 41, 3315; Thomas, Chem. Soc. Trans. 1909, 342). Its anhydride has m.p. 75° (Knoevenagel and Polack, Ber. 1908, 41, 3323).

Phenols or naphthols when heated with benzene and *p*-toluene sulphinic acid to 150°–180° yield dyestuffs which are readily reduced and are soluble in alkalis (Heiduschka, J. pr. Chem. 1910, 81, 320).

Mercury (Peters, Ber. 1905, 38, 2567), sodium (Gutmann, *ibid.* 1909, 42, 480) and other derivatives of toluene sulphinic acid have been described (Kohler and Reimer, Amer. Chem. J. 1904, 31, 163).

Potassium 4-xantho-2-nitrotoluene-5-sulphonate, $C_{10}H_{10}O_6NS_3K,1\frac{1}{2}H_2O$, forms small light brown prismatic needles, decomposing above 150°. When hydrolysed with potash, it yields dipotassium 6-nitro-4-thiotoluene-3-sulphonic acid, $C_7H_5O_5NS_2K_2,2H_2O$, dark red prisms, oxidised by atmospheric oxygen to the disulphide $S_2[C_6H_2Me(NO_2)SO_3K]_2,5H_2O$, long yellow needles yielding with phosphorus pentachloride the sulphochloride

$$S_2[C_6H_2Me(NO_2)SO_2Cl]_2$$

as light brown prisms, m.p. 208°. The last, on reduction is converted into 2-*amino*-4 : 5-*dithiotoluene* which gives well-characterised salts and esters and is oxidised by air with formation of a substance $(C_7H_7NS_2)_x$. The amino dithiotoluene derivative yields red azo wool dyes (Fichter, Fröhlich and Jalon, Ber. 1907, 40, 4420).

p-*Tolyl-α-naphthylamine* is used industrially in the manufacture of 'Night Blue.' The monosulphonic acid of *p*-tolyl-*α*-naphthylamine is prepared by treating the acetyl compound with sulphuric acid monohydrate. When treated with nitrous acid it yields the corresponding *nitrosamine*, golden yellow needles, m.p. 102°, which is converted by alcoholic hydrochloric acid into p-*tolyl*-4-*nitroso-α-naphthylamine*, crimson needles, m.p. 161°, reacting with *p*-nitrobenzoyl cyanide to form p-*tolylamino-α-naphthyl*-4-*cyanoazomethine*-p-*nitrophenyl*, lustrous violet scales, m.p. 218°.

A tolylated *Nile Blue* (tolylaminonaphthodimethylaminophenoxazonium chloride) is obtained by warming *p*-tolyl-*α*-naphthylamine with nitrosodimethyl-*m*-aminophenol in glacial acetic acid, or by heating Meldola's Blue with *p*-toluidine. If nitrosodiethyl-*m*-aminophenol is used, an analogous dyestuff—*Ethyl Nile Blue*—is formed (Gnehm & Rübel, J. pr. Chem. 1901, [ii.] 64, 497).

Tolyl sulphocarbazole, pale yellow needles, m.p. 127°–128°, is prepared from potassium carbazole and *p*-toluene sulphonyl chloride. It combines with *p*-nitrosophenol, yielding a dark blue powder which on reduction forms a greyish-white leuco compound (D. R. P. 224951).

m-*Tolylenediamine-carbamide* prepared by passing phosgene gas into a solution of *m*-tolylene-diamine and sodium acetate, is a white crystalline powder, m.p. above 300°, insoluble in ordinary solvents (D. R. P. 146914).

Tolylene dicarbamide when fused with sulphur at 200°–230° yields an orange dye (D. R. P. 153916).

m-*Tolyl semicarbazide* (*maretin*) may be obtained by treating *m*-tolyl hydrazine with cyanic acid or its salts or with urea, carbamic chloride or urethanes and by other methods (U. S. Pat. 765164, 1904; Eng. Pat. 7954, 12440, 18825, 1904; Fr. Pat. 349968, 1904; D. R. P. 157572; 160471, 162630, 163035, 163036). It forms colourless crystals, m.p. 183°–184°, soluble in hot water and alcohol and is said to possess antipyretic properties.

For *tolylcarbinol* and some of its derivatives *v.* Tiffeneau & Delange, Compt. rend. 1903, 137, 573; Fournier, *ibid.* 716; Perkin & Pickles, Chem. Soc. Trans. 1905, 652; D. R. P. 154658.

p-*Tolyl arsonic acid* $MeC_6H_4{\cdot}AsO(OH)_2$ is prepared by passing a rapid stream of chlorine through aqueous *p*-tolyl arsenious chloride $C_7H_7AsCl_2$ (Martindale, J. Soc. Chem. Ind. 1909, 910). The tolyl radicle enters into the composition of a large number of other substances (*v.* AZINES and AZO- COMPOUNDS).

Toluic acids are formed by oxidation of the corresponding xylenes with dilute nitric acid and also by other methods (D. R. P. 79028; Scholl and Nörr, Ber. 1900, 33, 1055).

The *o*-acid has m.p. 103·5°–104° and condenses with tertiary aromatic amines forming dyestuffs of the malachite green series (D. R. P. 101426).

The *p*-acid has m.p. 180°, b.p. 264°, and condenses with tetramethyldiaminobenzhydrol forming a triphenylmethane dyestuff (D. R. P. 90881). The *m*-acid has m.p. 108°–109°.

When sulphur monochloride reacts with silver *o*-, *m*-, or *p*-toluate, the *o*-, *m*-, or *p*-compound $(C_6H_4Me{\cdot}CO_2S)_2$ is formed. These compounds decompose gradually on standing and more quickly when heated, forming sulphur, sulphur dioxide, and the corresponding toluic anhydride (Denham, Chem. Soc. Trans. 1909, 1239).

For other information on the toluic acids and their derivatives see: J. Soc. Chem. Ind. 1895, 800; Labhardt, Zeitsch. Elektrochem. 1902, 8, 93; Fischer and Wolffenstein, Ber. 1904, 37, 3215; Langguth, *ibid.* 1905, 35, 2062; Jürgens, *ibid.* 1907, 40, 4409; Müller, *ibid.* 1909, 42, 423; Errera and Maltese, Gazz. chim. ital. 1905, 35, ii. 370; Puxeddu and Maccioni, *ibid.* 1907, 37, i. 68; Anschütz, Annalen, 1906, 346, 341, 349, 354; Freundler and Sevestre, Compt. rend. 1908, 147, 981; Sudborough and Roberts, Chem. Soc. Trans. 1904, 241; Crossley, *ibid.* 281; Kay and Perkin, *ibid.* 1905, 1071; Perkin and Tattersall, *ibid.* 1090; Robertson, *ibid.* 1908, 789; Cohen and Dudley, *ibid.* 1910, 1749; Baudisch and Perkin, *ibid.* 1909, 1870, 1883; Meldrum and Perkin, *ibid.* 1889; Bogert and Kropff, J. Amer. Chem. Soc. 1909, 31, 841; Wheeler and Hoffmann, Amer. Chem. J. 1910, 44, 113).

ψ-*m-Toluic acid* (Δ^{a} *δ-Heptadi-inene-δ-carboxylic acid*) $(C{:}HC{\cdot}CH_2)_2{\cdot}CH{\cdot}CO_2H$, m.p. 47°, is readily soluble in most organic solvents, but sparingly soluble in water. When boiled with water or acid it is readily converted to *m*-toluic acid. With ammoniacal cuprous chloride, it yields the yellow copper derivative (Perkin and Simonsen, Chem. Soc. Trans. 1907, 840).

Tolualdehydes or *toluic aldehydes* may be prepared by the oxidation of the corresponding xylenes or their derivatives (Moritz and Wolffenstein, Ber. 1899, 32, 2531; Sommer, *ibid.* 1900, 33, 1078; Fournier, Compt. rend. 1901, 133, 635). The *o*-aldehyde has b.p. 200°.

When *m*-tolualdehyde, b.p. 199°, is run into 10 times its weight of fuming sulphuric acid at about 0·5° and the mixture agitated until it is completely soluble in water, m-*tolualdehyde-*o-*sulphonic acid* is formed which is separated by pouring the mixture on ice and neutralising it with barium carbonate. The sulphonic acid yields, with aromatic amines, dyestuffs fast to alkalis (Fr. Pat. 311739 of 1901).

The *p*-aldehyde may be prepared by passing a stream of carbon monoxide and hydrogen chloride into toluene containing aluminium chloride (D. R. P. 98706; Gattermann and Koch, Ber. 1897, 30, 1623). It has b.p. 204°.

p-*Tolualdehyde diacetate* $C_7H_7{\cdot}CH(OAc)_2$ may be formed by the action of acetic anhydride on *p*-tolualdehyde at 150°–180°. It crystallises in colourless glistening leaflets, m.p. 69°, soluble in alcohol and forming a leuco malachite-green when heated with dimethyl aniline and zinc chloride (Claussner, Ber. 1905, 38, 2860).

For additional information on the aldehydes and their derivatives see: Auwers and Keil, Ber. 1905, 38, 1693; Rorive and Tollens, *ibid.* 1907, 40, 3107; Francis, *ibid.* 1909, 42, 2216; Gattermann, Annalen, 1906, 347, 347; Law, Chem. Soc. Trans. 1907, 748; Mascarelli and Russi, Atti. R. Accad. Lincei, 1910, [v.] 19, ii. 239.

TOLUHYDROQUINONE *v.* PHENOL AND ITS HOMOLOGUES.

TOLUIDINES $CH_3{\cdot}C_6H_4{\cdot}NH_2$ are prepared by the reduction of nitrotoluenes in the same way as aniline is obtained from nitro-benzene (*v.* ANILINE; D. R. P. 139457, 144809). The *o*-, *m*- and *p*- isomerides may be separated from one another by a variety of processes. The crude product which consists of about 35 p.c. *para*-, 63 p.c. *ortho*-, and 2 p.c. *meta*- toluidines may be strongly cooled, and the *p*- compound separated by filtration under pressure, or the mixture may be distilled fractionally, or treated with disodium phosphate with which the *p*-toluidine forms an insoluble compound; or it may be treated with hydrochloric and oxalic acids and heated to boiling, the sparingly soluble *p*-toluidine oxalate separates whilst *o*-toluidine hydrochloride remains in solution. But, according to Friswell, the quickest and cheapest method is to separate them by freezing in the presence of water or, better, ice. Under these conditions, the *p*-toluidine forms a hydrate (Walker and Beveridge, Chem. Soc. Trans. 1907, 1797), which can be readily separated from the other isomerides and from which pure *p*-toluidine can be prepared. A full description and figure of the apparatus employed in this process is given in the J. Soc. Chem. Ind. 1906, 258.

The separation of aniline and toluidine is based partly on the different strengths of the bases and partly on the difference in the solubility of their acetyl compounds.

Another method depends on the fact that only those amines in which the para- position is unoccupied can be converted into amino-azo compounds. The mixture is therefore treated with hydrochloric acid and sodium nitrite and the unchanged *p*-toluidine is then distilled off with steam. The successful sulphonation of the amines and also the formation of an additive compound with formaldehyde in the presence of hydrochloric acid also depend on the *p*-position being unoccupied, and these facts can be taken advantage of in the separation of *p*-toluidine (D. R. P. 40424; 37932; 87615; 59775; Lewy, Ber. 1886, 19, 1717, 2728; Wülfing, *ibid.* 2132; Heusserman, Frdl. i. 16; *see* also Schaposchnikoff, J. Russ. Phys. Chem. Soc. 1903, 35, 72; Oglobin, *ibid.* 1904, 36, 680).

p-Toluidine may be detected in the presence of aniline and *o*-toluidine by adding a few drops of ferric chloride to a hydrochloric acid solution of the mixture. If the *p*-compound only is present a Bordeaux red solution is formed. If *o*-toluidine and aniline are present then a greenish-blue precipitate is formed which on filtration gives a red filtrate (Biehringer and Busch, Chem. Zeit. 1902, 26, 1128). Small quantities of *o*- and *p*-toluidines may be estimated by converting them into the dibromoderivatives (Dobriner and Schranz, Zeitsch. anal. Chem. 34, 734). Or the proportion of the *p*- in the *o*-compound may be determined by finding the sp.gr. of the mixture (Lange, *ibid.* 24, 459) or by converting them into their acetyl derivatives and determining the solidification point of the mixture (Holleman, Rec. trav. chim. 1908, 27, 458; Proc. K. Akad. Wentensch, Amsterdam, 1904, 7, 395). For other methods, *see* Häussermann (Zeitsch. anal. Chem. 26, 750); Reinhardt (*ibid.* 33, 90); Raabe (Chem. Zeit. 1891, 15, 116, 179). For the detection and estimation of moisture, *see* Reinhardt, *l.c.*; Dobriner and Schranz, *l.c.*

o-**Toluidine** ($CH_3{:}NH_2 = 1:2$) is a colourless, thick, refractive liquid, with a characteristic odour, and b.p. 199·7°; sp.gr. 1·1012 at 4°/4°, 1·0031 at 15°/15°, 0·997 at 25°/25°, 0·9852 at 50°/50°. When dissolved in sulphuric acid it gives a blue coloration with chromic acid and this on addition of water turns red-violet (Rosenstiehl, Compt. rend. 1868, 67, 398; 1876, 82, 380). A weakly acid solution of *o*-toluidine gives, with a little pure 2 : 5 tolylenediamine and ferric chloride, an intense green coloration. This is a very delicate reaction for *o*-toluidine (Nietzki, Ber. 1877, 10, 1157). When passed through a red-hot tube, *o*-toluidine decomposes into iminoditolyl, ammonia and hydrogen (Seyberth, Ber. 1896, 29, 2594), whilst under the influence of the electric discharge, it gives off little ammonia, but forms a strongly basic polyamine (Berthelot, Compt. rend. 1898, 126, 780). In alkaline solution, it is oxidised with production of an azotoluene, oxalic acid and ammonia, whilst in acid solution it gives rise to quinone derivatives. Azo derivatives are also obtained when it is treated with nitric acid (Nietzki, *l.c.* 662; Ullmann and Forgan, Ber. 1901, 34, 3805; *see* also Bradshaw, Amer. Chem. J. 1906, 35, 326). Its hydrochloride when electrolysed or when treated with potassium dichromate yields dyestuffs (Goppelsroeder, Dingl. poly. J. 1877, 223, 347, 634; Coninck, Compt. rend. 1898, 127, 1221).

o-Toluidine, printed on the fibre, can be oxidised to a moderately permanent dark violet dye by means of sodium chlorate and potassium ferrocyanide; *m*-toluidine is so oxidised to a blackish-violet and *p*-toluidine to a chestnut-brown colour (Kirpitschnikoff, Zeitsch. Farb. Text. Ind. 1905, 4, 233).

o-Toluidine gives precipitates with the salts of the rare metals (Jefferson, J. Amer. Chem. Soc. 1902, 24, 540) and a violet colouring matter with thallium chloride (Renz, Ber. 1902, 35, 2768). It gives a calcium salt $(NHC_7H_7)_2Ca$ (Erdmann and Smissen, Annalen, 1908, 361, 52). When treated with hydrogen in presence of reduced nickel, *o*-toluidine yields methyl *cyclo*hexylamine (Sabatier and Senderens, Bull. Soc. chim. 1904, 31, 769).

o-Toluidine also reacts with diazo compounds (Mehner, J. pr. Chem. 1902, 65, 401); with methylene iodide (Senier and Godwin, Chem. Soc. Trans. 1902, 280); with phenyl urethane (Dixon, *ibid.* 1901, 102); and with phosphoryl trithiocyanate (*ibid.* 541).

When a mixture of *o*-toluidine and *p*-aminophenol in sulphuric acid is oxidised with sodium dichromate, a colouring matter is formed which, with sodium sulphide, yields the leuco base of p-*aminotolyl*-p-*hydroxyphenylamine*

$$NH_2{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_6H_4{\cdot}OH,$$

m.p. 159°–160° (Gnehm, J. pr. Chem. 1904, [ii.] 69, 161).

o-Toluidine also condenses with a number of aldehydes (Eibner and Peltzer, Ber. 1900, 33, 3460; Fosse, Bull. Soc. chim. 1901, 25, 375; Etard, *ibid.* 1883, 39, 530; Pictet, Ber. 1886, 19, 1063; Sachs and Kempf, Ber. 1902, 35, 2704; Cohn and Blau, Monatsh. 1904, 25, 365; Walther and Raetze, J. pr. Chem. 1902, 65, 258) and forms compounds with the halogen acids and with sulphuric, nitric, phosphoric and phosphorous acids (Ullmann, Ber. 1898, 31, 1699; Städl. Ber. 1883, 16, 28; Wellington and Tollens, *ibid.* 1885, 18, 3313; Lewy, *l.c.*; Hitzel, Bull. Soc. chim. 1894, [iii.] 11, 1054; Lemoult, Compt. rend. 1906, 142, 1193).

o-Toluidine itself and its halogen acid compounds form addition products with metallic halides, sulphates, sulphites and nitrates (Tombeck, Compt. rend. 1897, 124, 963, 1532; Ann. Chim. Phys. 1900, [vii.] 21, 397; Hauser and Vanino, Ber. 1900, 33, 2271; Higbee, Amer. Chem. J. 1900, 23, 150; Stagle, *ibid.* 1898, 20, 640; Base, *ibid.* 653; Swan, *ibid.* 622; Prokojeff, Chem. Zentr. 1897, i. 1028).

It also forms a chloracetate

$$C_7H_9N{\cdot}CH_2Cl{\cdot}CO_2H$$

m.p. 95° (Bischoff, Ber. 1888, 21, 1260); a *benzene sulphonate* $C_7H_9N{\cdot}C_6H_6SO_3$, m.p. 137° (Norton and Westenhoff, Amer. Chem. J. 1888, 10, 135); a p-*toluenesulphonate*, m.p. 180° (Norten and Otten, *ibid.* 144); a *toluene sulphinate* $C_7H_9N{\cdot}C_7H_8SO_2$, m.p. 124° (Hälssig, J. pr. Chem. [ii.] 56, 217); a *trichlorosuccinate* $(C_7H_9N)_2,C_4H_3Cl_3O_4,C_2H_5OH$ which decomposes on heating (Van der Riet, Annalen, 1894, 280, 232); an amidosulphonate $C_7H_9N{\cdot}SO_3H(NH_2)$

m.p. 131° (Paal and Jänicke, Ber. 1895, 28, 3162) and an *ethyl nitrosocyanacetate*

$$2(CN{\cdot}C(CO_2C_2H_5):NOH),C_7H_9N,$$

m.p. 85°–95° (Muller, Ann. Chim. Phys. 1894, [vii.] 1, 516).

m-**Toluidine** ($CH_3:NH_2 = 1:3$) is employed technically only to a limited extent in the production of dyestuffs (D. R. P. 93499, 219210; Monnet, Reverdin and Nölting, Ber. 1879, 12, 445; Rosenthiel and Gerber, Compt. rend. 1882, 95, 238).

It is a colourless oil, b.p. 203·3° (Kahlbaum, Zeitsch. Physikal. Chem. 1898, 26, 621, 648); sp.gr. 1·0041 at 4°/4°; 0·9961 at 15°/15°, 0·990 at 25°/25°. It becomes brown and resinous on standing and closely resembles the *o*-compound in most of its properties, but may be distinguished from the latter by its acetyl derivative, which has m.p. 65·5° (the *o*-acetyl derivative has m.p. 110°). It is also less poisonous to the animal organism than *o*-toluidine (Gibbs and Hare, Amer. Chem. J. 12, 365; Wertheimer and Meyer, Ber. 1891, 24, ref. 162). It may be detected and also estimated by converting it into its dimethyl derivative, which, unlike the corresponding *o*- and *p*- compounds, readily yields a nitroso derivative as a yellow crystalline precipitate, when treated with hydrochloric acid and sodium nitrite (Wurster and Riedel, Ber. 1879, 12, 1796).

m-Toluidine combines with methylene iodide (Senier and Godwin, *l.c.*); with diazo compounds (Mehner, *l.c.*); with chloracetyl urethane (Frerichs and Breustedt, J. pr. Chem. 1902, [ii.] 66, 231); with diphenyl thiocarbamide giving diphenyl-*m*-tolyl guanidine (Alway and Vail, Amer. Chem. J. 1902, 28, 294); with benzylidene acetyl acetone (Ruhemann and Watson, Chem. Soc. Trans. 1904, 1170); and with the cyanhydrin of benzaldehyde forming *a-cyanobenzyltoluidine*, m.p. 97° (Sachs and Goldman, Ber. 1902, 35, 3319).

m-Toluidine behaves like the *o*- compound on oxidation, on hydrogenation, and under the influence of an electric discharge, and it also yields similar addition compounds with acids and with metallic halides (Kraut, Annalen, 1881, 210, 323; Higbee, Chem. Zentr. 1900, i. 720; Slagle, *ibid.* 1898, ii. 1044; Base, *ibid.* 1045).

p-**Toluidine** ($CH_3:NH_2 = 1:4$) was the first of the 3 isomerides known and was at one time termed simply *toluidine* (Muspratt and Hofmann, Annalen, 1845, 54, 1); for various methods of preparation *see* D. R. P. 34234, 83544; Frdl. i. 15; *ibid.* iv. 52, 66. It forms leaflets, m.p. 45°, b.p. 200·4° (Hulett, Zeitsch. physikal. Chem. 1899, 28, 651, 657). When exposed to the air it gradually turns yellow, then brown. It has a burning taste, smells something like aniline, and has a similar physiological action to the other two isomerides, but is not so poisonous as the *o*-compound (Gibbs and Hare, *l.c.*; Wertheimer and Meyer, *l.c.*; Bokornoy, Zeitsch. angew. Chem. 1897, 10, 338; Hildebrandt, Hofmeister's Beitragen Chem. Physiol. and Path. 1903, 3, 372; *ibid.* 1905, 7, 433).

p-Toluidine acts as a very weak base (Walker, Zeitsch. physikal. Chem. 1890, 5, 195; Bredig, *ibid.* 1894, 13, 323; Lowenherz, *ibid.* 1898, 25, 394).

By the action of potassium dichromate on -toluidine sulphate, Perkin (in 1880) obtained two oxidation products $C_{21}H_{21}N_3$ and $C_{28}H_{27}N_5$. Oxidation with lead peroxide leads to one or other oxidation product, depending on the conditions of the experiment. In very dilute solutions the substance with fewer carbon atoms is formed, whilst in concentrated solution the compound of higher molecular weight is obtained (Börnstein, Ber. 1901, 34, 1274).

When treated in sulphuric acid solution with potassium permanganate, *p*-toluidine yields nitroso toluene (Bamberger and Tschirner, Ber. 1898, 31, 1524); whilst with chloroform and calcium chloride, azotoluene is formed (Meigen and Normann, *ibid.* 1900, 33, 2711): the latter is also formed when *p*-toluidine is oxidised with ozone, hydrogen peroxide, or potassium dichromate under certain conditions (Bamberger and Tschirner, *ibid.* 1899, 32, 1677; Otto, Ann. Chim. Phys. 1898, [vii.] 13, 142).

Heated with *aqua regia* it yields chlorotoluene; with hydrogen iodide, it gives toluene. When *p*-toluidine is heated with a *meta*- derivative of nitrobenzene, in the presence of hydrochloric acid, it yields dyestuffs of the chrysaniline series (D. R. PP. 65985, 78377, 79263, 79585, 79877, 81048).

Two parts of *p*-toluidine heated with 1–2 parts of sulphur at 180°, gives rise to the primuline bases (Green, Ber. 1889, 22, 968; Jacobson, *ibid.* 330; Gattermann, *ibid.* 422; Gattermann and Pfitzinger, *ibid.* 1063). Heated with ethyl alcohol and zinc chloride it forms 4-amino-1-methyl-3-ethylbenzene (Willgerodt and Brandt, J. pr. Chem. 1904, [ii.] 69, 433).

p- and *o*-Toluidines condense with bromo and with sulphonated methylamino-anthraquinones forming blue and green dyes (D. R. P. 159129; Wacker, Ber. 1902, 35, 2593; Friedlander and Schick, Zeitsch. Farb. Text. Ind. 1904, 3, 218; see also D. R. PP. 149780, 148767, 153517, 174131).

p-Toluidine also condenses with diazo-compounds (Mehner, *l.c.*); with phenylurethane (Dixon, *l.c.*); with methylene iodide (Senier and Goodwin, *l.c.*); with acetylene tetrabromide (Sabanéeff and Rakovsky, J. Russ. Phys. Chem. Soc. 1902, 34, 408); with phenyl isocyanate (Walther and Stenz, Bull. Soc. chim. 1901, 26, 395); and with epichlorhydrin (Cohn and Friedlander, Ber. 1904, 37, 3034). An additive compound of *p*-toluidine and trinitrotoluene; forms dark red crystals, m.p. 68° (Jackson and Clarke, Chem. Soc. Proc. 1906, 84).

When *p*-toluidine is heated on the water-bath with dichloraceto-*p*-toluidide, *p-methylisatin*-p-*tolylimide* is formed; the action of *p*-toluidine on similar di- and trichloraceto compounds is described by Heller (Annalen, 1904, 332, 247).

When *p*- or *o*- toluidine is diazotised in sulphuric acid solution, then saturated with sulphur dioxide, treated with copper, filtered and washed with ammonia, and the washings and filtrate treated with ferric chloride, the corresponding *ferric toluene sulphonate*

$$Fe(C_6H_4Me{\cdot}SO_2)_3$$

is formed from which the free acid may be readily obtained (Thomas, Chem. Soc. Trans. 1909, 343).

Like the *o*- and the *m*- isomerides, *p*-toluidine forms compounds with the halogen and other inorganic and organic acids, and also double salts with a number of metallic chlorides, and with other salts of both organic and inorganic acids. It yields a calcium salt similar to the *o*- compound (Erdmann and Smissen, *l.c.*).

p-Toluidine condenses with aromatic aldehydes in the presence of its hydrochloride, forming acridines (Ullmann, Ber. 1903, 35, 107); with benzylidene acetone it forms β-tolylaminobenzylacetyl acetone, m.p. 96° (Ruhemann and Watson, Chem. Soc. Trans. 1904, 1170).

For other condensation products of *p*-toluidine with aldehydes, *see* Eibner and Amann, Annalen, 1903, 329, 211; Friedländer, Ber. 1892, 25, 2049; Eibner and Parucker, *ibid.* 1900, 33, 3662; Hantzsch and Schwab, *ibid.* 1901, 34, 822, 841; Cohn and Friedländer, *ibid.* 1902, 35, 1265; Cohn and Blau, Monatsh. 1904, 25, 365; amongst others.

Halogen derivatives of o-*toluidine*. When *o*-toluidine is chlorinated in an excess of 98 p.c. sulphuric acid, a monochlorotoluidine, m.p. 119°–120°, of unknown constitution is formed (Hafner, Ber. 1889, 22, 2535, 2538). In general, the substituted halogen derivatives, of which a very large number are known, may be obtained by the reduction of the corresponding halogen nitrotoluene, as well as by various other methods (Reverdin and Crépieux, Ber. 1900, 33, 2505; Elbs and Silbermann, Zeitsch. Elektrochem. 1900–1901, 7, 590; Cohen and Dakin, Chem. Soc. Trans. 1901, 1127; Nölting, Ber. 1904, 37, 1019).

4-Chloro-2-toluidine has m.p. 21°–22°, b.p. 237°/22 mm. (Goldschmidt and Hönig, *ibid.* 1886, 19, 2441; Cohn, Monatsh. 1901, 22, 473).

5-Chloro-2-toluidine forms lustrous white crystals, m.p. 29·5°–30°, b.p. 245°–246·5°/753 mm. (Wynne, Chem. Soc. Trans. 1892, 1042).

6-Chloro-2-toluidine, colourless oil, b.p. 242°–244°, which rapidly turns brown on exposure to air (Cohn, *l.c.*; Nölting, *l.c.*).

3 : 5-Dichloro-2-toluidine forms long, colourless crystals, m.p. 53° (Claus and Stapelberg, Annalen, 1893, 274, 292).

4 : 5-Dichloro-2-toluidine forms silky plates, m.p. 100°–101° (Cohen and Dakin, *l.c.*).

3 : 4-Dichloro-2-toluidine is known in the form of its acetyl derivative, which has m.p. 158°–159° (Cohen and Dakin, *l.c.*).

Halogen derivatives of m-*toluidine* may be obtained by the reduction of the corresponding nitrohalogen toluene, or by the chlorination of aceto-*m*-toluidide (Bamberger and Werra, Ber. 1902, 35, 3718; Reverdin and Crépieux, *ibid.* 1900, 33, 2503; Cohen and Dakin, *l.c.*).

2-Chloro-3-toluidine, b.p. 228°–229° (Wynne and Greeves, Chem. Soc. Proc. 1895, 151), is an oil volatile in steam.

4-Chloro-3-toluidine (Claus, J. pr. Chem. 1892, [ii.] 46, 29) forms colourless, thin leaflets, m.p. 32°, b.p. 230°/758 mm.

5-Chloro-3-toluidine has b.p. 242°/730 mm. (Hönig, Ber. 1887, 20, 2419).

6-Chloro-3-toluidine forms colourless, long, lustrous needles, m.p. 83°, b.p. 241°–243° (Reverdin and Crépieux, *l.c.*; Chattaway and Orton, Chem. Soc. Trans. 1901, 461).

2 : 5-Dichloro-3-toluidine, m.p. 69°–70° (Cohen and Dakin, *l.c.* 1330).

2 : 6-Dichloro-3-toluidine, m.p. 59°–60°, and the 4 : 5-*dichloro* compound have been prepared by Cohen and Dakin (*l.c.* 1331, 1346).

4 : 6-Dichloro-3-toluidine, m.p. 85°–87° (Seelig, Annalen, 1887, 237, 163; Cohen and Dakin, *l.c.* 1332, 1348).

5 : 6-Dichloro-3-toluidine has m.p. 88°, b.p. 292° (Wynne and Greeves, *l.c.*).

2 : 4 : 6-Trichloro-3-toluidine forms fine white needles, m.p. 77°–78° (Reverdin and Crépieux, *l.c.*; Cohen and Dakin, *l.c.* 1335).

The *fluorine compound* $CFl_3{\cdot}C_6H_4{\cdot}NH_2$ (Swarts, Bull. Soc. chim. Belg. 1898, [iii.] 35, 388) has been prepared.

Halogen derivatives of p-*toluidine*. When *p*-toluidine is chlorinated in 97 p.c. sulphuric acid, it is partly converted into 3-chloro- (chiefly) and 2-chloro- derivatives. The same products, together with 3 : 5-dichloro-*p*-toluidine are obtained in 40 p.c. sulphuric acid. The latter, together with the 3-chloro- and also higher chlorinated products, are obtained by chlorinating aceto-*p*-toluidide (Hafner, Ber. 1889, 22, 2535; Wroblewsky, Annalen, 1873, 168, 196; Lellman and Klotz, *ibid.* 1885, 231, 308; Zincke, Ber. 1895, 28, 3121). Chlorinated products are also obtained when *p*-toluidine is electrolysed in excess of hydrochloric acid (Elbs and Brunschweiler, J. pr. Chem. 1895, [ii.] 52, 559).

2-Chloro-4-toluidine, m.p. 26°, b.p. 237°–238·5° (Lellmann, Ber. 1884, 17, 534), 245° (Wynne and Greeves, *l.c.*).

3-Chloro-4-toluidine, m.p. 7°, b.p. 223°–224° (Cohen and Dakin, Chem. Soc. Trans. 1902, 1324).

2 : 3-Dichloro-4-toluidine has m.p. 40°–42° (Cohen and Dakin, *ibid.*).

3 : 5-Dichloro-4-toluidine, m.p. 60° (Bamberger, Büsdorf and Szolayski, Ber. 1899, 32, 218; Chattaway and Orton, Chem. Soc. Trans. 1900, 789; Cohen and Dakin, *l.c.*).

2 : 3 : 5-Trichloro-4-toluidine is only known in the form of its acetyl derivative, which has m.p. 179° (Cohen and Dakin, *l.c.*).

Various other chlor-toluidines of unknown constitution have been prepared (Seelig, Annalen, 1887, 237, 141, 163; Wroblewsky, *ibid.* 1873, 168, 213; Schultz, *ibid.* 1877, 187, 278).

Bromo and iodo derivatives, as well as mixed bromo-iodo derivatives of the toluidines, have been prepared (Neville and Winther, Ber. 1881, 14, 419; Glassner, *ibid.* 1875, 8, 561; Michael and Norton, Amer. Chem. J. 1, 263; Wroblewsky, Annalen, 1878, 192, 210, 212; Orton and Reed, Chem. Soc. Trans. 1907, 1570; Wheeler, Amer. Chem. J. 1910, 44, 126; amongst others).

The *nitrotoluidines* are obtained by the nitration of the required toluidine or its acetyl derivatives, or by the reduction of the corresponding dinitrotoluene (Bamberger, Ber. 1894, 27, 586; 1895, 28, 399; 1897, 30, 1259).

3-Nitro-2-toluidine forms yellow crystals, m.p. 97° (Zincke and Schwarz, Annalen, 1899, 307, 44).

4-Nitro-2-toluidine forms light yellow prisms, m.p. 107° (Jäger, Chem. Zentr. 1903, ii. 1051; Willgerodt and Kok, Ber. 1908, 41, 2077).

5-Nitro-2-toluidine, yellow crystals, m.p. 129°–130° (Jäger, *l.c.*; Reverdin and Crépieux, Ber. 1900, 33, 2498).

p-Toluenesulphonyl-5-nitro-*o*-toluidine can be obtained by the action of *p*-toluenesulphonyl chloride on a boiling toluene solution of 5-nitro-*o*-toluidine. On reduction it yields the corresponding *p*-tolylenediamine

$$NH_2{\cdot}C_6H_3Me{\cdot}NH{\cdot}SO_2{\cdot}C_7H_7$$

m.p. 150°, the diazonium chloride of which, when treated with excess of sodium acetate solution, yields *p-toluenesulphonyl-p-aziminotoluene* $C_6H_3MeN_3\cdot SO_2\cdot C_7H_7$, a pale yellow substance which decomposes violently at 156°, and gives a red crystalline compound, m.p. 194°, with β-naphthol in pyridine solution (Morgan and Mickelthwait, Ber. 1906, 39, 2869).

6-Nitro-2-toluidine, long yellow silky needles, m.p. 92° (Nölting, *l.c.* 1018; Green and Lawson, Chem. Soc. Trans. 1891, 1014).

3 : 5-**Dinitro-2-toluidine**, small yellow needles, with a bluish or greenish lustre, m.p. 209°–210° (Hoff, Annalen, 1900, 311, 111).

4 : 6-**Dinitro-2-toluidine** depends for its properties on its mode of preparation (Cohen and Dakin, Chem. Soc. Trans. 1902, 26; Holleman and Boeseken, J. 1897, 1753).

5-Nitroso-2-toluidine $MeC_6H_3(NO)NH_2$ is obtained by melting together nitroso-*o*-cresol (1 part), with ammonium chloride (5 parts), and dry ammonium acetate (15 parts) for ½ hour on the water-bath. It forms green needles with a bluish lustre, m.p. 115°–118° (Mehne, Ber. 1888, 21, 731).

Nitro derivatives of m-*toluidine.* When *m*-toluidine is nitrated with nitric acid in concentrated sulphuric acid, it yields chiefly the 6-nitro-derivative, the 2- and 4- derivatives being obtained as by-products (Noelting and Stoecklin, Ber. 1891, 24, 564; Cohen and Dakin, Chem. Soc. Trans. 1903, 331).

2-Nitro-3-toluidine, m.p. 53°, crystallises in yellow needles (Staedel and Kolb, Annalen, 1890, 259, 216).

4-Nitro-3-toluidine (*ibid.* 224) forms gold-yellow tablets, m.p. 110°–110·5° (Cohen and Dakin, *l.c.*).

5-Nitro-3-toluidine crystallises in garnet or brownish-red needles, m.p. 98°–98·4° (Haibach, J. pr. Chem. 1902, [ii.] 65, 242).

6-Nitro-3-toluidine forms long, fine yellow needles, m.p. 137°–138° (Staedel and Kolb, *l.c.*; Cohen and Dakin, *l.c.*).

4 : 6-**Dinitro-3-toluidine** forms small, hard, golden-yellow crystals, m.p. 193°–195° (Hepp, Annalen, 1883, 215, 368; Staedel and Kolb, *ibid.* 1890, 259, 220; Bentley and Warren, Amer. Chem. J. 1890, 12, 1).

2 : 6-**Dinitro-3-toluidine** forms glistening yellow crystals, m.p. 132·5° (Meisenheimer and Patzig, Ber. 1906, 39, 2533).

2 : 4 : 6-**Trinitro-3-toluidine** forms small brownish-yellow crystals, m.p. 138° (Staedel and Kolb, *l.c.*; Noelting and Salis, Ber. 1882, 15, 1864; Blanksma, Chem. Zentr. 1903, i. 78).

6-Nitroso-3-toluidine $MeC_6H_3(NO)NH_2$ is obtained like the corresponding ortho- compound (Mehne, *l.c.*). It forms beautiful steel-blue needles, m.p. 178°.

Nitro derivatives of p-*toluidine.*

2-Nitro-4-toluidine forms yellow glistening broad needles, m.p. 81·5° (Haibach, J. pr. Chem. 1902, ii. 65, 246; Noelting and Collins, Ber. 1884, 17, 263).

3-Nitro-4-toluidine forms red crystals, m.p. 116°–117° (Jäger, *l.c.*; Noelting and Collins, *l.c.*; Noyes, Amer. Chem. J. 1888, 10, 475).

2 : 6-**Dinitro-4-toluidine**, yellow or red crystals, m.p. 171° (Holleman and Boeseken, Rec. trav. Chim. 1897, 16, 425; Beilstein, Ber. 1880, 13, 242).

3 : 5-**Dinitro-4-toluidine**, yellow needles, m.p. 167°–168° (Bamberger and Voss, Ber. 1897, 30, 1257; Niementowski, *ibid.* 1886, 19, 717).

Other dinitro-*p*-toluidines are described by Riggs (Inauguraldissertation Gottingen, 1883); and by Hepp (Annalen, 1882, 215, 371).

A number of halogen nitrotoluidines are also known (Morgan and Clayton, Chem. Soc. Trans. 1905, 944; Beck, Annalen, 1892, 269, 211; Blanksma, Chem. Zentr. 1903, i. 79; Chem. Weekblad. 1909, 6, 717; Wheeler, Amer. Chem. J. 1910, 44, 126; Wheeler and Liddle, *ibid.* 1909, 42, 441; among others).

Sulphonic acid derivatives. When *o*-toluidine is treated with fuming sulphuric acid, or with an acid sulphate, it is converted into the 3-, 4-, or 5-monosulphonic acid, or by further sulphonation, into the 3 : 5- or 4 : 5-disulphonic acids, the predominating product depending upon the conditions of the experiment (Pechmann, Annalen, 1874, 173, 215; Weckwarth, *ibid.* 172, 194; Claus, *ibid.* 1891, 265, 67; Hasse, *ibid.* 1885, 230, 297; Wynne and Bruce, Chem. Soc. Trans. 1898, 734, 743; D. R. PP. 48583, 74111; Reverdin and Crépieux, Ber. 1901, 34, 2993, 2996). A number of halogen and other derivatives of these acids are known.

Sulphonic acid derivatives of m-*toluidine.* When *m*-toluidine is sulphonated with fuming sulphuric acid, 3-toluidine-2-sulphonic acid, which is decomposed at 275° without melting, and the 2 : 4-disulphonic acid, colourless needles are formed (Lorenz, Annalen, 1874, 172, 185).

The 4-sulphonic acid is obtained by the reduction and subsequent debromination of 2-brom-5-nitrotoluene-4-sulphonic acid, the product then being treated with carbon dioxide. Like the other sulphonic acids it yields metallic salts (Hayduck, Annalen, 1874, 174, 350). Halogen, nitro, and other derivatives of these acids are also known.

A sulphonic acid of the constitution

$$SO_3H\cdot C_7H_6\cdot N:N\cdot C_7H_5(NH_2)_2$$

is formed when sulphur dioxide is passed into the cooled liquid obtained on diazotising *m*-toluidine in sulphuric acid solution. The formation of the yellow potassium or sodium salt of this substance is said to be an extremely good indicator for alkalis. The presence of alkali carbonate in tap water may be recognised by this means. With mineral acids it gives a red colour (Tröger and Hille, J. pr. Chem. 1903, 68, 297; *ibid.* 1905, [ii.] 71, 201, 236).

Sulphonic derivatives of p-*toluidine.* *p*-Toluidine is sulphonated with much greater difficulty than the *o*-isomeride, and requires a much higher temperature and more prolonged action, the actual products obtained depending on the conditions of the experiment (Pechmann, Annalen, 1874, 173, 195; Claus and Immel, *ibid.* 1891, 265, 82; Janovsky and Reimann, Ber. 1888, 21, 1216).

4-Toluidine-2-sulphonic acid gives a number of salts, a diazosulphonamide and many other derivatives (Ascher, Annalen, 1872, 161, 8; Jensen, *ibid.* 1874, 172, 233; Heffter, *ibid.* 1883, 221, 208; D. R. P. 103578).

4-Toluidine-3-sulphonic acid, and the 2 : 5- and 3 : 5-disulphonic acids and their salts and many derivatives, as well as some sulphonic toluidines of unknown constitution, have also been prepared (Sell, Annalen, 1863, 126, 155;

Richter, *ibid.* 1885, 230, 314, 331, and many others).

6-Chloro-*p*-toluidine-3-sulphonic acid gives a sparingly soluble diazo derivative which unites with β-naphthol, forming an azo dye which gives sparingly soluble calcium, barium, aluminium, and lead salts of brilliant scarlet hue, scarcely attacked by acids and alkalis, and very fast to light (D. R. PP. 175378, 175396).

Other derivatives of the sulphonated toluidines may also be employed in the preparation of dyestuffs.

Alkyl toluidines. *o*-, *m*-, and *p*-**Methyl toluidines** $C_7H_7NH{\cdot}CH_3$ may be prepared by methylating the corresponding toluidine with dimethyl sulphate (Ullmann, Annalen, 1903, 327, 104; Gnehm and Blumer, *ibid.* 1898, 304, 90).

Methyl-*o*-toluidine and its nitroso- derivatives, m.p. 151°, have been employed in the manufacture of the safranines and of azine dyestuffs (D. R. PP. 90256, 80758; Frdl. iv. 406, 376; Weinberg, Ber. 1893, 26, 307; Bernthsen, *ibid.* 992).

Ethyl-*o*-toluidine formed by the electrolytic reduction of acetyl-*o*-toluidine (Baillie and Tafel, Ber. 1899, 32, 73; Vorländer, *ibid.* 1901, 34, 1462); it has b.p. 214°–216°/737 mm.

Phenyl-*o*-toluidine, m.p. 41°, b.p. 305°/727 mm. is prepared by heating *o*-toluidine with aniline hydrochloride, *ditolylamine*, b.p. 312°, being formed at the same time (Girard and Willm, Bull. Soc. chim. 1876, [ii.] 25, 248; Merz and Paschkowetzky, J. pr. Chem. 1893, 48, 461).

Dimethyl-*o*-toluidine $C_7H_7N(CH_3)_2$, b.p. 184·8° D^{20}_{4} sp.gr. 0·9286 at 20°/4°, is formed by the distillation of trimethyl toluidine hydroxide (Monnet, Reverdin and Nölting, Ber. 1878, 11, 2279).

Phenyl-*m*-toluidine, b.p. 300°–305°, is obtained by heating strongly a mixture of phenylaminocresol with zinc powder (Zega and Buch, J. pr. Chem. 1886, 33, 542).

Dimethyl-*m*-toluidine may be prepared by the interaction of *m*-toluidine and methyl iodide, b.p. 215° (Wurster and Riedel, Ber. 1879, 12, 1797), 208° (Reinhardt and Stadel, *ibid.* 1883, 16, 31).

A number of azo derivatives of dimethyl-*m*-toluidine have been obtained by dissolving it together with a diazotisable amine in hydrochloric acid, and adding the solution to an alkaline solution of sodium nitrite (Samelson, Ber. 1901, 33, 3479).

Diphenyl-*m*-toluidine, b.p. 69°–70°, may be prepared like the *o*- isomeride by the interaction of the corresponding chlorotoluene with potassium diphenylamine (Heussermann, Ber. 1901, 34, 38).

Ethyl-*p*-toluidine, b.p. 217°, is formed by the action of ethyl iodide on *p*-toluidine (Morley and Abel, Annalen, 1855, 93, 311).

Phenyl-*p*-toluidine, m.p. 87°, b.p. 317°–318°/727 mm., is formed by heating bromobenzene with *p*-toluidine and caustic soda at 360°–380° (Merz and Paschkowetzky, J. pr. Chem. 1893, 48, 455).

Benzyl-*p*-toluidine is formed by the action of *p*-toluidine on nitrosobenzylbenzoylaniline (Sachs and Goldmann, Ber. 1902, 35, 3319).

Di-*p*-tolylamine, m.p. 79°, b.p. 328·5°, is formed by heating *p*-cresol with ammoniacal zinc chloride and ammonium chloride at 330°–340° (Merz and Müller, Ber. 1887, 20, 546; Merz and Paschkowetzky, *l.c.*).

Dimethyl-*p*-toluidine, b.p. 209·5°, sp.gr. 0·9287 at 20°/4°, can be formed by distilling trimethyl-*p*-tolyl ammonium hydroxide (Hübner, Tölle, and Athenstädt, Annalen, 1884, 224, 337; *see* also Clarke, Amer. Chem. J. 1905, 33, 496).

Many other alkyl compounds of the three toluidines are known, and also nitro, halogen, and other derivatives of these substances (Pinnow, Ber. 1895, 28, 3041; Gomberg, *ibid.* 1902, 35, 1822; Wedekind and Oberheide, *ibid.* 1904, 37, 2712, 3894; Simanowsky and Menschutkin, J. Russ. Phys. Chem. Soc. 1903, 35, 204; Friedländer and Cohn, Monatsh. 1902, 23, 543; Ber. 1902, 35, 1265; and many others).

The *toluidides* or *toluides* C_7H_7NHR may be prepared by treating the iodomagnesium derivative of the required toluidine with an ester of the required acid (Bodroux, Bull. Soc. chim. 1905, 33, 831; *see* also Compt. rend. 1905, 141, 195; *ibid.* 1907, 144, 1437). The *p*-toluides have also been prepared by heating the sodium salt of the required acid with *p*-toluidine hydrochloride (Amer. Chem. J. 1903, 29, 511), or by heating the acid and amine in a sealed tube at 160°–190° for 8–12 hours (Robertson, Chem. Soc. Trans. 1908, 1036). A number of *o*-, *m*-, and *p*-toluides of inorganic and organic acids have been prepared by these and other methods (Michaelis, Annalen, 1893, 274, 226; Michaelis and Schulze, Ber. 1894, 27, 2578; *ibid.* 1895, 28, 1243; *ibid.* 1896, 29, 726; Reynolds, Chem. Soc. Trans. 1889, 480; Lander, *ibid.* 1901, 690; Cohen and Dakin, *ibid.* 1903, 331; Wheeler, Amer. Chem. J. 1900, 23, 466; Kuhara and Chikashigé, *ibid.* 1902, 27, 1; Ley, Ber. 1898, 31, 241; Niementowski, *ibid.* 1892, 20, 1887; Ullmann and Uzbachian, *ibid.* 1903, 36, 1797; Lumière and Barbier, Bull. Soc. chim. 1905, 33, 784; Just, Ber. 1886, 19, 983; J. Soc. Chem. Ind. 1891, 1000; Orloff, J. Russ. Phys. Chem. Soc. 1905, 37, 439; Taussig, Monatsh. 1904, 25, 375; D. R. P. 183843, 156177, 157103; Ullmann and Gross, Ber. 1910, 43, 2694, amongst many others).

An iso*succinic*-p-*toluide* having a slight antipyretic and hæmolytic action, has been prepared by Malerba (Chem. Zentr. 1906, ii. 349).

For a number of other complex toluidine compounds, *see* Guerin, Bull. Soc. chim. 1903, [iii.] 29, 1117; Morgan and Clayton, *l.c.*; Schroeter, Ber. 1905, 38, 3181; Willgerodt and Simonis, *ibid.* 1906, 39, 269; Ostromisslensky, *ibid.* 1907, 40, 4972; *ibid.* 1908, 41, 3029; Kunckell, *ibid.* 4111; Robyn, Compt. rend. 1905, 140, 1644; Raper, Thompson and Cohen, Chem. Soc. Trans. 1904, 371; D. R. PP. 145189, 181929.

TOLYPYRIN, TOLYSAL, v. SYNTHETIC DRUGS.

TOMATO, *Solanum Lycopersicum* (Linn.) or *Lycopersicum esculentum vulgare.* A Peruvian plant now largely cultivated in many parts of the world for its fruit, which is esteemed as a vegetable. Several species and many varieties are known, differing greatly in size, shape, and colour of fruit.

König gives as the average composition—

Water	Protein	Fat	Sugar	Other N-free extract	Crude fibre	Ash
93·4	1·0	0·2	3·5	0·5	0·8	0·6

About half the total nitrogen is present as true proteids.

Passerini (Staz. Sper. Agrar. 1891, 18, 545) found the fresh fruit to consist of skin 1·3 p.c., pulp and juice 96·2 p.c., and seeds 2·5 p.c., and the pulp to contain two colouring matters —a yellow amorphous substance and a red crystalline compound—both insoluble in water, but soluble in amyl alcohol or ether, and bleached by chlorine. He attributes the acidity to citric acid, which he estimates as forming about 9 p.c. of the total dry matter of the whole fruit. The ash he found to contain—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
59·5	6·0	1·3	3·1	0·2	12·9	3·5	0·3	19·1

Albahary (Compt. rend. 1907, 145, 131) found in the fresh fruit—

Water	Protein	Fat	Carbo-hydrates	Malic acid	Citric acid	Oxalic acid	Ash
93·5	1·0	0·2	3·6	0·49	0·15	0·001	0·74

Traces of tartaric and succinic acids were also detected.

Stüber (Zeitsch. Nahr. Genussm. 1906, 11, 578) obtained somewhat similar results, but states that citric acid was the chief cause of the acidity (amounting to about 0·5 p.c. citric acid), and that he could not detect malic, tartaric, or succinic acids.

The juice of tomatos was found by Passerini (*l.c.*) to have a sp.gr. 1·01833 at 15°, to contain 2·44 p.c. of dry matter, of which rather more than ⅕ was protein, ⅕ ash, and a little more than half carbohydrates and acids.

Other analyses of the juice were made by Stüber (*l.c.*), who found water 96·1, nitrogen 0·093, ash 0·56, total sugars, after inversion, 2·15, acidity (as citric acid) 0·65 p.c. The red colouring matter of the tomato was investigated by Arnaud (Compt. rend. 1886, 102, 1119), who believed it to be identical with carrotene $C_{40}H_{56}$; Montanari (Chem. Zentr. 1905, i. 544) concluded that it had the composition $C_{52}H_{74}$; Willstätter and Escher (Zeitsch. physiol. Chem. 1910, 64, 47), who name it *lycopene*, find that it has the molecular composition $C_{40}H_{56}$, the same as that which Willstätter and Mieg (Annalen, 1907, 355, 1) have ascribed to carrotene. It, however, differs in its properties from that substance. It crystallises from light petroleum or a mixture of alcohol and carbon disulphide in dark, carmine-red, felted prisms; it melts at 168°–169° (corr.), but is less soluble in ether, alcohol, carbon disulphide, or light petroleum than carrotene. It absorbs oxygen much more readily than does carrotene and forms a di-iodide $C_{40}H_{56}I_2$, a dark green, gelatinous, insoluble substance.

The leaves and stems of tomatos were examined by Passerini (Staz. Sper. Agrar. 1893, 20, 471), who found in the fresh substance—

	Total dry matter	Ash
Stems . .	8·8–9·9	1·6–2·0
Leaves . .	11·6–14·6	1·6–3·2

The ash contained—

	K_2O	Na_2O	CaO	MgO	Fe_2O_3	Mn_3O_4	P_2O_5	SO_3	SiO_2	Cl
Stems	25·0	11·1	32·8	7·9	0·8	—	2·3	4·7	6·0	14·5
Leaves	2·0	1·4	38·1	9·0	0·1	0·05	1·4	12·8	33·8	1·8

Lithium, boron, and copper were also present in the ash of the stems.

Salicylic acid occurs naturally in tomatos, although in very small quantity. Pellet (Ann. Chim. anal. 1907, 12, 10) considers that the presence of 10 mgm. of salicylic acid in 1 kilog. of tomatos should not be regarded as proof of adulteration.

Tomatos are often canned. American analyses (Bull. 28, U. S. Dept. of Agric.) give, as the mean of 19 samples—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
94·0	1·2	0·2	3·5	0·5	0·6

In the ash was included about 0·1 p.c. common salt. Tomatos are largely used in the preparation of sauces and chutneys, in some of which the red colour is enhanced by the addition of eosin (König). H. I.

TONITE v. EXPLOSIVES.

TONKA BEAN. *Tonquin bean* (*Fève tonka*, Fr.; *Tonkabohnen*, Ger.). The seed of the fruit of the leguminous tree *Dipterix odorata* (Willd.) which inhabits Guiana and Venezuela. Each pod contains a single seed, which is about 2 ins. long and ⅓ in. wide. It has a dark-brown colour, is deeply wrinkled externally, and characterised by an agreeable odour and bitter aromatic taste. The tree flourishes in the forests of the Caracas district of Venezuela. The first crop of beans is gathered when the tree is three years old, but a full crop is not obtained until two years later. The fruit bears some resemblance to a small mango, and contains the odorous bean in its centre. The seed of *D. oppositifolia* (Willd.), the so-called English Tonka bean, has similar properties to that of *D. odorata*, but it is smaller and darker in colour.

Besides sugar, gum, malic acid, and woody fibre, tonka bean contains *fixed oil* and about 1·5 p.c. of *coumarin* (Boullay and Boutron-Charlard, J. Pharm. Chim. 11, 480). It is to the presence of coumarin that the odour and taste of the seed are due, and crystals of this compound often occur as an efflorescence on commercial specimens. To extract the coumarin, the finely-chopped beans, according to Gössmann, are heated for some time nearly to boiling with an equal bulk of 80 p.c. alcohol; the whole is then filtered and the residue again heated in the same manner; the extracts are mixed together, and the alcohol removed by distillation until the residue becomes turbid, when it is mixed with four times its volume of water, which precipitates the coumarin in somewhat impure crystals. Adhering fat may be removed by heating the mixture to boiling, and filtering through a moistened filter. On cooling, the crystals which re-dissolve in the hot liquid again separate, and they may be further purified, if necessary, by treatment with animal charcoal (Annalen, 98, 66), *v.* Coumarin.

Tonka bean is used to flavour tobacco, and especially snuff, as an ingredient of sachet powder, and in alcoholic solution as a flavouring essence. A. S.

TOPAZ (*Topas*, Ger.). A gem-stone composed of aluminium fluo-silicate $(AlF)_2SiO_4$ crystallised in the orthorhombic system. As shown by S. L. Penfield and J. C. Minor (Amer. J. Sci. 1894, 47, 387) the fluorine (15·48–20·37 p.c.) is replaced isomorphously by hydroxyl (0·18–2·50 p.c., as shown by analyses), so that the formula becomes $[Al(F,OH)]_2SiO_4$; and, chemically, a fluor-topaz and a hydro-fluor-topaz may be distinguished. Although these two varieties show slight differences in sp.gr. (3·574 in the former. and 3·523 in the latter). and in optical constants, the distinction is of no practical importance. The mineral is very resistant to acids, and water is expelled only at an intense heat. Topaz usually occurs as crystals in granitic and gneissose rocks, and is often associated with tin-ore. An important character is the presence of a perfect cleavage in one direction, perpendicular to the prism. The crystals may be dull and opaque, or more often clear and transparent, and colourless, bluish, greenish, yellow, or pink. The sherry-yellow crystals from Brazil become pink when heated ('burnt topaz'). Most of the gem material comes from Brazil and Russia, but it is also found in many other countries. Colourless topaz, when faceted, is sometimes mistaken for diamond, and much yellow quartz ('Spanish topaz,' 'Scotch topaz,' 'occidental topaz') is passed off as topaz. The more valuable yellow corundum, on the other hand, is known as 'oriental topaz.' The distinguishing characters of these are shown in the following table :—

—	Topaz	Quartz 'Occidental topaz'	Corundum 'Oriental topaz'
Comp.	$(AlF)_2SiO_4$	SiO_2	Al_2O_3
Cryst.	Orthorhombic	Rhombohedral	Rhombohedral
Sp.gr.	3·55	2·65	4·0
H.	8	7	9
Refr. indices	1·61–1·63	1·54–1·55	1·76–1·77

L. J. S.

TOPAZ, ORIENTAL, *v.* Corundum.

TOPAZ, SCOTCH, *v.* Cairngorm.

TOPAZ, SPANISH, *v.* Cairngorm.

TORBANITE or **TORBANEHILL MINERAL** *v.* Paraffin.

TORBERNITE or **CUPRO-URANITE** (*Kupferuranit*, Ger.). A mineral consisting of hydrated phosphate of uranium and copper

$$Cu(UO_2)_2P_2O_8,8H_2O.$$

It crystallises in square (tetragonal) plates, which possess a perfect micaceous cleavage, with pearly lustre, parallel to their surface. The colour is bright grass-green, which distinguishes cupro-uranite at a glance from the closely-allied mineral autunite (*q.v.*) or calco-uranite. Sp.gr. 3·5; H. 2½. It is a mineral of secondary origin, occurring in the upper portions of lodes containing pitchblende and copper ores, and sometimes as an incrustation on the joint faces in granite. Fine specimens have been found at Gunnislake, Grampound Road, and Redruth in Cornwall. Other localities are Joachimsthal in Bohemia, Johanngeorgenstadt in Saxony, Sabugal in Portugal, &c. To a limited extent the mineral has been mined, together with autunite, as a source of uranium and radium. L. J. S.

TORMENTILLA. The underground stems of *Potentilla Tormentilla* (Neck.) have been occasionally substituted for those of rhatany in medicine. They contain from 5 to 6 p.c. of a tannin, giving a dark-green precipitate with ferrous sulphate, bluish-red with ferric acetate; is also precipitated by gelatin and by tartar-emetic (Stenhouse) (*v.* Tannins).

TORREFACTION. Roasting ores in order to expel volatile substances, *e.g.* sulphur, arsenic, &c.

TOULOUCOUNA or **TULUCANA OIL.** An oil obtained by pressing the kernels of *Carapa Guianensis* (Aubl.), *v.* Carapa oil.

TOULOURON OIL. A brown oil obtained from *Pagarus Latro.* Used in Senegal as a remedy for rheumatism.

TOURMALINE (*Turmalin*, Ger.; from the Cingalese *turamali*). A complex boro-silicate of aluminium, together with variable and mutually-replaceable amounts of ferrous oxide, magnesia, and alkalis. As chemical types there may thus be distinguished iron-tourmaline, magnesium-tourmaline, and alkali-tourmaline. Analyses show: SiO_2, 35–38; TiO_2, 0–1; B_2O_3, 9–11; Al_2O_3, 30–42; Cr_2O_3, 0–10 (rarely); Fe_2O_3, 0–6; FeO, 0–17; MnO, 0–2; MgO, 0–14; CaO, 0–2; Na_2O, 0–3; K_2O, 0–2; Li_2O, 0–1·7; H_2O, 1–4; F, 0–1 p.c. Many different formulæ have been suggested. Penfield and Foote (1899) regard the several varieties as salts of the hypothetical alumino-boro-silicic acid

$$H_9Al_3(BOH)_2Si_4O_{19}.$$

With these wide differences in chemical composition, the sp.gr. ranges from 3·0 to 3·2, and the refractive indices (Na) $\epsilon=1·6123–1·6515$, $\omega=1·6315–1·6854$ (E. A. Wülfing, 1900), but there are only very slight variations in the crystallographic constants (this being attributed by Penfield and Foote to the mass effect of the large acid radicle). The crystals are rhombohedral-hemimorphic, there being a different development of faces at the two ends. The habit is almost invariably prismatic, with deeply-grooved prism faces; the cross-section of the prism is triangular with straight or curved outlines. These peculiarities of form render tourmaline a mineral readily recognisable. As a consequence of the hemimorphism the crystals are pyroelectric. The material ranges from colourless to jet-black in colour, and may be any shade of red, yellow, green, or blue. In one and the same crystal there are often striking contrasts in the differently coloured zones. The more darkly coloured crystals are strongly dichroic, the ordinary ray vibrating perpendicular to the principal axis being almost completely absorbed. On this property depends the use in polarising apparatus (*e.g.* the well-known tourmaline-tongs) of tourmaline plates cut parallel to the principal axis of a crystal.

Common black tourmaline (*schorl*) is of abundant occurrence in granitic and metamorphic rocks, and is a frequent associate of tin ores. Coloured tourmalines are much used in jewellery, either as clear faceted stones or, when cloudy, as beads (H. 7½). The red is often called *rubellite*, and the blue *indicolite*, whilst fanciful names such as 'Brazilian emerald,' 'Siberian ruby,' &c., are also sometimes used. Within recent years large quantities of gem material have been quarried from the pegmatites of California and Madagascar. L. J. S.

TOUS-LES-MOIS is a species of arrowroot procured from the tubers of *Canna edulis* (*Ker-Gawl.*) nat. ord. *Marantaceæ*. The starch is obtained in the same manner as other descriptions of arrowroot. Under the microscope the granules show themselves to be unusually large, measuring from 0·0015 to 0·0037 inch in length and from 0·001 to 0·0027 in breadth; broad, flat, ovate. The hilum is situated at the narrow extremity, and the rings are very close, firm, and regular.

Tous-les-mois is used in admixture with cocoa preparations and as a food for infants, for which latter purpose it is bleached. *V.* Starch.

TOXINS and **ANTITOXINS.**

Toxins.

Infective diseases of man and animals, that is diseases which are contagious, infectious, or transmissible by inoculation, are caused by pathogenic (*i.e.* disease-producing) living organisms which are parasitic on or in the individual attacked. The parasitic organisms may be minute vegetable ones, principally bacteria, minute animal protozoa, or higher and larger forms such as moulds, insects, and worms. The bacteria, and presumably also the protozoa, as a rule produce their deleterious effects principally by means of substances which are poisonous to the host, and which are elaborated by, or are derived from, the parasitic organisms. Even the larger parasites, such as worms, though acting mechanically and in other ways, may also elaborate poisonous substances.

In the early days of bacteriology, under the influence of the work of Panum, Selmi, Nencki, and others on the products of putrefaction, attempts were made to isolate from the cultures of the pathogenic organisms and from the tissues of the disease-stricken patients nitrogenous bodies of a basic and alkaloidal nature similar to the ptomaines of putrefaction, and Brieger in particular isolated such substances as typhotoxine from cultures of the typhoid bacillus and tetanine from the tissues of a case of tetanus (*see* art. Ptomaines). It was soon found, however, that such basic substances are not, as a rule, the essential or specific toxic agents of the pathogenic bacteria, and some of those described by Brieger are quite likely artifacts, due to the methods of extraction employed.

The specific toxic agents of the bacteria, or *toxins*, as they may conveniently be termed, are substances of complex composition, which, so far as they have been investigated, seem occasionally to be protein in nature, or to be allied to the proteins or to the enzymes. The whole subject of the nature of toxins is still in a very indeterminate condition, so that any views expressed here must be regarded as tentative. In some instances the toxin appears to be a substance *sui generis*, in others it may be proteose in nature (tox-albumose), and in others it may be albuminous (tox-albumin). The toxin may be an excretory product, as it were, of the micro-organism, *e.g.* tetanus toxin (S. Martin), or may be formed by the action of enzymes, excreted by the micro-organism, on the constituents of the culture medium or of the tissues, *e.g.* anthrax toxin, or it may be a mixture of these two, *e.g.* diphtheria toxin (S. Martin), or it may be a protein or other constituent of the bacterial cells themselves, *e.g.* typhoid toxin. Toxins which are excretory products, or are formed by the action of the organism on the culture medium, are termed exo-toxins or simply toxins, *e.g.* diphtheria, tetanus, and botulismus toxins; those which are intimately associated with the bacterial cells are termed endo-toxins; the toxins of the majority of pathogenic bacteria belong to the latter class. The term toxin has also been extended so as to include various toxic bacterial extracts, such as tuberculin, the toxic proteins, &c., which are found in the higher plants and animals, *e.g.* abrin and ricin of the jequirity and castor-oil beans respectively, substances like eel serum, which is toxic on injection into other animals, and snake venom.

The bacterial exo-toxins may be prepared by cultivating the organisms in a suitable fluid culture medium under appropriate conditions for 1–4 weeks, and then filtering the fluid culture through a Pasteur-Chamberland porcelain, or a Berkefeld, filter. The filtrate is more or less toxic, and may be termed the toxin broth, the actual toxin contained in it may be concentrated in various ways, but extraction in a pure condition is at present impossible, owing to the difficulty of separating it from the constituents of the culture medium. Bacterial endo-toxins may be obtained by growing the organisms on a solid culture medium and extracting the bacterial mass with weak alkalis, &c., or by grinding up the bacterial paste in a mechanical disintegrator, such as Macfayden and Rowland's or Barnard's, and subsequent filtration through a porcelain filter (Proc. Roy. Soc. 1902 and 1911).

The bacterial toxins generally are unstable bodies, disappearing, or being converted into non-toxic modifications, on keeping, and destroyed by light, warming to 60°–70°, by acids, alkalis, and oxidising agents, and by digestive enzymes; owing to the last-named fact, the toxins usually are not toxic when taken by the mouth, but only on inoculation. They are much more stable in the dry condition than when in solution. They are insoluble in, and are precipitated by strong alcohol, and are precipitated on saturation of their solutions with ammonium sulphate. Diphtheria and tetanus toxins dialyse very slightly through parchment, and they will pass through a gelatin-coated porcelain filter, which does not permit of the passage of serum albumin, suggesting that their molecules are smaller than those of the latter (Brodie, Journ. Path. and Bacter. 1897). They are probably lævorotatory. The 'toxin,' in some instances at least, may contain more than one toxic constituent.

Diphtheria toxin was first investigated by Löffler. By precipitating broth cultures of the diphtheria bacillus with alcohol, he obtained a white toxic powder which he classed among the enzymes (Deut. med. Woch. 1890, Nos. 5 and 6). Roux and Yersin, by the cautious addition of calcium chloride, obtained the toxin entangled with the precipitate of calcium phosphate which comes down, and similarly regarded it as an enzyme (Ann. Inst. Pasteur, iii.). Brieger and Fränkel concluded that the toxin is a protein ('tox-albumin'); they found that it is precipitated by ammonium sulphate, but not by magnesium sulphate, contains a relatively high percentage of sulphur and gives the biuret and Millon's reactions (Berl. klin. Woch. 1890, 241, 1133).

Brieger and Fränkel's method of preparing the diphtheria toxin was to saturate broth cultures with magnesium sulphate at 30°, filter from the precipitated globulin, &c., saturate the filtrate with ammonium sulphate at 30°, wash and dissolve the precipitate, dialyse to remove as much adherent salts as possible, and remove remaining traces of ammonium sulphate by the cautious addition of barium chloride; evaporate the filtrate to half the volume *in vacuô* at 40°, and precipitate with absolute alcohol. The precipitate was collected, redissolved, and precipitated with alcohol 6–8 times. Ultimate analysis gave the following figures: C 45·35, H 7·13, N 16·33, S 1·39, O 29·80.

Brieger and Boer subsequently prepared the diphtheria toxin in as pure a form as it has yet been obtained by precipitating broth cultures with a 1 p.c. solution of zinc sulphate or chloride. The precipitate of the zinc double salt is washed with feebly alkaline water and decomposed with carbon dioxide. The purified product gave the xanthoproteic, biuret, Adamkiewicz's, and Millon's reactions. A litre of broth culture gave about 3 grm. of the zinc double compound (Zeitsch. Hygiene, xxii. 267).

Sidney Martin isolated from diphtheritic membrane and from the spleen and other organs of diphtheria cadavers proteoses, chiefly deutero-albumose, and from the membrane alone an organic acid which was not identified. The latter is a yellowish amorphous body, becoming deep brown with alkalis, and is soluble in water and absolute alcohol, but not in ether, chloroform, or benzene. The proteoses were extracted by placing the minced tissues in absolute alcohol until the ordinary proteins were coagulated and rendered insoluble, extracting with water, and precipitating this extract with alcohol many times. Similar proteoses were obtained from cultures in alkali-albumin of the diphtheria bacillus (Brit. Med. Jour. 1892, i.).

Ehrlich concluded that the diphtheria 'toxin' contains two or more toxic constituents, as well as non-toxic bodies, 'toxoids,' derivatives, or degradation-products, of the toxin (*v. infra*, under *Antitoxins*).

Tetanus toxin was obtained in a somewhat concentrated form by Kitasato from anaërobic broth cultures of the tetanus bacillus (which produces lock-jaw), and he gave a detailed account of the action of heat and of a number of chemical reagents on the toxin broth (Zeitsch. Hygiene, x. 267). Brieger and Cohn precipitated veal-broth cultures by saturation with ammonium sulphate (*ibid.* xv. 1). The toxin formed a flocculent precipitate which floated; it was purified by redissolving, precipitating the protein with basic lead acetate, removing other soluble impurities by dialysis, and finally precipitating the dialysed solution with alcohol. Thus prepared, the tetanus toxin formed pale yellow, odourless, easily soluble scales, having a gummy taste. The solution was feebly lævorotatory. It contained only a trace of ash, but did not give the Millon's and xanthoproteic reactions, and gave no precipitate with potassium ferrocyanide and acetic acid, nitric acid, or mercuric chloride. Boiled with ferric chloride it gave no red colour. With copper sulphate and sodium hydroxide it gave a slight violet colour. It contained no phosphorus and only a trace of sulphur, and ultimate analysis gave the following figures: C 52·08, H 8·1, N 15·71 (Brieger, Zeitsch. Hygiene, xix. 101). Subsequently, Brieger and Boer obtained the toxin by the method employed by them for isolating the diphtheria toxin (*vide ante*). On these facts Brieger considered that the tetanus toxin is not a true protein.

Hayashi, however, employing the Brieger-Boer method, or a modification of it, came to the conclusion that the tetanus toxin is a protein, and is a primary proteose (Arch. f. exper. Pathol. xlvii. 9). S. Martin also isolated proteoses, chiefly deutero-albumose, from the spleen of a cadaver, but they did not induce tetanic convulsions on inoculation. Tetanus cultures contain methyl-mercaptan and other sulphur compounds (Nencki, Monatsh. x.); but Fermi and Pernossi were unable to extract any basic substance from them (Zeitsch. Hygiene, xvi. 385). Besides the convulsive constituent, 'tetano-spasmin,' the toxin broth also contains a substance, 'tetano-lysin,' which is a solvent for red-blood corpuscles. The purified tetanus toxin is probably the most toxic substance known, less than 0·5 mgrm. being a fatal dose for a man.

Anthrax toxin. Hankin obtained proteoses from cultures of the anthrax bacillus, and Brieger and Fränkel a tox-albumin from animals dead of anthrax. Marmier, by precipitating cultures with ammonium sulphate, isolated a toxic substance which he considered to be neither protein nor basic (Ann. Inst. Pasteur. ix. 533). S. Martin (*l.c.*) obtained both from cultures in alkali albumin, and from animals dead of anthrax, proteoses, chiefly deutero-albumose, and a nitrogenous basic substance, both of which were toxic. The toxins are formed mainly by the action on the culture medium of enzymes excreted by the bacillus. Endo-toxins may also be formed.

The toxins of the majority of other pathogenic bacteria are endo-toxins. That is to say, if the organisms be grown in a fluid medium, the filtrate is almost non-toxic, but the dead and disintegrated bacterial cells yield toxic substances. Toxins of protozoan organisms are not known with certainty.

Tuberculin. The original or *old* tuberculin of Koch is obtained by boiling, concentrating over a water-bath and filtering glycerin broth cultures of the tubercle bacillus. It is toxic to healthy animals only in large doses, but minute doses cause considerable disturbance in tuberculous patients and animals, and this reaction is made use of for the detection of tuberculous infection. It contains small quantities of proteoses, extractives, and salts, and traces of basic bodies. Small quantities of an acid substance, probably teraconic acid, possibly derived from the bacillar cells, are also present in cultures of the tubercle bacillus. Other tuberculins and bacterial extracts have been prepared.

It must be clearly recognised that in those cases in which the toxin is supposed to be a proteose or other protein, the latter may be merely constituents of the culture medium by which the toxin is entangled or adsorbed.

[On toxins, &c., *see* Oppenheimer in Kolle and Wassermann's Handbuch der Pathogenen Mikroorganismen, vol. i. (Bibliog.); Vaughan and Novy, Cellular Toxins, 1902 (Bibliog.); S. Martin, Man. of Gen. Pathology, 1904, and Reps. Med. Off. Loc. Gov. Bd. 1889–1900; also various papers in the Ann. Inst. Pasteur; Zeitsch. Hygiene, Centr. Bakteriol. Abstracts also in chemical journals.]

Snake venom. Poisonous snakes are divided into two groups, the colubrine and viperine. The venom, which is secreted by glands in connection with the mouth, may be limpid or syrupy, pale yellow, orange or greenish in colour, odourless and tasteless, sp.gr. 1·04 (rattlesnake), 1·11 (cobra), 1·08 (Russell's viper). Microscopically, it contains few elements, and when dry resembles dry albumin. The reaction of the pure venom is acid; it contains C, H, O, N, and S in the proportions found in proteins, gives the protein reactions, is precipitated with alcohol, ammonium sulphate, sodium chloride, and coagulates on heating. Viperine venoms lose their toxicity on heating to 80°–85°, but colubrine venoms require to be heated to 120° to destroy their toxicity. The active toxic substances of venom are coagulable protems (globulin), proteoses, toxins allied to bacterial toxins, and Faust has separated a non-nitrogenous toxic substance, *ophiotoxin*. The proteoses are chiefly proto- and hetero-proteose. The venoms are complex mixtures containing some, but not in any venom all, of the following active substances: 1. *Neurotoxins* acting on (*a*) respiration, (*b*) heart, (*c*) muscle, particularly the diaphragm; 2. *Cytolysins*, solvents for (*a*) blood corpuscles, (*b*) vascular endothelium, (*c*) other cells; 3. *Fibrin ferment* inducing blood-clotting, and others. The venoms thus produce paralysis of voluntary muscles and of the heart and respiration, solution of the red- and white-blood corpuscles and hæmorrhages, and the blood may be either fluid or coagulated in the vessels, and the bodies of the dead putrefy rapidly owing to the destruction of the anti-bacterial properties of the blood. The venom is most active when injected into a blood-vessel, whereas in the subcutaneous tissues it may take some time to act: it is also readily absorbed from the eye. Taken by the mouth, provided there are no cracks or abrasions, colubrine venom is harmless, but viperine venom may cause gastritis, &c., and even death. The hæmolysins which cause solution of the red-corpuscles are of the nature of 'amboceptors,' requiring a 'complement' (*v. infra* under *Bactericidal sera*) to activate them. In some cases the venom alone can hæmolyse *washed* red-corpuscles *in vitro*, *e.g.* man, dog, &c., in others it has no action on *washed* corpuscles but becomes active on the addition of serum. Some corpuscles, therefore, ontain the activating 'complement,' others do ot, and, hence, are not hæmolysed when washed. Kyes, Sachs, Flexner, and Noguchi have shown that lecithin and lecithides in the corpuscles are the complement-like activators of the hæmolytic amboceptors. A venom which is inactive on washed corpuscles becomes active on the addition of lecithin or even of oleic acid or other fatty acids and soaps.

By the cautious treatment of an animal with increasing doses of venom an antitoxin ('antivenin') is formed which has the power of neutralising the particular venom.

The venom of scorpions (against which an antitoxin can be prepared) and spiders is probably protein in nature; of mosquitos and gnats it may be the products of certain bacteria or moulds present in the œsophageal sacs; of bees a protein-free organic base. The formic acid present in the 'venom' of ants, bees, &c., is probably not the active toxin. Many fish are also poisonous by their bites or by spines connected with special glands. Toads and salamanders have acid and basic poisons in the skin glands. Jelly-fish and sea-anemones have stinging glands. Extracts of intestinal worms may be toxic.

[On snake venom, *see* Martin and Lamb in Allbutt and Rolleston's System of Med. vol. ii. pt. ii. (Bibliog.); Sc. Memoirs of the Gov. of India, Nos. 1, 3, 4, 5, 7, 10, 16, 17; Faust, Die Tiereschen Gifte (Braunschweig, 1906, Bibliog.); Noguchi, Journ. Exper. Med. viii. and ix.; and Snake Venoms (Smithsonian Inst. Publication); Calmette, Venoms and Venomous Animals (Bale). On other animal toxins, *see* Castellani and Chalmers, Manual of Tropical Med. (Bibliog.).]

ANTITOXINS.

It is a remarkable fact that proteins on injection into a suitable animal (the domestic mammals generally) give rise to the formation of 'anti-bodies'—substances having properties in some way opposed to those of the proteins injected—which accumulate in the blood of the treated animal. This property of generating anti-bodies, according to Abderhalden, is characteristic of the animal body and is most active against injected cells, proteins, and allied substances. The substance which generates the anti-body is termed the 'antigen.' If a protein such as human serum is injected into a rabbit, the serum of the treated rabbit gives a white precipitate when mixed with human serum, and to a less extent with apes' serum, but with no other sera—a specific 'precipitin' for human serum has been formed. By this means blood-stains, flesh, &c., can be identified with great certainty. By injecting an enzyme, such as rennin, anti-enzyme is formed which inhibits the action of the enzyme; by injecting red-blood corpuscles 'hæmolysin,' solvent for red-blood corpuscles, is formed. If a poisonous protein is injected (in properly graduated doses so as to avoid killing the animal), such as ricin or snake venom, an anti-body is generated which completely neutralises the poisonous action of the substance injected. The same is the case with toxins like diphtheria and tetanus toxins. By repeated injections of a horse with increasing doses of the toxin, the animal becomes less and less susceptible, so that it can finally tolerate huge doses of the toxin without harm, and coincident with the development of this insusceptibility antidotal substances appear in its blood, and may be obtained in the blood-serum by bleeding the animal and allowing the blood to clot. The antidotal or neutralising substance to toxin is termed antitoxin; it is a fairly stable substance, and by obtaining and bottling the serum aseptically it may be preserved, and is employed to treat the respective disease in man.

The antitoxic serum contains a variable amount of the antitoxic constituent and for therapeutic use must be standardised.

The antitoxic constituent is probably protein (globulin) in nature, or at least is associated with the globulin constituent of the serum. The globulin content of the blood of antitoxin-yielding horses is frequently higher than normal, and the antitoxin may be precipitated by saturation of the serum with magnesium sulphate, or by partial saturation with ammonium sulphate; it comes down with the eu-globulin fraction of the serum globulin.

Brieger and Boer (*l.c.*) separated the antitoxic constituent by the following methods: (*a*) 4 grms. of potassium iodide or chloride are added to 10 c.c. of the antitoxic serum diluted with an equal quantity of distilled water. After solution, 4–5 grms. of finely-powdered sodium chloride are added, the mixture is kept at 30°–37° for 18–20 hours, and the precipitate (0·4 grm.) is collected; it is the antitoxic portion of the serum with a slight admixture of protein and salts.

(*b*) The proteins of the antitoxic serum are precipitated with basic lead acetate containing a trace of ammonia, the precipitate is filtered off and the filtrate is saturated with ammonium sulphate. The precipitate is collected and redissolved, the solution is dialysed, and evaporated to dryness. A light powder is obtained (0·06 grm. from 10 c.c. serum) which contains the antitoxic constituent.

(*c*) 10 c.c. of the serum are diluted with 50 c.c. of distilled water, and 20 c.c. of a 1 p.c. solution of zinc sulphate or chloride are added. The precipitate is collected, dissolved in feebly alkaline water, and the zinc compound is decomposed with carbon dioxide. The antitoxic constituent is present in solution when the precipitant is zinc chloride, but is entangled in the zinc carbonate precipitate when the precipitant is zinc sulphate.

Dzerzgowski and Predtétchensky have elaborated a very exact method by partial saturation of the serum with ammonium sulphate, whereby practically the whole of the antitoxin may be concentrated and recovered from a weak antitoxic serum (Archives des Sc. Biologiques, St. Petersbourg, xvi.).

Anti-venin, the antidotal serum for snake-bites, is a truly antitoxic serum.

In the case of pathogenic micro-organisms which do not form an exo-toxin, an antidotal anti-serum can also be prepared by the injection of the bacterial cells, first killed cultures, and subsequently the living organisms, but such serums are not nearly so potent as the antitoxic serums produced by exo-toxins, and many are practically useless for treating the respective diseases, *e.g.* typhoid and cholera serums. The principal action of such an anti-serum is bacteriolytic, *i.e.* it brings about solution of the microorganism.

In this bacteriolytic reaction (and similarly in the solution of red-blood-corpuscles by a 'hæmolytic' serum) two protein substances seem to be concerned. The fresh anti-serum is solvent for bacteria, but not the old, nor the heated (to 56°C.) anti-serum. The two latter may be rendered active again by the addition of *fresh normal* serum. That is to say, by injection of the bacteria (or blood corpuscles), a new and relatively stable substance is formed, which reacts with an unstable normal constituent of the serum, the two together bringing about bacteriolysis (or hæmolysis). To the former, the name of 'immune body' or 'amboceptor,' to the latter, 'alexin' or 'complement,' is given.

Specificity is the distinguishing feature of the anti-bodies; the anti-body produced by an antigen always reacts most actively with this particular antigen.

The formation of anti-bodies is usually explained by Ehrlich's 'side-chain theory.' This supposes that the protoplasmic molecules of the cells of the animal have an affinity for the substance injected (the 'antigen') which gives rise to the anti-body, so that the antigen becomes incorporated with the protoplasm. The union of the antigen with the protoplasm is assumed to be brought about by the combination of atomic groups comparable to the side-chains of a ring nucleus, those of the protoplasmic molecule being termed 'receptor groups,' those of the antigen 'haptophore (=binding) groups.' The poisoning caused by a toxin is thus due to the union of the toxin with the protoplasm by the combination of the haptophore groups of the toxin with the receptor groups of the protoplasm. Should the animal's protoplasm not possess receptor groups having an affinity for the haptophore groups of the toxin, the toxin would not be poisonous to this animal. This is often the case—a toxin is never poisonous to all animals. Now Ehrlich assumes that the protoplasmic receptor groups fulfil physiological functions in the animal, *e.g.* nutrition, &c., so that when a toxin becomes united with the protoplasm a defect is created, whereby the latter cannot properly fulfil its physiological functions. Provided the dose of toxin be not too large, recovery ensues, due to the regeneration by the protoplasm of the particular receptor groups involved. This process is repeated again and again, and as a result of the continued stimulation by the numerous doses of toxin, the protoplasm ultimately forms the receptor groups in question in large excess—much more than is necessary simply to repair the damage done. A considerable proportion of the now very numerous receptor groups then becomes detached from the protoplasm, accumulates in the blood, and constitutes the anti-body. The antidotal property of antitoxin is, therefore, due to the fact that it saturates the haptophore groups of the toxin so that the latter is then unable to combine with the protoplasm.

[On antitoxins, &c., *see* Ehrlich, Die Wertbemessung des Diphtherieheilserums. 1897; Trans. Jenner Inst. of Prev. Med. ii.; Croonian Lect. Roy. Soc. Lond. 1900; and Collected Papers on Immunity, 1909; Hewlett, Serum and Vaccine Therapy, Churchill, 1910 (Bibliog.); Emery, Immunity and Specific Therapy (Lewis, 1909, Bibliog.).]

Toxin-antitoxin reaction. The neutralisation of toxin by antitoxin is approximately quantitative, and the toxin and antitoxin unite. This is shown by the fact that if a recently-made mixture of toxin and antitoxin be filtered through a gelatin-coated porcelain filter, the toxin passes through into the filtrate, but not the antitoxin (*see ante*). If, however, the mixture be allowed to stand so that interaction may occur, the toxin can no longer be separated from the antitoxin by this method. The interaction between the two is slow, is retarded by cold, and is hastened by warming (Brodie, *l.c.*; Martin and Cherry, Proc. Roy. Soc. Lond. lxiii.).

The exact nature of the union of toxin with antitoxin, 'the toxin-antitoxin reaction,' has been the subject of much controversy, and three principal hypotheses have been formulated to explain it. Ehrlich held that the union is comparable to the combination of a strong acid with a strong base, *i.e.* the reaction is a complete one, and there cannot be at the same time in a mixture of toxin and antitoxin, free toxin and antitoxin, together with neutralised toxin. The strictly quantitative relation of toxin and antitoxin supported this view, viz. if 10 equivalents of antitoxin exactly neutralise 10 equivalents of toxin, then 100 equivalents of antitoxin will exactly neutralise 100 equivalents of toxin. But it is found that if 100 fatal doses of toxin (for the guinea-pig) are just neutralised by 100 equivalents of antitoxin, 101 fatal doses of toxin + 100 equivalents of antitoxin is *not* a fatal mixture, and generally 108–116 (sometimes many more) fatal doses of toxin must be added to the 100 equivalents of antitoxin to render the mixture a fatal one (the Ehrlich phenomenon). Ehrlich explained this by supposing that the 'toxin broth' contains not one toxic substance only, but is a mixture of toxin and toxone, the latter being much less toxic than toxin, though requiring as much antitoxin to neutralise it as toxin does. Toxin has, however, a greater affinity for antitoxin than toxone has, so that when more toxin is added to a neutral mixture of toxin and antitoxin, the toxone-antitoxin complex in the latter is dissociated, and the antitoxin so set free then combines with the added toxin, and it is not until the added toxin is more than can be neutralised by the freed antitoxin that the mixture becomes fatal. Ehrlich, in fact, was forced to conclude that toxin broth contains diverse toxic bodies. The second hypothesis, that of Arrhenius and Madsen, while admitting that the union of toxin with antitoxin takes place in definite proportions, regards it as comparable to the neutralisation of a weak base by a weak acid, *e.g.* ammonia and boric acid, the reaction is incomplete, though resulting in equilibrium, so that free toxin and antitoxin exist in the mixture, together with the toxin-antitoxin complex. The quantity of free toxin would be a function of the relation existing between the initial quantities of the two substances. The Ehrlich phenomenon is quite explicable on this hypothesis, and there is no need to postulate the existence of toxone or other toxic constituents in toxin broth. But other phenomena concerning the neutralisation of toxin by antitoxin do not seem explicable by either of these hypotheses. One of these is what is known as the 'Danysz effect,' which is obtained with many different toxins and their corresponding antitoxins. If a mixture consisting of *a* parts of toxin and *b* parts of antitoxin is exactly neutral, when the whole of the toxin *a* is mixed with the antitoxin; a similar mixture of *a* parts of toxin and *b* parts of antitoxin, prepared by adding the toxin in several fractions to the antitoxin is *still toxic*. This is explained according to Arrhenius and Madsen as being analogous to the neutralisation of chloracetic acid by sodium hydroxide. If equivalent quantities of the acid and base are taken, and only half the acid is added in the first instance to the whole of the hydroxide, the acid is wholly neutralised, leaving half the base free. This then slowly reacts upon the sodium chloracetate forming sodium chloride and glycollate, and the solution ultimately becomes neutral. (Communications from the Nobel Institute, 1, iii. 1906.) The Danysz effect has its counterpart in the neutralisation of arsenious acid with ferric hydroxide. Bordet maintains that the union of toxin with antitoxin takes place in variable proportions, and resembles the phenomenon of adsorption, similar to the colouring of filter-paper with a dye. Thus, if pieces of filter-paper be placed in a dilute solution of a dye at sufficiently long intervals, the first pieces become distinctly coloured, but the last pieces remain colourless through lack of free dye in the solution. On the other hand, if all the pieces of paper are simultaneously placed in the solution, they all become similarly coloured. Likewise, a mixture of toxin and antitoxin, in which the latter is in insufficient quantity to render the mixture completely innocuous, does not contain, according to Bordet, a certain quantity of free toxin, together with neutralised toxin, but contains only molecules of toxin insufficiently neutralised, because the antitoxin is diffused over all the molecules of toxin, each of which, therefore, fixes an amount of antitoxin too small completely to inactivate it. In a series of mixtures containing increasing quantities of antitoxin for a uniform amount of toxin, each molecule of the latter will, therefore, be united to increasing quantities of antitoxin. The toxicity of the poison will thus become weaker and weaker, and such a series of mixtures will possess all degrees of toxicity. From this conception, reversibility of the toxin-antitoxin combination should exist, and this reversibility must be variable according to the condition, as is the case with adsorption phenomena in general. Reversibility can be demonstrated in the case of some antigen-antibody systems, a reversibility which is variable and generally incomplete. On the whole, almost every phenomenon of the toxin-antitoxin reaction seems to be explicable on Bordet's adsorption hypothesis, which is not the case with other hypotheses. Specificity is not completely explained by it, nor, however, is it explained by other hypotheses.

[On the toxin-antitoxin reaction, *see* Ehrlich, Deutsch. med. Woch. 1898; Arrhenius, Immuno-Chemistry (Macmillan Co., 1907), Ergebnisse der Physiol. vii. Jahr., 1908, and Jour. of Hygiene, viii.; Bordet, Ann. Inst. Pasteur. 1899, 1900, 1903; Craw, Jour. of Hygiene, vii., ix.; McKendrick, Proc. Roy. Soc. Lond. B. 1911; Gengou, Jour. State Med. 1912, xx. (Summary and full Bibliog.). Many abstracts in J. Chem. Soc.] R. T. H.

TOXICODENDROL. The active principle of the 'Poison Ivy' (*Rhus Toxicodendron* [Linn.] and *R. venenata* [DC.]), is an oily substance possessng intensely irritating properties, found in all parts of the plant, the fruits giving 3·6, the eaves 3·3, and the stem 1·6 p.c. The degree of activity varies in the case of different persons: in some cases 1 mgm. produced hundreds of vesicles, and even $\frac{1}{1000}$ mgm. proved active in one case. The vesicant action was not immediate, a period of 24 hours to 7 or 9 days elapsing before the eruption appeared (Pfaff, J. Soc. Chem. Ind. 1897, 1037).

The poisonous substance is probably a glucoside; it is decomposed by acids yielding gallic acid, fisetin, and rhamnose. Cases of poisoning are said to be best treated with potassium permanganate (Acree and Syme, Amer. Chem. J. 1906, 301).

TRAGACANTH. *Tragacanthin* v. GUMS.

TRAUMATOL v. SYNTHETIC DRUGS.

TRAVERTINE. A limestone deposited by calcareous springs, known also as *calc-sinter* and *calcareous tufa.* The typical travertine occurs near Tivoli, the ancient Tibur, whence the name *apis Tiburtinus.* The most important sources at this locality are the sulphuro-calcareous springs, known as the Acque Albule, surrounded by a plain representing the floor of an ancient ake, and consisting of thick beds of travertine. This stone, being easily worked and of great durability, and presenting a pleasing tone, has for ages been the favourite building material in Rome. The quarries of Barco, on the Anio, furnished the stone for the Coliseum, and those of Fosse the material for St. Peter's. To supply modern Rome new quarries have been opened at the Villa Adriana, below Tivoli (N. Pelati, I Travertini della Campagna Romana, Rome, 1882; P. Zezi, in Johnston-Lavis's South Italian Volcanoes, Naples, 1891).

Springs issuing from limestone rocks commonly precipitate calcium carbonate upon objects with which they come in contact, and are thus improperly termed 'petrifying springs.' Calcareous incrustations are formed, for instance, by water issuing from the carboniferous limestone at Matlock, in Derbyshire; whilst extensive accumulations of tufa are produced by the thermal springs of Clermont, in Auvergne, and of Hieropolis, in Asia Minor.

The deposition of travertine, or tufa, may result from the mere exposure of highly calcareous waters to atmospheric influences, carbon dioxide being removed and the normal calcium carbonate precipitated. Agitation of the water facilitates the loss of carbon dioxide, and hence calcareous deposits often occur where the water falls in a spray or cascade. Deposition is also favoured by the action of heat, by diminution of pressure, and by the agency of plants. It was shown by F. Cohn that in the hot springs of Carlsbad microscopic plants are important agents in determining the deposition of calcareous tufa, or *Sprudelstein.* F. W. R.

TREACLE v. SUGAR.

TREE WAX v. *Insect wax*, art. WAXES.

TREHALOSE v. CARBOHYDRATES.

TREMOLITE-ASBESTOS v. ASBESTOS.

TRENT SAND. A sand found in the Trent, Severn, and in other rivers; used for polishng.

TRIDECATOIC or **TRIDECYLIC ACID** $C_{12}H_{25}·COOH$ is obtained by the oxidation of methyl-tridecyl-ketone; it crystallises in thin plates; m.p. 40·5°; b.p. 236° (100 mm.) (Krafft, Ber. 1879, 1668).

TRIDYMITE v. QUARTZ.

TRIFOLIN v. GLUCOSIDES.

TRIGEMIN, TRIPHENIN, v. SYNTHETIC DRUGS.

TRIGONELLINE (*Methyl betaïne of nicotinic acid*) $C_7H_7NO_2$ is an alkaloid which occurs in the seeds of *Trigonella Foenum-graecum* (Linn.); in ordinary peas (*Pisum sativum* [Linn.]); in hemp seeds (*Cannibis sativa* [Linn.]) (Jahns, Ber. 1885, 18, 2518; Schulze and Frankfurt, *ibid.* 1894, 27, 769; Schulze and Winterstein, Landw. Versuchs. Stats. 1895, 46, 23); in commercial strophanthine and in the seeds of *Strophanthus hispidus* (DC.) and *S. Kombé* (Oliver) (Thoms, Ber. 1898, 31, 271, 404; Karsten, Chem. Zentr. 1902, ii. 1514).

Preparation. The powdered seeds are extracted with alcohol; after distilling off the latter, lead acetate and caustic soda are added, and the alkaloid is separated by means of potassium bismuth iodide and sulphuric acid. The precipitate is then treated with caustic soda to separate albuminoids, the filtered solution is neutralised with sulphuric acid and precipitated with mercuric chloride. The cholin so precipitated is removed by filteration, the filtrate acidified with sulphuric acid, and the trigonelline in the form of its mercury iodide salt is then precipitated. The free base is obtained by decomposing the double salt with a sulphide (*see* Schulze, Zeitsch. physiol. Chem. 1909, 60, 155).

Trigonelline has also been obtained by treating nicotinic acid with methyl iodide, and the product of the reaction with silver hydroxide (Hantzsch, Ber. 1886, 19, 31); or by the oxidation of nicotine *iso*-methohydroxide, with potassium permanganate (Pictet and Genequand, Ber. 1897, 30, 2117, 2122).

Trigonelline crystallises with one molecule of water, forming colourless, flat prisms of feeble saline taste and neutral reaction. It is hygroscopic, is readily soluble in water, sparingly soluble in alcohol, insoluble in ether, benzene, and chloroform. When heated, it loses its water of crystallisation and dissolves or melts in the latter at 130°. The anhydrous alkaloid darkens when heated at 200°, and melts at 218° (decomp.). When heated with barium hydroxide at 120° trigonelline evolves all its nitrogen as dimethylamine, and when heated with excess of hydrochloric acid, it yields nicotinic acid and a gas, probably methyl chloride (Jahns, Ber. 1887, 20, 2840). It gives the usual reactions of an alkaloid with reagents.

A *hydrochloride, platinochloride,* and two *aurochlorides* $C_7H_7NO_2·HCl·AuCl_3$, m.p. 198°, and $4(C_7H_7NO_2)3HCl·3AuCl_3$, m.p. 186° (Jahns, *l.c.*; Schulze and Frankfurt, *l.c.*), are known. For the physiological action of trigonelline, *see* Kohlrausch, Chem. Zentr. 1909, ii. 465; for its origin, *see* Schulze and Trier, Zeitsch. physiol. Chem. 1910, 67, 46) v. VEGETO-ALKALOIDS.

TRIHYDROXYBENZENE v. PHENOL AND ITS HOMOLOGUES.

TRIKETOHYDRINDENE v. INDENE.

TRIKETONES v. KETONES.

TRIMETHYLACETIC ACID v. VALERIC ACIDS.

TRIMETHYLBENZENES *v.* Cumenes.

TRIMETHYLENE *v.* Propyl.

TRIMETHYLHYDROXYBENZENE *v.* Phenol and its homologues.

TRINITROPHENOL *v.* Picric acid.

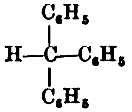
TRIONAL (*diethylsulphonemethylethylmethane* or *methyl sulphonal*) $CH_3(C_2H_5)C(SO_2C_2H_5)_2$ is prepared, like sulphonal and tetronal, from methylethylketone and ethyl mercaptan (Fromm, Annalen, 1889, 253, 150; D. R. P. 49073; Frdl. 1887–1890, ii. 521). It forms colourless, odourless, lustrous square tablets, m.p. 76°, soluble in 320 parts of cold water, but more readily so in boiling water, in ether, and in alcohol. It is employed in medicine for the same purposes as sulphonal and tetronal, *v.* Synthetic Drugs. For its detection, *v.* Sulphonal and Tetronal.

TRIPHANE *v.* Spodumene.

TRIPHENYLMETHANE COLOURING MATTERS. This is the generic name of a very large and varied class of artificial dye-stuffs which have been obtained by very different methods. Some of the oldest artificial dye-stuffs belong to this group. Their generic connection was, in many instances, not known until their constitution was fully ascertained. When this had been done, a large number of new dye-stuffs belonging to the same class was prepared by direct synthesis. The members of this group vary more than those of any other in their physical properties; they represent almost every possible shade, and include dye-stuffs suitable for almost every kind of dyeing and printing process. They are applicable to silk, wool, and cotton dyeing; as a rule, they are of very pure and brilliant shades—in fact, the most brilliant of all colouring matters are found amongst them. Many are rather fugitive, especially the older ones—magenta-red and its congeners. It is for this reason that aniline dyes generally have been declared fugitive and unstable by people of hasty judgment. This want of stability is, however, not characteristic of the triphenylmethane group; some of the best and most permanent dye-stuffs belong to it. It may be well to remark at once that resistance to light and other influences seems not to be directly related to the chemical constitution of these substances, as it is frequently observed that of two dye-stuffs of very similar constitution one may be very fugitive, whilst the other is remarkable for its fastness. The fastness of these and other dye-stuffs also depends to some extent on the manner in which they are applied to the textile fibre.

The members of this family are not, like those of the azo- group, connected by one generic method, by which all of them might be produced from various materials. Nor is it possible to enumerate a number of general synthetic methods which result in their production. The methods applicable are so numerous that no generalisation is possible. The only connecting link between all these dyes is their chemical constitution, which is now well established in almost every case; it is also in this constitution that we find the necessary criteria for the subdivision of the group. Some introductory remarks about the constitution of these dyes are therefore necessary for a complete revision of the subject.

If we consider the constitution of these colouring matters, we observe that there is but one characteristic feature common to them all. This is the presence of an atom of carbon connected by three of its valencies to three aromatic radicles. The compound of the simplest constitutional formula in which this 'central carbon' (as we will henceforth call it) is observed is the hydrocarbon triphenylmethane, the formula of which is $C_{19}H_{16}$:

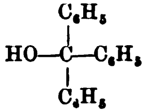


$$H-\overset{\displaystyle C_6H_5}{\underset{\displaystyle C_6H_5}{C}}-C_6H_5$$

Triphenylmethane thus becomes the prototype of all the members of this group; it is for this reason that the name of *triphenylmethane colouring matters* was chosen.

Triphenylmethane was first prepared by Kekulé and Franchimont, in 1872, by heating benzylidene chloride with mercury diphenide to 150° (Ber. 5, 907). Its formation has since been observed in numerous reactions. The best method for preparing it consists in treating a mixture of two parts of chloroform and seven parts of benzene with aluminium chloride, until no more hydrogen chloride is given off. The resulting liquid is washed with water and dried. On distillation it yields benzene, diphenylmethane, and triphenylmethane. The last may be purified by crystallisation. This method was indicated by Friedel and Crafts (Ann. Chim. Phys. [vi.] 1, 489). Triphenylmethane is obtained in colourless crystals; m.p. 92°; b.p. 358°–359°. It is capable of forming a molecular compound with benzene. Of its derivatives the following three are important on account of their relations to the colouring matters under consideration.

Triphenyl carbinol $C_{19}H_{16}O$ is the tertiary alcohol derived from triphenylmethane:

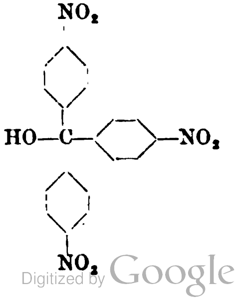


$$HO-\overset{\displaystyle C_6H_5}{\underset{\displaystyle C_6H_5}{C}}-C_6H_5$$

It is easily obtained by oxidising the hydrocarbon by means of chromic acid. It forms colourless crystals, melting at 159° and boiling at 360° (E. and O. Fischer, Annalen, 194, 274).

Trinitrotriphenylmethane $C_{19}H_{13}N_3O_6$ is obtained by treating the hydrocarbon with strong nitric acid. Crystals, melting at 203°. Chromic acid transforms it into trinitrotriphenylcarbinol (E. and O. Fischer, *ibid.* 194, 256).

Tri-*p*-nitrotriphenylcarbinol $C_{19}H_{13}N_3O_7$:

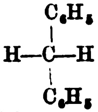


is best crystallised from glacial acetic acid and forms small crystals, melting at 171°–172° and soluble in alcoholic potash solution with a beautiful reddish-blue colour.

None of the above substances is a colouring matter, nor are they even coloured. But if we reduce trinitrotriphenylcarbinol by adding zinc-dust to its solution in acetic acid, we obtain triaminotriphenylcarbinol, which is identical with pararosaniline. By showing this identity, E. and O. Fischer solved the problem of the constitution of this very important colouring matter. Leucaniline, the reduction product of rosaniline, was shown to be identical with triaminotriphenylmethane. This discovery became the starting-point for very important theoretical and practical work. All the congeners of rosaniline were shown to be derivatives of triphenylmethane or analogous hydrocarbons, and new synthetical methods were devised by which such derivatives could be obtained.

It is quite obvious that not only triphenylmethane, but also all its homologues and analogous hydrocarbons, are parent substances of dye-stuffs. The number of such hydrocarbons indicated by theory is very large, since every one of the three phenyl radicles connected with the central carbon may be replaced by any other aromatic radicle. Every one of the hydrocarbons thus formed is capable of yielding, like triphenylmethane itself, a very large number of colouring matters, as will be seen from subsequent considerations. It thus becomes evident that the theoretical number of possible triphenylmethane colouring matters is almost unlimited. It has, however, been shown that the variation of the aromatic radicles connected with the central carbon is not the only point of importance as regards the variation of the shades and properties of the resulting dye-stuffs. The triphenylmethane colouring matters in actual use are the derivatives of a very few hydrocarbons, of which triphenylmethane itself is by far the most important. Tolyldiphenylmethane, ditolylphenylmethane, tritolylmethane, and naphthyldiphenylmethane are the principal parent substances of a large number of colouring matters, which at present form the object of regular and extensive manufacture, and of several hundred more which have been prepared and patented without coming into general use. The extensive range of shade and general applicability, so characteristic of the colouring matters of this class, and unequalled by any other class of dye-stuffs known, is not so much a result of the variation of the hydrocarbons forming their parent substances, as of the extremely large number of coloured derivatives which may be produced from every one of these hydrocarbons. No other branch of the chemistry of dye-stuffs is so extremely fertile in the synthetical methods at its disposal as this, and every one of these methods forms an easy way for the production of a considerable number of dye-stuffs, which can generally be produced by this one method alone. Many of these methods, both empirical and synthetical, have been patented, and some of these patents are of great value and importance. They are generally "process" patents, claiming new methods of manufacture; in this respect they form the exact counterpart of the still more numerous "substance" patents for azo- colouring matters, which, being all based on the same method of work, only claim the novelty of the product obtained by varying the ingredients of the process.

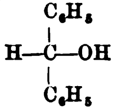
Before entering into the details of the constitution of triphenylmethane dye-stuffs, and the connection of this constitution with the properties of the dyes, we have to describe another substance closely related to triphenylmethane, some of the derivatives of which are dye-stuffs similar to those derived from triphenylmethane itself, whilst others play an important part in the processes for the production of triphenylmethane colouring matters. This substance is also a hydrocarbon, derived from methane by replacing only two of its hydrogen atoms by the aromatic radicle phenyl. This hydrocarbon is *diphenylmethane*, or benzyl-benzene $C_{13}H_{12}$:



$$\begin{array}{c} C_6H_5 \\ | \\ H—C—H \\ | \\ C_6H_5 \end{array}$$

It was discovered by Zincke in 1873 (Annalen, 159, 374), and is best prepared by the method indicated by Friedel and Balsohn (Bull. Soc. chim. [ii.] 33, 337), by adding aluminium chloride to a mixture of 1 part benzyl chloride with 5 parts of benzene. It melts at 26°–27°, and boils at 261°–262°. It forms white crystals, possessing an agreeable odour of oranges. Of its derivatives the following are of practical importance:—

Diphenylcarbinol or **benzhydrol** $C_{13}H_{12}O$ is the corresponding alcohol:



$$\begin{array}{c} C_6H_5 \\ | \\ H—C—OH \\ | \\ C_6H_5 \end{array}$$

It is prepared by boiling benzophenone with alcoholic potash solution and zinc-dust. It forms white crystals, melting at 67·5°–68°, boiling at 297°–298° (Linnemann, Annalen, 133, 6; Zagumenny, *ibid.* 184, 174).

Benzophenone $C_{13}H_{10}O$ is the second product of oxidation of diphenylmethane, to which it stands in the same relation as that which exists between propane and acetone. Benzophenone is the typical ketone of the aromatic series

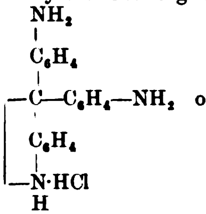
$$\begin{array}{c} C_6H_5 \\ | \\ C=O \\ | \\ C_6H_5 \end{array}$$

It is prepared by the process which led to its original discovery, by distilling calcium benzoate, or, better still, by distilling a mixture of calcium and zinc benzoate. Another process consists in adding aluminium chloride to a solution of carbonyl chloride $COCl_2$ (phosgene) in pure benzene, or to a mixture of benzene with benzoyl chloride. Benzophenone forms beautiful prismatic crystals, melting at 48°–48·5°, distilling at 305° (Péligot, Annalen, 12, 41; Chancel, *ibid.* 72, 279; Friedel, Crafts and Ador, Ber. 10, 1854) (*v.* QUINONES).

The amino derivatives of diphenylmethane, diphenylcarbinol, and benzophenone, which are of special importance in the chemistry of the triphenylmethane dye-stuffs, will be described subsequently in connection with the dye-stuffs to which they give rise.

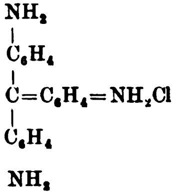
The substances mentioned so far, although the parent substances of so many beautiful dyes, are all perfectly colourless. Even triaminotriphenylcarbinol, which is identical with *p*-rosaniline, is perfectly colourless; it only becomes a dye-stuff by being dissolved in an acid, a reaction from which one might infer that *p*-fuchsin, the typical magenta colour, is merely a salt of *p*-rosaniline. This is, however, not the case, although colour-makers are apt to call, for simplicity's sake, the rosanilines 'magenta bases.' The dissolution of any or either of the aminocarbinols in an acid is invariably accompanied by a condensation in the molecule, and a loss of one molecule of water. The basic triphenylmethane colouring matters are therefore free from oxygen (unless they contain it in the shape of water of crystallisation); if we decompose the salts, by the addition of an alkali, coloured bases are formed, which, however, are very unstable. They take up, at once, one molecule of water, and re-form the original colourless or faintly-coloured carbinol base. If the precipitation is carried out by means of ammonia instead of sodium hydroxide or carbonate, or if ammonia be present in the liquid, the carbinol base is partly or wholly transformed into the corresponding amino compound, as has been shown by Villiger and Kopetschni, Ber. 45, 2910, and by Nölting and Saas, *ibid.* 46, 952. By this observation it is clearly shown that something more than the presence of the 'central carbon' is necessary for the formation of a triphenylmethane colouring matter. We have, therefore, to consider the constitution of the colouring matters themselves to obtain a knowledge of the chromophoric group of these dye-stuffs. This consideration leads at the same time to an easy and useful classification, to a subdivision into a series of smaller groups, the members of which show a closer connection in their methods of formation, their physical properties, and their manner of application.

The constitution of parafuchsin is now established beyond any doubt. It may be represented by the following formulæ:



$$\begin{array}{l} NH_2 \\ | \\ C_6H_4 \\ | \\ -C-C_6H_4-NH_2 \\ | \\ C_6H_4 \\ | \\ -N{\cdot}HCl \\ H \end{array}$$

or



$$\begin{array}{l} NH_2 \\ | \\ C_6H_4 \\ | \\ C=C_6H_4=NH_2Cl \\ | \\ C_6H_4 \\ NH_2 \end{array}$$

I. II.

which are practically identical, II. corresponding to the modern way of expressing 'quinonoid' structure. This formulation will therefore be used exclusively in this article to explain the constitution of the dyestuffs to which it refers, whilst formulæ corresponding to I. have been used in the first edition of this work. The formulæ chosen show also the typical constitution of all the congeners of magenta, every one of which may be represented by similar formulæ, in which either one or more of the phenyl radicles is replaced by other aromatic radicles, or one of the amino groups replaced by hydrogen, or one of the six available hydrogen atoms of the amino groups replaced by radicles of the fatty or aromatic series, or several of these changes introduced at the same time. It will at once be obvious that several thousand different combinations may thus be produced, all colouring matters of different shades, but showing in their properties a general resemblance to parafuchsin. The constitutional formulæ of all these colouring matters have but one thing in common besides the 'central carbon' (which is, as has been said, characteristic not only of these, but also of all the other triphenylmethane colouring matters); this one essential feature is the quinonoid nature of the substance, expressed in the structural formula either by the connection between the central carbon atom and the pentavalent nitrogen (as shown in formula I.), or, as it has become customary of late, by shifting the double valencies in the benzene hexagon and connecting it accordingly with the other parts of the molecule, as shown in formula II. We have, therefore, a perfect right to claim this invariably present quinonoid configuration as the essential feature of the whole molecule, and as the cause of its being a colouring matter. It forms a part of the chromophoric group of the fuchsin family.

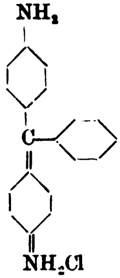
It is, however, important to notice that, no matter how we write the structural formula of *p*-fuchsin or any of its congeners, whether we use the older or the more modern way of expressing the quinonoid nature of the substance, one of the amino groups present is always taking part in the quinonoid chromophoric group and therefore is no longer available as an auxochromic group. To supply this, at least one more amino-group must be present, and this is the reason why only di- or poly-amino derivatives of triphenylmethane can become mother-substances of dye-stuffs belonging to this group. On the other hand, both the amino groups of auxochromic nature, as well as the one entering into the chromophoric part of the molecule, may be replaced by other suitable groups. The hydroxyl group with its tendency to form salts by combining with metallic ions is as important an auxochromic group in the series of triphenylmethane dye-stuffs as in any other. And the quinonoid imino group contained in the chromophore, may, as in other dye-stuffs, be replaced by an oxygen atom acting in similar capacity. Thus we obtain two separate groups of dye-stuffs, the first of which, generally called the *fuchsin group*, is characterised by the presence of nitrogen and the basic nature of its members; the second, called the *aurin group*, by the absence of nitrogen and the phenolic character of the dyestuffs it embraces. In addition to these two groups, a third one, the *phthalein group*, has been established by the common consent of all authors on the subject. This group contains a large number of important dye-stuffs of both basic and acid nature, which have this in common, that they are all derived from phthalic acid and take their 'central carbon' from one of the carboxyl groups of this acid, whilst the other, remaining available, enters the molecule of the dye-stuff and thus renders the latter a true organic acid, which is not necessarily the case amongst the members of the fuchsin and aurin group. Moreover, almost all the phthalein dye-stuffs of any practical importance contain, in addition to the typical chromophor of the triphenylmethane colouring matters, an additional one in the shape of the 'pyrone' ring, formed by the elimination of water from certain suitably placed hydroxyl groups of the molecule. This pyrone ring will be easily recognised in the formulæ of the members of the phthalein group to be given subsequently. The fact that only those phthaleins, which contain this pyrone ring, are colouring matters of any practical value, greatly diminishes the number of possibilities for the synthesis of such dye-stuffs, which might be made to form a class of their own, if it had not become customary to treat them as a special division of the triphenylmethane group of colouring-matters.

We now proceed to give a detailed account of these three groups and their various members, of which, however, we shall enumerate only those which are, either scientifically or practically, important. For a complete list we refer the reader to the well-known tables of Schultz and Julius.[1]

I. The Fuchsin Group.

(A) *Diaminotriphenylmethane derivatives.* The simplest type of these colouring matters is

1. **Benzaldehyde violet** $C_{19}H_{17}N_2Cl$ or

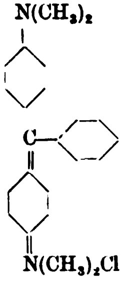


which may be prepared from diaminotriphenylmethane by oxidation. The yields are, however, very poor, and the colour itself is of no great value. Its manufacture has, therefore, never been taken up.

The derivatives of this substance, however, in which the hydrogen of its two amino groups is replaced by various radicles of either the fatty or aromatic series, are of great value and importance. Of these, the oldest, best known, and simplest in its constitution, is

2. **Benzaldehyde green.** (Syn. *Malachite green, New green, Victoria green, Fast green, Diamond green, Benzoyl green, Benzal green.*)

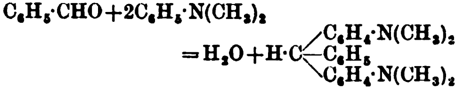
$C_{23}H_{25}N_2Cl$ or



This product was discovered almost simultaneously by Otto Fischer (1877; Ber. 10, 1625) and O. Döbner (1878; *ibid.* 11, 1236), who prepared it by different methods. For some time it was believed that Döbner's product was different from Fischer's until their identity was finally established. Döbner's process was patented (D. R. P. 4322). Fischer's process found, however, more favour with the majority of manufacturers, and has mostly been adopted.

Fischer's process gave bad yields and a poor product at first, until the best method for its manufacture was worked out. It consists in the following operations:—

(*a*) Manufacture of tetramethyldiaminotriphenylmethane by the action of benzaldehyde on dimethylaniline:



$$C_6H_5{\cdot}CHO + 2C_6H_5{\cdot}N(CH_3)_2 = H_2O + H{\cdot}C\begin{cases}C_6H_4{\cdot}N(CH_3)_2\\C_6H_5\\C_6H_4{\cdot}N(CH_3)_2\end{cases}$$

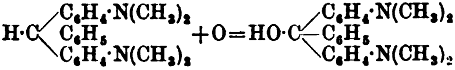
The base obtained in this reaction is generally called 'green leuco base' by the manufacturers. For preparing it one molecule of benzaldehyde is mixed with very little more than two molecules of absolutely pure dimethylaniline, a substance capable of absorbing the water formed in the reaction being added. Dry zinc chloride was originally employed, and is still used by many manufacturers. In quantity it should be equal in weight to the aldehyde employed. Hydrochloric, sulphuric, or anhydrous oxalic acid, or acid sodium sulphate may be used instead of the zinc salt. The mixture is heated in a jacketed still to 100°–110° for about forty-five to forty-eight hours. The product is then transferred to a still, a sufficient quantity of caustic soda is added to make the mixture alkaline to test-paper, and a current of steam is blown through the liquid in order to remove every trace of dimethylaniline and benzaldehyde. The leuco base is not volatile; it remains in the still in the shape of a viscid mass, which solidifies into white crystals after a while. This base is now subjected to the second operation.

(*b*) Oxidation into green. It is here that great difficulties were encountered in the beginning of the manufacture. Special conditions are required to obtain a good crystallisable dye-stuff. If these are not strictly adhered to, a non-crystallisable green is the result. The latter is different from the crystallisable substance in composition, containing one methyl group less, which is lost in the shape of formaldehyde by a too powerful action of the oxidising agents. The following conditions give excellent results: 33 kilos of leuco base are dissolved in 25 kilos of ordinary hydrochloric acid, and diluted with 200 litres of water; 30 kilos of ordinary acetic acid of 45–50 p.c. are then added. It is necessary that these two acids should be present; neither of them can be replaced by another acid of equal strength. The solution is then oxidised in the cold (in the summer it is advisable to add some ice) with a paste of lead peroxide of known strength. The peroxide should be tested by the oxalic acid method (determination of the CO_2 evolved from an excess of oxalic acid by the peroxide in question), and not by the iodometric method, as the latter gives too high results. Every kind of lead peroxide contains a certain amount o

---

[1] *Gustav Schultz und Paul Julius.* Tabellarische Uebersicht der künstlichen organischen Farbstoffe. Vierte Auflage, Berlin, 1902. (Fifth edition now in progress.)

crystalline peroxide, which neither acts on the leuco base, and is therefore quite irrelevant in its oxidation into green, nor on oxalic acid, whilst the iodometric method gives values for both modifications indiscriminately. For oxidising the leuco base the exact quantity of peroxide should be taken, which is indicated by the following equation:

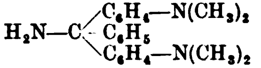


$$H\cdot C\begin{cases}C_6H_4\cdot N(CH_3)_2\\ C_6H_5\\ C_6H_4\cdot N(CH_3)_2\end{cases}+O=HO\cdot C\begin{cases}C_6H_4\cdot N(CH_3)_2\\ C_6H_5\\ C_6H_4\cdot N(CH_3)_2\end{cases}$$

One molecule of active peroxide is, therefore, required for every molecule of the base.

As soon as the peroxide has been added with constant stirring, the liquid turns a deep green. From this liquid the dye-stuff may be separated by various methods; an addition of zinc chloride solution is generally recommended. This, however, precipitates both the crystalline green and the tarry modification which is never quite absent. The following process has given excellent results in the hands of the writer.

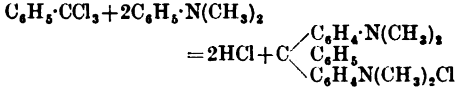
The green liquid obtained by oxidation is saturated with common salt. On standing small glittering scales of the lead double chloride of the crystallisable green very soon make their appearance, and are collected on a filter. From the mother-liquor an inferior quality of green may be obtained by adding a solution of sodium sulphate, filtering, and precipitating with zinc chloride and common salt. The crystals of the lead double chloride are dissolved in hot water, and sufficient sodium sulphate is added to precipitate the lead. The liquid is then filtered and precipitated with ammonia. The 'green base' (a mixture of tetramethyl-diaminotriphenyl carbinol with the corresponding amino derivative



$$H_2N-C\begin{cases}C_6H_4-N(CH_3)_2\\ C_6H_5\\ C_6H_4-N(CH_3)_2\end{cases}$$

discovered by Villiger and Kopetschni) settles out in the shape of a pink precipitate, which is filtered off and washed. From it the 'green crystals' of commerce may be prepared, either by dissolving it in a hot solution of oxalic acid and allowing the liquid to cool very slowly, or by dissolving it in dilute hydrochloric acid and adding a solution of zinc chloride. Besides these two the iron double salt is also occasionally met with in commerce. The picrate is also sold under the name of 'spirit green.'

Döbner's process. This consists in heating dimethylaniline with benzotrichloride in presence of metallic chlorides. This process has certain advantages if benzotrichloride is available at a low price. It may be represented by the following equation:



$$C_6H_5\cdot CCl_3+2C_6H_5\cdot N(CH_3)_2$$
$$=2HCl+C\begin{cases}C_6H_4\cdot N(CH_3)_2\\ C_6H_5\\ C_6H_4N(CH_3)_2Cl\end{cases}$$

The following proportions are recommended in the patent:

3 parts dimethylaniline,
2 „ benzotrichloride,
1·5 „ zinc chloride,

These are to be heated for three hours to 110° in an enamelled iron vessel with constant stirring. The resulting melt is transferred to a still, and steam is blown through it to remove all excess of trichloride. It is then thoroughly extracted by boiling water. The filtrate is now precipitated by salt, and the precipitate recrystallised from water. The dye-stuff is always obtained in the shape of the zinc double chloride.

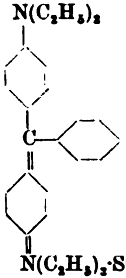
The oxalate of benzaldehyde green forms large plates of an intense grass-green colour, which dissolve easily in hot water. It contains three molecules of oxalic acid to every two of green base.

The zinc double chloride, which has the composition $3(C_{22}H_{25}N_2Cl),2ZnCl_2,2H_2O$, forms green crystals with a fine yellow metallic lustre. It is not quite so easily soluble as the oxalate.

The application of these salts is similar to that of all the basic dye-stuffs, and need not here be described.

3. **Brilliant green.** (Syn., *Ethyl green*, *Emerald green*; also all the other names given for the preceding compound, with the addition of the letters G, J, or Y (meaning *gelb*, *jaune*, or *yellow*).

$C_{27}H_{34}N_2O_4S$:



is prepared from diethylaniline by exactly the same process as described for benzaldehyde green. After precipitating the free green base, it is transformed into its sulphate by mixing it with the theoretical quantity of sulphuric acid diluted with its own weight of alcohol. The mixture forms a thick tar at first, but suddenly solidifies into a mass of well-defined crystals.

The shade of this green is considerably yellower than that of the ordinary benzaldehyde green.

4. **Victoria green** 3 B, $C_{23}H_{22}N_2Cl_2$. This is a colouring matter prepared from dichlorobenzaldehyde instead of the ordinary benzaldehyde. It is considerably bluer in shade than the ordinary benzaldehyde green. A large number of similarly constituted bluish-greens and greenish-blues is manufactured and sold, especially by the Swiss colour-works.

Acid greens. Considerable importance has always been attached by dyers to the sulpho derivatives of basic colouring matters, because these are more easily and evenly dyed on wool than the hydrochlorides and other salts of the bases themselves. Many attempts have, therefore, been made to obtain acid greens. They were at first only partly successful; at present there are, however, several acid greens in commerce, ranging in shade from a yellowish green to a clear greenish indigo blue. They are very largely used in wool dyeing, especially for mixed shades.

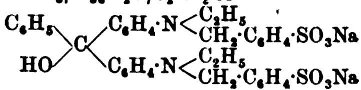
The oldest of these acid greens, which appeared in the market in 1878, was called

5. **Helvetia green** or **Acid green C.** It was the sodium sulphate of the mono-sulpho derivative of

the ordinary benzaldehyde green, prepared either by sulphonating the green itself by means of chlorosulphonic acid, or by sulphonating tetramethyldiaminotriphenylmethane and oxidising the resulting colourless acid by means of lead peroxide. Neither of these two methods works satisfactorily. For this reason the product has gradually been abandoned, and replaced by the benzyl derivatives, which are more easily prepared, and at the same time much more brilliant in shade.

6. **Benzyl acid greens.** In the various attempts to prepare acid greens it was found that the phenyl groups, combined with the central carbon, show little tendency to permit of the introduction of the sulpho group. This reluctance is, indeed, quite characteristic of all triphenylmethane derivatives. It is the cause of the difficulties experienced in preparing sulphonated derivatives of these dye-stuffs. It was, therefore, a happy thought to introduce into the molecule of the green an independent radicle, capable of receiving the sulpho group without influencing more than necessary the shade and other properties of the green. Such a radicle was found in the benzyl group. If we introduce this, instead of methyl and ethyl, into the amino groups of the green, it acts in the manner of a radicle of the fatty series, influencing the shade of the green very little. The C_6H_5 group, however, brought into the molecule as a constituent of the benzyl radicle, is capable of being sulphonated with the greatest facility. Various dye-stuffs have been prepared according to this principle. Of these *Guinea green B* is the simplest. It is the disulpho derivative of diethyl dibenzyldiaminotriphenyl carbinol

$C_{37}H_{36}N_2O_7S_2Na_2$ or



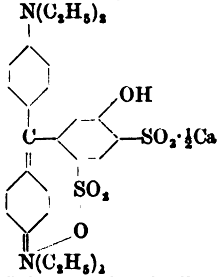
$$\begin{array}{l} C_6H_5 \\ HO \end{array} \!\!>\! C \!<\! \begin{array}{l} C_6H_4 \cdot N \!<\! \begin{array}{l} C_2H_5 \\ CH_2 \cdot C_6H_4 \cdot SO_3Na \end{array} \\ C_6H_4 \cdot N \!<\! \begin{array}{l} C_2H_5 \\ CH_2 \cdot C_6H_4 \cdot SO_3Na \end{array} \end{array}$$

obtained by combining benzaldehyde with two molecules of ethylbenzylaniline sulphonic acid, and oxidising the leuco compound thus obtained. This product was discovered by G. Schultz and Streng, in 1883, and patented (D. R. P. 50782, 1889; Eng. Pat. 7550, 1889). It is an excellent and very useful dye-stuff. *Guinea green B V*, which dyes a more yellowish shade, is obtained in the same manner, using *m*-nitrobenzaldehyde instead of the ordinary benzaldehyde.

The various shades of *light green* or *acid green* sold by the majority of manufacturers are prepared somewhat differently. Benzaldehyde is combined with two molecules of benzyl-methyl or benzyl-ethylaniline. The base thus obtained is treated with sulphuric acid, when *three* sulpho groups enter the molecule, one of which is linked to the phenyl radicle containing no amino group, whilst the two others are combined with the benzyl radicles. The resulting trisulpho derivatives are oxidised in the usual manner, yielding the dye-stuffs in the shape of a very soluble green powder.

7. A curious product, belonging to the class of acid greens, was described by R. Meldola, under the name of *Viridin* (Chem. Soc. Trans. 1882, 187; Ber. 14, 1385). It was prepared by oxidising benzyl diphenylamine, and sulphonating the resulting green, dissolved in spirit. This green, or a substance very similar to it, had already been prepared by Ch. Girard (Wurtz, Progrès de l'Ind. des Mat. col.; Paris, 1876: p. 134).

8. **Patentblau, Patent blue**, a product of the Farbwerke vorm. Meister, Lucius und Brüning, in Höchst-am-Main. This is a dye-stuff closely allied to the acid greens. It was discovered by Hermann, and patented by the Farbwerke (D. R. P. 46384, 1888, and many additional patents). It is prepared by a somewhat complicated method. *m*-Nitrobenzaldehyde is combined with two molecules of dimethylaniline. The resulting base is reduced, the amino derivative diazotised, and, by boiling with water, transformed into *m*-hydroxytetramethyldiaminotriphenylmethane. This is sulphonated by treatment with sulphuric acid. The resulting sulpho derivative is oxidised and transformed into a calcium salt, which is delivered into the market. The constitution of the dye-stuff is represented by the following formula:

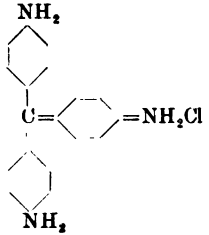


This dye-stuff dyes wool and silk a beautiful greenish-blue of great brilliancy and clearness. Several other dye-stuffs of very similar composition are on the market.

(B) *Derivatives of triaminotriphenylmethane.* This group contains some of the oldest artificial dye-stuffs, which were prepared by strictly empirical methods. When the constitution of the triphenylmethane group was established, synthetical methods for producing dye-stuffs of this group were gradually introduced. At the present time the old empirical processes hold their own for the production of the old colouring matters, whilst the synthetical methods, which are mostly patented, are used for preparing new dye-stuffs of great beauty and perfection.

The prototype of this group is—

1. **Parafuchsin**, *Paramagenta*, the anhydrochloride of triaminotriphenylcarbinol $C_{19}H_{18}N_3Cl$ the constitution of which is:



It always crystallises with four molecules of water of crystallisation, which should be added to the above formula.

This is the dye-stuff which was used by O. and E. Fischer for the elucidation of the chemistry of this class of substances (O. and E. Fischer, Annalen, 1878, 194, 242; Ber. 11, 1079; 13, 2204). It is one of the oldest artificial dye-stuffs; it was discovered in 1858 by A. W. Hofmann (J. 1858, 351); and re-discovered by Rosenstiehl in 1869 (Bull. Soc. Ind. Mulhouse, 36, 264). For a long time it was considered a substance of merely theoretical interest, because its shade is almost identical with that of ordinary fuchsin or magenta (see under 2), which is much more easily prepared. At present, however, it is manufactured on a large scale, not as a dye-stuff for sale, but as a raw material for certain blues, which will be mentioned later on.

A large number of reactions have been observed and described which result in the formation of pararosaniline. Of these the following may be mentioned:

(*a*) Pure aniline heated with carbon tetrachloride yields parafuchsin. This method was used on a manufacturing scale by Monnet and Dury in Lyons.

(*b*) Pure aniline, heated with iodoform, gives a fair yield of parafuchsin hydriodide.

(*c*) Pure aniline, heated with *p*-nitrobenzyl chloride in the presence of iron filings or iron salts gives a good yield of parafuchsin. This method, or modifications of it, form the substance of Greiff's and Baum's patents (D. R. PP. 15120 and 19304 Greiff, and 14929 Baum).

(*d*) Pure aurin (rosolic acid), which will be described subsequently, yields parafuchsin if strong ammonia be allowed to act on it for a long time at a high temperature.

(*e*) It has been shown (*v.* introduction) that the reduction-product of parafuchsin is para-leuco-aniline, and that the latter is identical with triaminotriphenylmethane. The latter may easily be prepared from triphenylmethane by nitration and reduction, and by various other methods. Attempts have not been wanting to work out a method for the production of parafuchsin from synthetical leucaniline. No good method, however, has hitherto been discovered for this purpose, and all the patents based on this reaction have proved failures. It is very easy to produce a trace of fuchsin in a solution of leucaniline; but no method is known for finishing the reaction.

(*f*) Mixtures of pure aniline with pure *p*-toluidine yield parafuchsin if subjected to oxidation. This is the usual practical way for the production of parafuchsin. The oxidation may be effected either by arsenic acid or by nitrobenzene. Other oxidising agents—such as mercuric chloride, stannic chloride, &c.—produce the same result, but at a higher cost. The arsenic acid process (which will be described later on) was for some time almost exclusively used for the production of parafuchsin. The chemical reaction which takes place is very simple. Arsenic acid is reduced to arsenious acid. The oxygen which is thus obtained combines with hydrogen of the aromatic bases:

$$2C_6H_5\cdot NH_2+C_6H_4(CH_3)NH_2+3O$$
$$=2H_2O+C_{19}H_{18}N_3OH$$

Triaminotriphenyl carbinol

The methyl group of *p*-toluidine is used up for yielding the central carbon around which the other radicles are grouped.

(*g*) Diaminodiphenylurethane, mixed with aniline and heated with oxidising agents, yields parafuchsin. This synthesis forms the basis o a more modern manufacturing process.

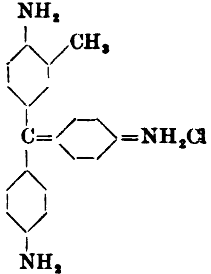
It has already been said that parafuchsi has no advantages over ordinary magenta re for dyeing purposes. It is, therefore, rarely t be met with as a dye-stuff in the market. As rule the melts are worked up in the same manne as ordinary magenta melts, but the resultin crystals of the pure hydrochloride are re dissolved and precipitated in the shape of para rosaniline base by the addition of soda or mil of lime. The base is then used for the production of blues.

Parafuchsin hydrochloride forms smal glistening crystals having a metallic gree lustre. As a rule, they are very small. muc smaller than the crystals of ordinary magenta Parafuchsin acetate is similar in appearance an crystallises much more easily than the ordinar magenta acetate.

Pararosaniline is important because it is th parent substance of all the various violets, an of some of the blues, which will be describe subsequently.

2. **Ordinary fuchsin, magenta red, rose** (*rubesine, harmaline, aniline red, azalein, solferino, erythrobenzine*) $C_{20}H_{20}N_3Cl$, is an articl of great importance and of very general application. The latter is due to the fact that it wa one of the first artificial dye-stuffs, although no one of the best. A great demand for it ha gradually been established, which forces th manufacturers to carry on its production on a large scale, even now, when much better dye-stuffs may be prepared by other methods.

Chemically, this colouring matter may b defined as the higher homologue of parafuchsin, in which one of the phenyl groups has been replaced by a tolyl group:



Ordinary fuchsin

The product of commerce, though chiefly composed of this substance, invariably contains an admixture of parafuchsin as wel as of the higher homologues $C_{21}H_{22}N_3Cl$ and $C_{22}H_{24}N_3Cl$. Like parafuchsin, it contains four molecules of water of crystallisation.

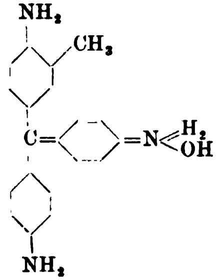
Fuchsin is invariably prepared by oxidisin a mixture of aniline with *p*-toluidine an *o*-toluidine. This mixture is generally known as 'aniline for red,' and was originally produced by the nitration and subsequent reduction of a certain fraction of crude benzene, which consisted of benzene and toluene. Sometime it even contained some xylene; in this ca xylidine entered into the composition of 'anilin for red.' At present most of the 'aniline fo red' is a mixture of pure aniline with crud toluidine. By the latter we mean the mixtur of *o*- and *p*-toluidine which is obtaine by the nitration and subsequent reduction of pure toluene. Crude toluidine consists as a rule of 55 p.c. *o*-toluidine and 45 p.c. *p*-toluidine. The quantity of aniline added to crude toluidine in order to produce the 'aniline oil for red' varies according to the recipes of various manufacturers. As a rule, half of the weight of the toluidine is added. A certain boiling-point (for instance, 188°–200°) and a certain specific gravity (for instance 1·010) are prescribed, and should be strictly adhered to by the aniline oil manufacturer. In some cases an addition of xylidine is necessary in order to produce a product of the desired boiling-point and density. Theoretically, an oil containing equal molecules of the three bases would be required; but for practical work an excess of aniline and *o*-toluidine is used, because a part of these two compounds escapes the reaction, whilst the *p*-toluidine is entirely used up.

Of all the methods which in the course of time have been proposed for oxidising this mixture, only two have survived, one of which is also rapidly disappearing. They are known under the names of the *arsenic acid melt* and the *nitrobenzene process*. From a practical point of view they are of equal value, but the arsenic acid melt is being abandoned on account of the poisonous nature of the arsenic compounds required.

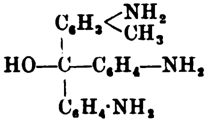
Magenta was originally prepared by Natanson, in 1856, by heating aniline with ethylene chloride. In 1858 Hofmann observed its formation when allowing carbon tetrachloride to act on aniline. In 1859 Verguin prepared it by the action of stannic chloride on aniline. Verguin's employers, the dyers Renard Frères and Franc, in Lyons, took up its manufacture on a large scale, and invented the name *fuchsin*. Later on a company was formed, under the name of 'La Fuchsin,' for working Verguin's patent. Gerber-Keller invented a process for oxidising aniline by means of mercuric nitrate. The dye-stuff thus obtained was believed to be different from fuchsin, and received the name *azalein*. In 1860 Medlock invented the arsenic acid process, which for a long time was considered the only practical method of manufacturing magenta. His patent was invalidated owing to a clerical error contained in the description. In 1869 Coupier described his process for producing fuchsin by the nitrobenzene process. This method, which did not give good results at first, was gradually worked out by various manufacturers, and is now equivalent, if not superior, to the best forms of the arsenic acid process.

Various salts of rosaniline were formerly in commerce. The original fuchsin was the hydrochloride, azalein was the nitrate; whilst magenta and rosein were the names applied to the acetate, produced by Nicholson, the first to manufacture this colouring matter in a practical and rational manner. Gradually the nitrate and acetate disappeared from the market. At present the hydrochloride is the only salt produced, to which, therefore, the original name of fuchsin should be applied. English manufacturers still use the names magenta and rosein for the hydrochloride. A large quantity of the fuchsin manufactured is transformed into rosaniline, which is delivered into the market either under this name or as 'magenta base,' 'red base,' or 'rosein base.' These names are not quite correct, because rosaniline may not strictly be considered as the true base of the hydrochloride of fuchsin.

The true base of fuchsin is



which, in the moment of its formation, undergoes a molecular transformation into



$$\begin{array}{c} C_6H_3{<}^{NH_2}_{CH_3} \\ | \\ HO{-}C{-}C_6H_4{-}NH_2 \\ | \\ C_6H_4{\cdot}NH_2 \end{array}$$

Rosaniline
(Triaminodiphenyltolylcarbinol)

Manufacture of Fuchsin.

1. *Arsenic acid process.* The properties of the 'aniline oil for red' have already been discussed. The mixture of bases known under this name is transformed into the dye-stuff by heating it with arsenic acid. The latter is prepared by oxidising arsenious acid (white arsenic) by means of nitric acid in closed earthenware pots. The escaping nitrous fumes are condensed in a tower, in which they meet an opposing current of water and air. The nitric acid is thus regenerated, and may be used again. Practically, therefore, the formation of the arsenic acid is accomplished by the oxygen of the air. The arsenic acid solution obtained has a sp.gr. of 1·85–2·3, and contains from 60–75 p.c. of arsenic acid H_3AsO_4. 1,500–1,700 kilos of this solution are required in order to oxidise 1,000 kilos of 'aniline oil for red.' These quantities of the reagents are introduced into enamelled cast-iron pots, closed by lids; a mechanical stirrer and a tube for the escape of the vapours should be provided. The mixture is then gradually heated to 180°. This temperature should be strictly maintained during the whole operation. If the temperature rise above 190°, the dye-stuff already formed is decomposed. From eight to ten hours are required in order to complete the reaction. During the whole time vapours escape, which should be condensed in a leaden coil connected with the escape tube, and cooled by a current of water. At first the distillate consists chiefly of the water introduced with the arsenic acid. Later on, the water formed in the reaction distils; at the same time some aniline oil goes over. The total quantity of the aniline escaping the reaction is one-third, or even one-half, of the quantity originally used. The melt, which is very thin at first, gradually becomes viscid; at the same time it assumes a brown, metallic lustre. Samples should be taken from time to time. When the melt becomes brittle on cooling, the reaction is finished, and the fire

should be drawn. The melt is then at once removed from the pot. In some factories an opening is provided for this purpose in the lowest part of the pot, which is closed by a lid and screw whilst the heating lasts. As a rule, however, it is preferred to remove the cover of the pot, and to ladle out the melt. The latter is spread on trays made of sheet iron. On cooling, it solidifies into cakes, which are very brittle, and break up into small lumps on being handled.

The crude melt contains the colouring matter in the shape of arsenite, together with an excess of arsenious and arsenic acids, some coloured by-products (*v. infra*), and a large quantity of tarry impurities. In order to obtain the pure dye-stuff, the crude melt is introduced into horizontal wrought-iron boilers, in which an eccentric horizontal stirrer is made to rotate. Water is added, the lid of the boiler is closed, and steam is introduced at a pressure of from four to five atmospheres. After several hours' vigorous stirring, the greater part of the rosaniline arsenite has been dissolved by the water. The liquid is then forced through felt into iron tanks, where it is allowed to cool down to 50°. A sufficient quantity of salt is then added to precipitate the whole of the colouring matter. By the addition of the salt a mutual decomposition takes place. Sodium arsenite is formed, and remains in the liquid, whilst the colouring matter is precipitated in the shape of chloride. It settles out as a thick green tar of metallic lustre, which solidifies into a brittle substance on cooling. The supernatant aqueous liquid is then drawn off, the crude fuchsin is chipped out, and introduced into another extractor, similar to the one used for treating the melt. A very small quantity of soda ash or chalk (about ½ p.c. of the weight of the crude dye-stuff) is added, and a second extraction takes place. The liquid is again forced through felt into large wooden vats, in which some wooden boards are suspended. When the vats are filled, a small quantity of hydrochloric acid and clean butter-salt is added to each vat. In these vats the dye-stuff separates out, in the shape of fine glistening green crystals. The largest crystals are generally deposited near the surface of the liquid. When the crystallisation is finished, the mother-liquor is drawn off, and the crystals are collected and sorted according to their shape and size. The largest crystals are sold under the name of 'diamond fuchsin.'

By-products. The residues of the first boiling may be subjected to a second extraction; as a rule, some hydrochloric acid is added in this case. A deeply-coloured solution is thus obtained, from which an impure colouring matter may be precipitated by the addition of salt. This colouring matter is sold under various names (*magenta cake, cerise, grenadine, maroon*), and finds a ready market. It dyes a magenta colour, which is less brilliant than the shade obtained with the crystals. A third boiling is sometimes necessary. The colouring matter obtained from this is very impure. It is, therefore, dissolved in weak hydrochloric acid, and some zinc-dust is added, which reduces the magenta contained in the liquid. On precipitating with salt, a colouring matter of a brown shade is obtained, which is sold as 'Nangking,' or 'leather brown.' The black insoluble residue of the third boiling still contains some dark-blue colouring matters of the induline series, which are, however, not worth the trouble of extracting.

The mother-liquors from the crystals contain a yellow colouring matter of great fastness and purity. This substance, known under the name of *phosphine*, belongs to another group of dyestuffs, being a salt of diaminophenylacridine. For extracting it from these mother-liquors, the latter should be acidified with hydrochloric acid, and some zinc-dust added until all the fuchsin present in the liquid is reduced. The phosphine, which is not so easily reduced by zinc dust, may then be precipitated by the addition of sodium nitrate. The amount of phosphine formed varies according to the composition of the aniline oil and the temperature of the melt. It is never considerable, and very often the quantity present is so small that it is not worth while to separate it (*v.* CHRYSANILINE, vol. ii. 63).

Recovery of the arsenious acid. Formerly the residues of the manufacture of magenta were left in the factory yards or thrown into the sea. At present this is not allowed, and the manufacturers are invariably forced to recover their arsenious acid, so as to prevent the poisoning of wells and streams. The recovery, as it is now carried out, is so economical that the value of the arsenious acid obtained covers the cost of working the process. The process, which was worked out by A. Leonhardt, consists in burning the solid residues and using the heat for evaporating the arsenical liquids. The dry residue of the evaporation is introduced into the furnace, and burned along with the solid residues. Care is taken to introduce no more air than is necessary for burning the organic matter. By this precaution a complete volatilisation of the arsenic in the metallic state is obtained. The vapours of arsenic are led into a highly-heated combustion-chamber. Here they are mixed with the necessary quantity of hot air to completely burn the metallic arsenic into arsenious oxide As_4O_6. The vapours of the latter are then led through condensing chambers similar to those used in the manufacture of white arsenic. In these chambers the arsenious acid is deposited in the shape of a white powder. From time to time the chambers are opened, the arsenic is removed, and used again for the manufacture of syrupy arsenic acid by the aid of nitric acid. A certain stock of arsenic is thus sufficient to carry on the manufacture of fuchsin for an indefinite period.

2. *The nitrobenzene process.* This process was originally invented by Coupier, of Paris; but it was for the first time successfully worked on a large scale by the firm of Meister, Lucius und Brüning, of Höchst-am-Main. Other firms followed in the course of time, and at present this process has practically superseded the one with arsenic acid.

It was originally supposed that the nitrobenzene used in this process enters into the rosaniline formed, after having served as an oxidiser. At present it is generally recognised that the nitrobenzene merely acts as an oxidising agent, and that, in so doing, it is transformed into tarry matters, which are useless and remain in the residues. The nature of the nitro compound used is, therefore, of no influence on the composition of the dye-stuffs obtained. Pure nitrobenzene, or a mixture of nitrobenzene with nitrotoluene, may be used. *o*-Nitrotoluene acts more easily than any other nitro compound; it has, therefore, been used with advantage by the writer. *p*-Nitrotoluene has little tendency to act as an oxidiser. If, therefore, a mixture of nitrobenzene with the two nitrotoluenes (the so-called 'nitrobenzol for red') be used, the *p*-nitrotoluene escapes with the distillate.

The advantage of the nitrobenzene process consists, therefore, not in an economy of ingredients, but in the fact that by its application magenta free from arsenic may more easily be obtained. The yield in good crystallised fuchsin is slightly larger (if only the aniline used be taken as basis of the calculation) than in the arsenic acid process. This increase of yield pays for the increased price of the oxidising agent. In times when commercial benzene is cheap the process compares favourably with the arsenic acid process, whilst it was at a disadvantage when the prices of benzene were high. At the present time, benzene is so cheap and plentiful that the nitric acid consumed in this process is perhaps a more important item in the calculation of its cost than the benzene. For working this process it is a condition that the manufacture of aniline be carried on in the same works; the distillates are a mixture of aniline and nitrobenzene, which must be returned into the reduction process before they can be used again.

The process is worked with different proportions and in a different manner in different works. It is based on the following facts: aniline and nitrobenzene do not react upon each other; nor does a reaction take place if aniline hydrochloride be added. But if a small quantity of iron chloride be present, a reaction sets in, at a temperature of 160°. If the aniline and aniline salt used are pure, a dye-stuff of the induline group is obtained; but if *p*-toluidine and *o*-toluidine be present in the necessary proportions ordinary fuchsin is the result of the reaction. The nitro compound, however, attacks the fuchsin already formed, and part of it is therefore decomposed again. For this reason, quantitative yields cannot be obtained. At 190° the action of the nitrobenzene becomes so violent that all the colouring matter is destroyed. The greatest care is, therefore, required in this process, and the temperature should never be allowed to rise over 175°. Cold-air flues, and even arrangements for cooling with water or ice, are therefore invariably provided in connection with the melting-pots. The size of the latter has been constantly increased, because it is easier to keep large vessels at a constant temperature than small ones. Enormous pots, capable of working one or two tons of melt, have been used. Excellent arrangements for stirring should be provided. It is a good plan to make the melting-pots of spherical shape, and to give the stirrer an oblique position in this spherical pot. No water should be present in the mixture, as in this case the nitro compound is simply reduced into aniline by the ferrous chloride, and the reaction stops. The hydrochloric acid used should, therefore, be mixed with the necessary quantity of the aniline and the mixture evaporated until it solidifies into 'aniline salt cake on cooling. Sometimes the iron chloride solution is added, so that the cake obtained is intimately mixed with the iron salt. This cake is then dissolved in the rest of the aniline, the nitro compound added, and the mixture heated until the reaction sets in. Other manufacturers prefer to add iron filings or dry ferrous chloride to the mixture of aniline with aniline cake and nitrobenzene. An ingenious patent, taken out by Herran and Chaudé, proposed the use of certain double salts of the general formula $R_2Cl_6,2RCl_2$, such as ferric ferrous chloride, ferric zinc chloride, aluminium zinc chloride, and others. The addition of iron filings, originally proposed by Coupier, is not customary at present. Anhydrous zinc chloride, which has also been proposed as a means of starting the oxidising action of the nitro compound, has not proved satisfactory.

The following proportions have been proposed:

100 parts aniline for red,
50 „ nitrobenzene,
3–5 „ iron filings,

and a sufficient quantity of hydrochloric acid to neutralise two-thirds of the aniline (Häussermann). The quantity of nitrobenzene is too large; it may very well be reduced to 40 parts, or even less.

Wurtz gives the following proportions:

38 parts aniline,
17–20 „ nitrobenzene,
18–22 „ hydrochloric acid,
2 „ iron filings.

The following is Coupier's mixture:

67 parts toluidine,
95 „ nitrotoluene,
65 „ hydrochloric acid,
7 „ ferrous chloride.

The large quantity of nitrotoluene proposed in this prescription is due to the fact that only the *o*-nitrotoluene, of which about 50 parts are present in the mixture, acts as an oxidiser. The *p*-nitro compound is recovered in the distillate.

The following proportions were used by the writer in regular factory work:

400 kilos aniline for red,
222 „ hydrochloric acid, 20°Bé.,
247 „ *o*-nitrotoluene,

and the ferrous chloride prepared from

9 kilos iron borings, and
41 „ hydrochloric acid.

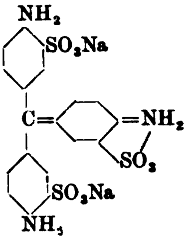
Half of the aniline is dissolved in the 222 kilos of hydrochloric acid, the solution of the ferrous chloride is added, and the whole evaporated in a stone still before being mixed with the remainder of the aniline and the nitrotoluene.

The nitrobenzene melt cannot be pushed so far as the arsenic acid melt. When finished it should not solidify into a brittle mass on cooling. It should be still soft, owing to a proportion of uncombined aniline which it still contains. This aniline must be extracted by boiling with a small quantity of dilute hydrochloric acid. After its removal, the melt becomes brittle on cooling. It is worked up in the Leonhardt extractors, in exactly the same manner as described for the arsenic acid melt.

Later improvements. It has already been said that several synthetical methods have been proposed for the manufacture of magenta, which met, however, with no success. Gradually, however, improvements have been introduced into the old melting processes, which, being based on theoretical considerations, have given favourable results. The most important of these improvements is the one described in the German patent 53937 (and additional patent) of the Farbwerke vorm. Meister, Lucius und Brüning in Höchst-am-Main, dated November 27, 1889. It consists in replacing, in the nitrobenzene process, the 'aniline for red' by a mixture of diaminodiphenylmethane and aniline. The patents refer only to the production of the diaminodiphenylmethane, which is prepared by first acting with formaldehyde (the well-known 'formalin' of commerce) upon aniline. The methylene aniline obtained is heated with aniline and aniline hydrochloride, by which means diamino-diphenylmethane is easily formed. If instead of $C_6H_5N:CH_2$, methylene aniline, any of its higher homologues be heated with the corresponding bases, the homologues of diamino-diphenylmethane are produced. By introducing these bases instead of *p*-toluidine into the magenta melt, very large yields of the dye-stuff are said to be obtained. The dye-stuff prepared by this method is sold under the name of 'Neu-Fuchsin' (new magenta).

Later on a patent was obtained by Cassella & Co., of Frankfurt-am-Main, the essence of which is probably the same. It consists in introducing methyl alcohol into the arsenic acid melt. Formaldehyde is probably thus produced, which is at once transformed into diaminodiphenylmethane. By introducing chlorinated anilines into the pararosaniline melt the chlorine substitution products of rosaniline have been obtained, which are remarkable by being much more bluish in shade than either pararosaniline or ordinary magenta (Cassella & Co., D. R. P. 21923, 1913).

Acid magenta. The ordinary fuchsin or magenta has been used for dyeing cotton, wool, and silk. But its properties make it necessary to use neutral or very slightly acid baths. This is a considerable drawback to its use on silk or wool, especially in combination with other dye-stuffs which require distinctly acid dyebaths for their successful application. It was, therefore, a decided advance to introduce a sulpho derivative of magenta into the market. This step was realised by H. Caro in 1877 (Eng. Pat. 3731, 1877; D. R. P. 2096, Badische Anilin- & Soda-Fabrik). Caro proved that magenta, which shows a marked resistance to ordinary sulphuric acid, may easily be converted into a trisulpho derivative by treatment with fuming sulphuric acid. The ordinary crystallised hydrochloride of magenta is used. It is introduced in a finely-powdered condition into fuming sulphuric acid; the mixture is then heated to a temperature not below 120° and not above 170°. Hydrogen chloride is given off, and the sulpho derivative is formed. When the operation is finished, it is diluted with water and worked up in the usual manner, by first preparing the lime-salt and then converting it into the sodium salt. The para derivative has the composition $C_{19}H_{15}N_3O_{10}S_3Na_2$, the higher homologue $C_{20}H_{17}N_3O_{10}S_3Na_2$: the ordinary acid magenta is a mixture of the two. The constitution of the para derivative may be represented by the following formula:



from which it will be seen that the sulpho-groups occupy the *ortho* positions relative to the amino groups. It forms a metallic green powder, very soluble in water with magenta colour, which disappears completely on addition of caustic alkali, the sulpho derivative of the colourless triamino-triphenyl carbinol being formed.

Acid magenta may also be obtained by acting with chlorosulphonic acid upon dry magenta base (E. Jacobsen, D. R. P. 8764, 1879; Eng. Pat. 2828, 1879).

By using the various by-products of magenta instead of the pure dye-stuff, acid derivatives of these may be obtained which prove particularly valuable for dyeing mixed shades.

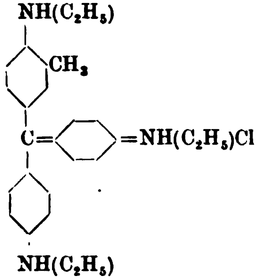
Magenta base (red base, rosein base). A large proportion of the fuchsin produced is transformed into the corresponding base, the composition of which has already been discussed. For the production of a good base, crystallised fuchsin only should be used. This is dissolved in a large volume of boiling water, and made alkaline either with milk of lime or with ammonia. In the latter case, the product obtained consists partly of the amino derivative already mentioned. No caustic alkali should be used. From the filtered solution the base settles out on cooling in crystals, which have the shape of a fern-leaf of pale-pink colour. In the air they generally become darker, because a certain amount of magenta carbonate is formed on their surface. The base thus prepared is sold for conversion into violets and blues (*q.v.*).

COLOURING MATTERS DERIVED FROM ROSANILINE.

The brilliant researches of A. W. Hofmann proved, at an early period, that rosaniline is capable of having the hydrogen atoms of its amino groups replaced by alkyl groups, and that the substances so formed are remarkable not only for the brilliancy, but also for the great variety, of their shades. Hofmann himself introduced the alkyl radicles of the fatty series into the molecule of rosaniline, and thus obtained the colouring matters which for a long time played an important part under the name of Hofmann's violets. Girard and De Laire discovered a method of introducing the phenyl and other aromatic groups into the molecule of rosaniline, and thus inaugurated the manufacture of aniline blues. It was then attempted, first by Lauth, to produce alkylated rosaniline by direct oxidation of alkylated aniline, and this method proved of great practical importance in the hands of Bardy, although the theory of the process was only understood at a much later period. Finally, a synthetical method for the production of certain alkylated rosaniline derivatives which cannot be produced by direct alkylation of rosaniline itself, was discovered by Kern, whose processes are based on the theoretical researches of Michler.

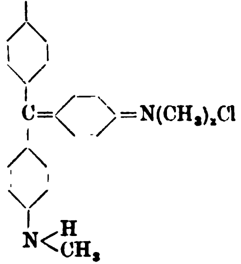
All these colouring matters will now be described, and the methods of their formation discussed.

1. **Hofmann's violet** $C_{26}H_{32}N_3Cl$, hydrochloride of triethyl rosaniline



is obtained by heating magenta base with ethyl iodide, bromide, or chloride, and a sufficient quantity of alcoholic soda solution to neutralise the acid formed in the reaction. The magenta base is prepared by decomposing a very weak fuchsin solution with milk of lime or ammonia. From the filtered solution the base crystallises in small leaflets of a pink colour. The alkylation is effected in closed vessels of copper or cast-iron, which are heated to 80°–100° by steam or in a water-bath. The trimethyl rosaniline hydrochloride, which is slightly bluer in shade, was formerly also prepared. This is no longer employed. By using less of the alkyl haloids than is necessary for completing the reaction, redder shades were obtained, which were mixtures of the mono- and di-ethyl- or methyl-rosanilines. In commerce, the more or less reddish tinge of their shade is marked by the addition of the letter R, thus: Violet R, RR, up to 5 R.

2. **Methyl violet B.** C. Lauth, wishing to find a new method for the production of Hofmann's violets, tried to oxidise methylated aniline. He obtained a violet of much bluer shade. Bardy worked out the method, which was patented by Poirrier and Chappat (Fr. Pat. 71970, dated June 16, 1866). The product obtained was proved to be the hydrochloride of pentamethyl para-rosaniline $C_{24}H_{28}N_3Cl$:—



This dye-stuff, which became of great importance, was for a long time known under the name of *Violet de Paris*. At present it is sold by the various colour works under the name Methyl Violet B to 3 B.

The mode of formation of this colouring matter is very interesting. Many researches have shown that it is best prepared from pure dimethyl aniline, which should be as free as possible from every trace of monomethyl aniline. If three molecules of dimethylaniline be oxidised into one molecule of the dye-stuff, one of the six methyl groups present serves to form the central carbon atom, whilst the other five remain combined with the amino groups of the dye-stuff formed.

The process of oxidation employed is totally different from those resorted to in the manufacture of magenta or fuchsin. Cupric chloride is used as an oxidiser at a temperature which is little above that of the atmosphere. The cuprous chloride formed is again transformed into cupric salt by the oxygen of the air. The air should, therefore, have ready access to the mixture. To fulfil this condition, a porous condition is given to the melt by the admixture of sand or other indifferent materials. Cakes are formed of the mass, and these are left on trays in a hot chamber. The following proportions have been recommended:

100	parts	sand,
10	„	dimethylaniline,
3	„	cupric nitrate,
2	„	sodium chloride,
1	„	weak acetic acid.

The cakes, which show a dull greenish colour at first, gradually assume a bronze lustre and become hard and brittle. They now contain the violet formed as an insoluble compound with cuprous chloride. To obtain the violet, the cakes should be powdered, and all soluble substances extracted with water. The double salt of violet and cuprous chloride should then be decomposed. Various means have been adopted for this purpose.

The original process consists in treating the material with a weak solution of sodium sulphide. Insoluble copper sulphide is formed, and the free violet is dissolved. From the filtered solution it may be precipitated by the addition of salt. It comes out in the shape of a gold-coloured tar of metallic appearance, which is collected and dried in jacketed pans. When dry it forms a brittle mass of metallic aspect, showing no tendency whatever to crystallise. It is sold under the name of 'Methyl violet B' or 'direct violet.'

The use of sodium sulphide has this inconvenience, that any excess of the reagent acts as a reducing agent on the violet, transforming it into its leuco compound, which cannot be separated from the violet, and impairs its strength, besides producing other complications. To remedy this drawback, several factories used gaseous hydrogen sulphide instead of the sodium compound. Hydrogen sulphide has no reducing action on the violet in neutral or slightly acid solutions. The use of this gas on a large scale is, however, extremely dangerous and accidents, which happened repeatedly, have led to the abandonment of its use.

The following methods admit of the extraction of the violet without the use of sulphides.

The first is based on the fact that, although the violet combines with cuprous chloride in the shape of its hydrochloride, this is not the case if the two be present as sulphates. If, therefore, the crude insoluble melt is boiled with dilute sulphuric acid, the violet goes into the solution together with the copper. The solution is then filtered off from the sand. If now salt were added in order to precipitate the violet, the insoluble compound would be re-formed. To prevent this, sodium sulphate (free from chloride) is used for precipitating the violet, which comes out as sulphate, whilst the copper remains in the solution. The violet sulphate is now carefully washed, re-dissolved, and re-precipitated in the shape of chloride by the addition of common salt.

Another process, which gives equally good results, is based upon the fact that the insoluble compound becomes soluble if the cuprous chloride contained in it be oxidised into cupric salt. For this purpose the crude cake is triturated with a solution of ferric chloride. It is then filtered off and washed. The violet, which has become soluble, may now be extracted with water, and precipitated by the addition of salt.

Great improvements have been effected in the melt itself. First of all, it was recognised that the cakes, if left to themselves, were apt to lose too much dimethylaniline by evaporation; they also remained insufficiently oxidised in their interior. To obviate this, the use of bread-kneading machines was resorted to, through which a current of air was blown. This current was made to pass through a vessel containing sulphuric acid, after leaving the machine. Complete oxidation was thus obtained, whilst the base which distilled over was recovered in the acid.

Later on, the quantities of the copper salt were reduced, and some potassium chlorate was added to the mixture. This yielded the necessary oxygen, the presence of a current of air became superfluous, and the evaporation of the base could be stopped by using closed vessels or kneading machines.

Another great inconvenience is the sand. It is necessary as a diluting agent, but in the after-operations it is very troublesome, being very heavy and producing great wear of the apparatus. It was, therefore, a great improvement to use clean salt instead of sand. The salt is quite as indifferent as the sand, but after having done its duty, it may be easily removed by solution, leaving the insoluble compound of the violet and cuprous chloride in the shape of a fine dark powder, which is admirably fitted for being worked up into soluble product.

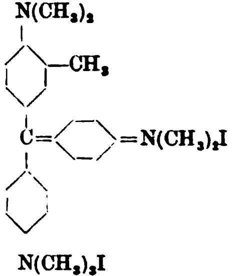
By such improvements it was possible to raise the yield of colouring matter, which at first hardly reached 45 or 50 p.c. of the dimethylaniline used, to 90 p.c. and more. If we remember that 30 p.c. of pure colouring matter is a fair yield in the manufacture of magenta, we may well understand that methyl violet, although manufactured from a much more expensive raw material than fuchsin, soon became much cheaper than its parent substance.

The yields of violet have been further increased by a curious procedure. It consists in adding some phenol to the mixture. The action of the phenol, which may be recovered, is that of a solvent; by its use the yield of violet becomes very nearly theoretical.

In the manufacture of violet, especially by the older methods, there is always some tri- and tetra-methylrosaniline formed along with the penta-methyl derivative, because the methyl groups are attacked, and transformed into formaldehyde, which escapes. The violet is, therefore, slightly redder than it ought to be. To compensate for this loss, Bardy treated his direct violet with benzyl chloride, and thus introduced benzyl groups wherever methyl was wanting. The violet of very blue shade thus obtained was brought into commerce under the name of *Methyl violet 5 B* or *Benzyl violet*. It has now lost its importance, having been to a great extent replaced by the very beautiful crystallised violets obtained by the synthetical method of Kern.

3. Iodine green and **Methyl green.** It has already been said that Hofmann's process of direct alkylation of rosaniline does not go beyond the tri-alkyl derivatives. If the action of alkyl halides be still continued, ammonium bases are formed. Thus by heating Hofmann's violet with methyl iodide in a methyl alcohol solution, Keisser obtained (1866) a green colouring matter, which was manufactured and sold for many years under the name of *iodine green*. A very similar dye-stuff was prepared from methyl-violet in a like manner by Bardy, who used, however, methyl nitrate instead of the iodide. After several explosions, the use of the nitrate was abandoned, and methyl chloride or bromide, also ethyl bromide, were used instead. The dye-stuff thus obtained was sold under the name of *methyl green*. It did not contain any iodine, and was therefore much cheaper than the iodine green, which it quickly replaced.

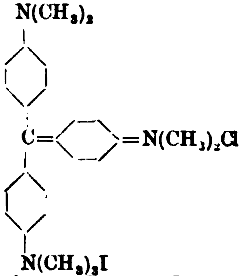
Chemically, the two may be considered as homologues of similar constitution, viz. as methyl ammonium derivatives of hexamethyl-rosaniline and hexamethyl-pararosaniline. Iodine green, being a derivative of ordinary rosaniline, contains one tolyl group:



Iodine green, $C_{27}H_{35}N_3I_2$

The methyl groups in this formula may also partly be replaced by ethyl groups if ordinary Hofmann's violet were used as a raw material.

Methyl green is the corresponding derivative of pararosaniline:



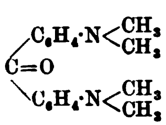
Methyl green $C_{26}H_{33}N_3Cl_2$

Both these dye-stuffs were brought into commerce in the shape of their zinc double chlorides. The iodine green formed a dark powder, whilst the methyl green formed pretty green needles or leaflets.

To prepare these dye-stuffs the violets were simply heated with the alkyl halides in closed enamelled iron vessels to 120°. Some wood spirit, or common alcohol, was added as a solvent. A pressure of 10–12 atmospheres was observed, which decreased when the reaction was finished. The crude product was dissolved in water. This solution was of dark-blue colour, because there was always some violet which remained unattacked. To separate this, the solution was shaken up with amyl alcohol, which dissolved out the violet. The green remained in the aqueous solution, from which it could be precipitated by the addition of zinc chloride and common salt. To obtain crystals, the crude green was re-crystallised from spirit.

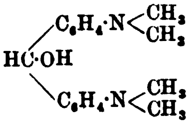
These greens have now almost entirely been replaced by the diaminotriphenylmethane derivatives already described, which are not only more brilliant in shade, but also much more stable and at the same time very much cheaper. Iodine green and methyl green are decomposed and turn a dirty violet even by the action of a gentle heat, as produced in the process of cylindering fabrics, and on many other occasions.

Pararosaniline derivatives prepared by Kern's method. Another way of preparing alkylated pararosanilines was indicated by Kern, who started from the observations published by W. Michler (Ber. 1876, 9, 716). This chemist had shown that by acting with carbonyl chloride $COCl_2$ upon dimethylaniline, dimethylaminobenzoyl chloride is formed, which acts again on dimethylaniline, yielding tetramethyldiaminobenzophenone:



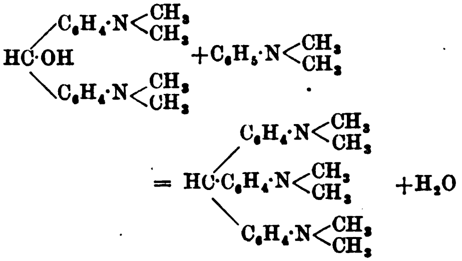
At the same time, as Michler observed, an intense blue colouring matter is formed. A. Kern (1883) followed up Michler's observations, and discovered not only the nature of the blue colouring matter, but also the conditions under which it may be obtained as the sole product of the reaction. The colouring matter proved to be pure hexamethylpararosaniline, the formation of which is due to the action of another molecule of dimethylaniline upon tetramethyldiaminobenzophenone. This action is, however, not very energetic, and must be intensified by the addition of certain substances, or by substituting for the ketone certain of its more active derivatives. A number of different processes have thus been worked out, the more important of which will now be described.

A. Kern's original modification of Michler's experiment is based upon the fact that tetramethyldiaminobenzhydrol, the secondary alcohol derived from the ketone tetramethyldiaminobenzophenone, acts readily upon aromatic bases, forming triphenylmethane derivatives. This process is described in Kern's Eng. Pat. 5450 (1883), and the corresponding D. R. P. 27032, Bad. Anilin- und Soda-Fabrik. Tetramethyldiaminobenzhydrol:



which had already been obtained by Michler by the action of sodium-amalgam upon the ketone may, according to this patent, be prepared industrially by boiling a solution of the ketone in amyl alcohol with caustic soda and zinc-dust. When the reduction is finished, the alcohol is blown off with steam, the residue dissolved in hydrochloric acid, and purified by fractional precipitation with caustic soda.

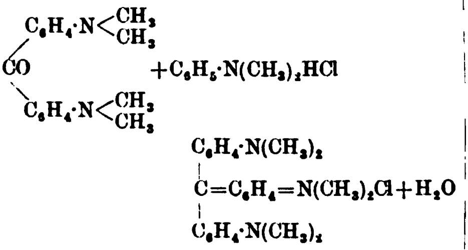
The product thus obtained may be condensed with primary, secondary, and tertiary aromatic bases, yielding in every case alkylated derivatives of paraleucaniline; thus, for instance, with dimethylaniline the leuco base of hexamethylrosaniline is formed, if the two be brought together in a solution in weak sulphuric acid



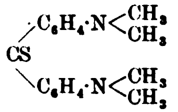
This leuco base may be oxidised into the corresponding dye-stuff by the method indicated for the production of benzaldehyde green—viz. by the action of lead peroxide upon the hydrochloride of the leuco base. The *hexamethylrosaniline hydrochloride* thus obtained is a beautifully crystallised substance, which forms green crystals if anhydrous, $C_{25}H_{30}N_3Cl$, or bronze-coloured prisms if containing water of crystallisation. In the latter case, its composition is $C_{25}H_{30}N_3Cl,8H_2O$. The power of crystallisation of this substance is very remarkable if we compare it with the ordinary violet obtained by direct oxidation of dimethylaniline; this, being a mixture of the tetra-, penta- and hexamethyl-rosanilines, shows no tendency whatever to crystallise.

If in the process described diethyl aniline be substituted for dimethyl aniline, both for the production of the hydrol base and its subsequent transformation, the result is, of course, hexaethylrosaniline, which cannot be prepared by any other process. This product is manufactured and sold under the name of '*Ethyl-purple*, 6 *B*' (ethyl violet). It is a very beautiful colouring matter, dyeing fine bluish-purple shades.

Very soon a simpler method than the one described was discovered by Kern and Caro (D. R. PP. 26016 and 29943; Eng. Pat. 4428, 1883). It was based upon the fact that the action of tetramethyldiaminobenzophenone upon dimethylaniline, which, in Michler's experiment, already had yielded a small amount of colouring matter, may be modified by the addition of certain substances, such as aluminium chloride, zinc chloride, and others. If these be present, the reaction of phosgene gas (carbonyl chloride $COCl_2$) upon dimethylaniline does not result in the formation of tetramethyldiaminobenzophenone; this is only formed as an intermediate product, which reacts at once upon another molecule of the base, forming hexamethylpararosaniline:



Many modifications of the processes here described have also been indicated and patented. Thus, instead of the carbonyl chloride, thiocarbonyl chloride $CSCl_2$ may be used, which yields with dimethylaniline the thioketone



The latter may replace the oxygen compound in all its applications.

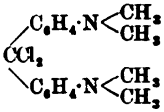
Again, trichloromethyl chloroformate

$$Cl{\cdot}CO{\cdot}O{\cdot}CCl_3$$

and similar substances have been proposed as substitutes for the carbonyl chloride.

The following is the method used at present for preparing *Crystal Violet* and *Ethyl Purple* 6 *B*: 100 kilos of dimethylaniline (or diethylaniline) are acted upon in a high-pressure pot at a temperature of 20° with 18–20 kilos of carbonyl chloride; after 24 hours' standing another 50 kilos of the base and 30 kilos powdered zinc chloride are added. The mixture is now heated to 40°–50°, and 20 kilos more of the carbonyl chloride are introduced. After 6 hours' heating to 50°, the reaction is finished. The mixture is now introduced into a still, made alkaline with caustic soda, and the excess of dimethylaniline driven off with steam. The base of the colouring matter is then dissolved in weak sulphuric acid, and precipitated in the shape of its chloride by the addition of common salt. It is then recrystallised from water.

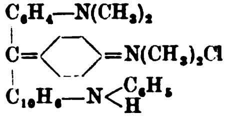
This process leads, of course, only to pararosaniline derivatives in which the three amino-groups are substituted in the same manner. Besides the hexamethyl- and hexa-ethyl derivatives, the trimethyltriphenyl derivative has been obtained from methyldiphenylamine (Amer. Pat. 327953, Kern and C. Müller). It was, therefore, a great improvement when a method was found for effecting the condensation of tetramethyldiaminobenzophenone with all kinds of primary, secondary, and tertiary bases. This method, which was worked out by Kern and H. Caro, consists in the intermediate formation of the tetramethyldiaminobenzophenone chloride:



which, being much more active than the ketone itself, reacts most easily upon bases of every description. For the manufacture of colouring matters it is not necessary to isolate the chloride, an extremely unstable substance. It is sufficient to react with phosphorus trichloride upon a mixture of the ketone with the base which is to be introduced into the triphenylmethane derivative.

This process is described in the D. R. P. 277891, the Eng. Pats. 4850 and 5038, 1884, and a large number of corresponding American patents, which contain many examples of its application to the production of dye-stuffs. Of these, however, only few have obtained lasting importance. These are basic colouring matters of a beautiful blue shade, and interesting because they are the only members of the triphenylmethane group which contain the naphthyl radicle.

Victoria blue B $C_{33}H_{32}N_3Cl$ has the constitutional formula:



It is prepared by mixing together

10 kilos tetramethyldiaminobenzophenone and

9 kilos α-naphthylphenylamine,

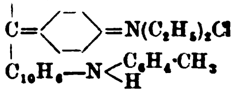
and adding

7 kilos phosphorus trichloride to the mixture.

The reaction, which sets in at once, is finished by heating to 110°. The product is dissolved in water, and the solution precipitated with salt.

A similar dye-stuff, analogous in its constitution, but of a somewhat more reddish shade, is obtained if instead of α-naphthylphenylamine, monoethyl-α-naphthylamine be used. It is known under the name *New Victoria blue R*.

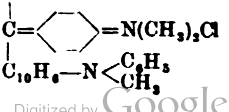
If α-naphthyl-*p*-tolylamine be taken instead of the naphthylphenylamine, and condensed with tetra-ethyldiaminobenzophenone, a blue of a very greenish shade is obtained. It is sold under the name *Night blue* (*Nachtblau*) and has the composition $C_{38}H_{42}N_3Cl$:



Another blue of very red shade is the one sold under the name *Victoria blue* 4 *R*

$$C_{34}H_{34}N_3Cl.$$

It is prepared from tetramethyldiaminobenzophenone and α-naphthylmethylphenylamine. Its constitution is probably



In describing both the green dye-stuffs derived from diaminotriphenylmethane and the old and important magenta group, it has been mentioned how much the dyer values the possibility of dyeing the useful shades which these colouring matters supply from an acid bath and of thus being enabled to combine them with all the other wool dyes capable of such application, especially the azo colouring matters. The same necessity exists for the various shades of violet here described.

This want was at first supplied by the means which had proved successful in the case of magenta, viz. by the direct sulphonation with fuming sulphuric acid of the various violets, especially the redder shades obtained by the reaction of alkyl halides upon magenta base. The colouring matters thus produced were introduced at the end of the seventies under the name of *Acid violets* to which letters denoting the shade (R and B) were added. But they did not meet with the same ready reception that had been offered to acid magenta. It is now known that the sulphuric anhydride of the fuming acid is very apt to attack the alkyl groups and thus to tarnish the shade of the violets.

The new synthetical method which had produced *Crystal violet* and its many congeners and which is apparently analogous to the synthesis of *Victoria green* and its numerous homologues, could not fail also to indicate rational methods for the production of acid violets of every conceivable shade.

Some of these methods consisted—in strict analogy to what had been done in the group of the *greens*—in introducing the benzyl group into the molecule of the dye-stuff and utilising the capacity of this radicle for sulphonation. All the variations of this method given in the description of the acid greens are admissible in the violet group. In this way the following dye-stuffs have been obtained, the structural formulae of which need not be given :—

Acid violet 4BN, *6B*, *7B* and *N*, prepared by the sulphonation of pentamethylbenzyl-pararosaniline or by the oxidation of the monosulpho derivative of pentamethylbenzyl-leucaniline.

Acid violet 6B or Guinea violet 4B. This is a disulpho derivative, obtained by oxidising the acid, which may be obtained by the condensation of dimethyl-*p*-aminobenzaldehyde with ethylbenzylaniline-sulphonic acid. The corresponding derivative of diethyl-*p*-aminobenzaldehyde is also manufactured.

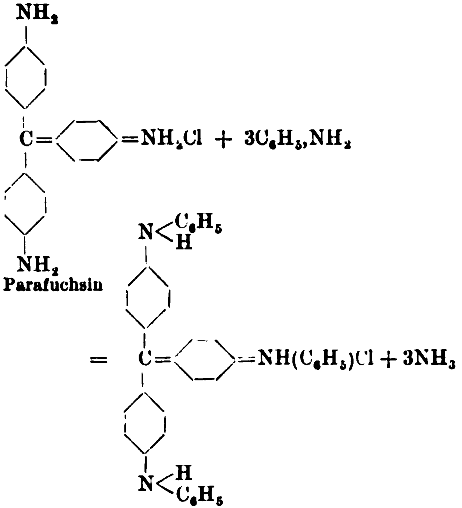
Another class of acid violets is derived from methyldiphenylamine, which may be introduced instead of dimethylaniline by all the synthetical processes described. The additional phenyl group entering into the molecule of the leuco base or the dye-stuff derived from it by oxidation is capable of carrying a sulpho group which may be introduced into it by the usual means. Thus *Alkali violet 6B* and *Acid violet 7B* can be prepared, whilst in *Acid violet 7BN* ready formed methyldiphenylsulphonic acid is condensed with dimethyl-*p*-aminobenzoic acid.

The process of introducing elements capable of being sulphonated into the synthesis of rosaniline derivatives may be carried still farther. Thus a useful dye-stuff, called *Wool green*, is manufactured by several firms by condensing tetramethyldiaminobenzophenone (Michler's ketone) with β-naphthol and subsequently sulphonating the insoluble dye-stuff so obtained.

Rosaniline blues or **phenylated rosanilines.** These are of great importance, forming by far the majority of blue aniline dyes in the market. The chemistry of these compounds is, however, extremely complicated. The blues sent into commerce are not chemically pure substances, but mixtures of various isomerides; it is very difficult to classify them. Moreover, they are known under a great variety of fancy names, many of which are applied to products of different composition by different firms. The following is an attempt to classify the various blues.

It has already been shown that a considerable difference exists between pararosaniline hydrochloride or parafuchsin and the ordinary fuchsin of commerce. The former is a uniform compound $C_{19}H_{18}N_3Cl,4H_2O$, whilst the latter is a mixture of parafuchsin with at least two isomeric homologues. Both these substances may be phenylated; their phenyl derivatives are blue colouring matters of great intensity and beauty. But a greater difference is found to exist between the phenyl derivatives of pararosaniline and those of ordinary magenta than even between the two kinds of fuchsin themselves.

The method of phenylation is very remarkable, and quite different from the methods of substituting fatty radicles for hydrogen in the amino groups of rosaniline. The general method in this case consisted in treating rosaniline base with the halogen derivatives of these radicles. Owing to the great stability of chlorobenzene C_6H_5Cl, the same process cannot be applied to the phenylation of rosaniline. This takes place, however, with great facility if we allow aniline to act upon rosaniline, ammonia being given off as a by-product :



Triphenyl-pararosaniline hydrochloride
(Rosaniline blue)

This method of phenylation, which has been indicated by Ch. Girard and G. de Laire, is invariably resorted to. It cannot, however, be applied on a practical scale to the hydrochloride, as assumed for simplicity's sake in our equation. Experience has shown that organic acids must be used in order to get good results. The majority of organic acids have been tried for the purpose; at present, however, only two are used, which give distinctly different results, viz. acetic and benzoic acids. The reason for this difference has not been definitely ascertained, but it is a fact known to every manufacturer that blues of a greenish shade can only be obtained with benzoic acid, whereas acetic acid yields more reddish compounds.

The phenylation of rosaniline cannot be pushed further than the formation of triphenylrosaniline. The tetra-, penta-, and hexaphenyl derivatives are not known. But even the formation of triphenylrosaniline, such as it is indicated by our equation, takes place in three successive stages, the phenyl groups entering the molecule one after another. It is, however, practically impossible to separate these stages. If, in the beginning of a blue melt, a certain amount of mono-phenylrosaniline be formed, the reaction proceeds simultaneously on this and on rosaniline, which has not yet been attacked; thus, in a second phase, monophenyl and diphenyl rosaniline, and rosaniline (which has not yet been attacked) will be present together. To these the triphenyl compound will presently be added, a very complex mixture being the result. By a more prolonged action it is possible to eliminate rosaniline itself and its monophenyl derivatives completely from the mixture. But some diphenylrosaniline will always remain present. Moreover, all these compounds seem to exist in various isomeric modifications. It is a mixture of these which forms the ordinary *crude* or *Opal blue.*

If, instead of pararosaniline, the ordinary rosaniline of commerce be used for the production of the blue (as is the case in most instances) the product becomes even more complicated by the presence of the homologous compounds. Some process of separation which splits up the crude product into fractions of different shades and reactions must be resorted to; and although some of these are crystallised, it cannot be said with certainty that they represent chemically pure individuals.

Mono- and di- phenylpararosaniline have hitherto not been prepared in a pure state. Nothing can, therefore, be said of their properties.

Triphenylpararosaniline hydrochloride

$C_{37}H_{30}N_3Cl$

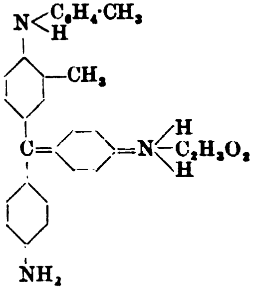
is the purest and brightest blue known. It is now invariably prepared by the phenylation of pararosaniline, but it may also be obtained by melting together diphenylamine and oxalic acid. The formic acid evolved in the decomposition of oxalic acid serves to link together three molecules of diphenylamine into one of triphenyl leuco aniline, which is then slowly oxidised into the rosaniline compound. It was this method which was formerly used for the production of this blue, which therefore is still frequently described as *Diphenylamine blue*; it is also sometimes called *Methyl blue*, because methyldiphenylamine was occasionally used for its production. Other names for the same product are:

Bleu direct, bleu lumière, bleu de Lyon, bleu de Mulhouse, bleu de nuit, bleu de Paris, light blue, night blue, Paris blue, Bavarian blue.

This product forms a microcrystalline powder of a bronzy appearance, completely insoluble in water, sparingly soluble, with a brilliant blue colour, in spirit. Its transformation into the soluble diphenylamine blues of commerce will be described hereafter.

When the same process of phenylation (the particulars of which will be given below) is applied to the ordinary rosaniline of commerce—which is, as will be remembered, a mixture—various products are obtained. Of these the following may be said to have been isolated:—

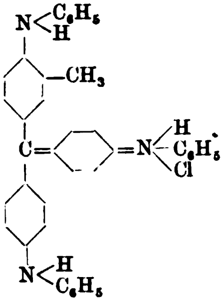
Monophenyl rosanilines. These are the product of a very moderate phenylation. They are still soluble, in the shape of their acetates, in water, and dye fine purple shades. They have now, owing to the greater cheapness of methyl violets, almost completely disappeared from the market, in which they formerly played an important part under the name of *Regina purples* or *Regina violets.* It was customary to prepare them, not by the action of pure aniline on magenta acetate, but rather by that of the recovered oils or *échappés* from the magenta process, which contained a large proportion of o-toluidine. The action of the latter is slower than that of aniline; it is, therefore, easier to stop the reaction before a considerable proportion of the diphenyl or ditolyl rosaniline is formed. The regina purples consisted, therefore, to a great extent of the *o*-tolylrosaniline, the acetate of which is represented by the following formula:



Regina purple

Diphenylrosanilines. These were invariably obtained, together with the regina purples, from which they are distinguished by their complete insolubility in water. They are, however, still of a purple shade; they are invariably present to some extent in crude tri-phenylrosaniline blue, if the latter be prepared with acetic instead of benzoic acid. This is the reason why such blue is always of a redder shade than the blue prepared with benzoic acid, in which the proportion of diphenyl derivatives is reduced to a minimum. A product which consists chiefly of diphenyl rosanilines, is known under the name of *spirit purple, spirit violet*, or *opal violet*; it has also been sold as *regina spirit purple.* From it the *soluble violets* and *purples* and *alkaline purples* of commerce are derived by sulphonation.

Triphenylrosanilines. The triphenyl derivatives of ordinary rosaniline may be subdivided into two classes: crystalline and uncrystallisable blues. The former may be extracted from every crude blue melt prepared with benzoic acid. They represent in a state of approximate purity the triphenyl derivative of the higher homologue of pararosaniline, and may therefore be represented by the following formula:



It is to this product, which forms the base of the high-class alkaline and water blues of commerce, that one should reserve the name of *Opal blue*, which has, however, been indiscriminately applied to a number of various products. This opal blue forms, in the shape of its pure hydrochloride, a mass of distinct, though very small, glistening crystals of a greenish brass-colour. It is completely insoluble in water and in spirit. If it be treated with alcoholic caustic soda, the free base is obtained in the shape of a tarry substance from which the acetate may be prepared by dissolving it in glacial acetic acid, and re-precipitating with water. This acetate is soluble in spirit, and, though sparingly, also in water. It was formerly sold and used under the name of *Opal blue* 6 *B for cotton*, *Gentian blue*, *Hessian blue*; also the names of *Bleu lumière*, *Bleu de nuit* (originally used for the para derivative), were occasionally applied to it. In Germany it was sold under the name of *Feinblau*, *Sprit-blau*. The latter expression is applied, however, to all blues soluble in spirit, not only to this acetate. Its use has been much restricted of late, owing to the unwillingness of the dyer to use spirit in the dye-bath.

The second class of triphenyl derivatives of ordinary rosaniline, comprises the uncrystallisable portions of crude blue melts. They contain a mixture of triphenyl- and diphenylrosanilines in various proportions, quite inseparable by the means which are at our disposal. They are (in the shape of hydrochlorides) insoluble in water, soluble in spirit. Caustic soda transforms them into a mixture of the corresponding bases, which are tarry masses. Their shade varies from a purplish-blue to a distinct clear blue of great strength and purity which, however, always shows a purplish hue if looked at by artificial light. This blue forms the starting-point for the production of innumerable brands and qualities of alkaline and water blues, varying in their shade and in the purity and strength of their colour. They are designated, according to the redness of shade, by the letters 3 R, 2 R, R, B, 2 B, and 3 B, whilst 4 B, 5 B, and 6 B may be said to be reserved for the derivatives of the true opal blue of varying purity. A large number of fancy names, such as *China blue*, *Marine blue*, *Serge blue*, &c., have been invented for this kind of blues.

Besides these blues a special kind of low-class blue should be mentioned which, under the name of *Blackley blue*, has enjoyed, and still enjoys, much favour, especially for dyeing paper-pulp, and also for the production of cheap woollen materials. This is the sulphonation product of a peculiar kind of phenyl rosaniline, prepared by acting with aniline upon crude magenta. It is consequently very impure, but also very cheap. It contains a mixture of the phenylation products of all the substances contained in crude magenta.

Tri-*p*-tolylrosaniline has been prepared by acting with *p*-toluidine in the presence of benzoic acid upon ordinary rosaniline base. It is a blue of remarkable beauty and brilliancy of shade, which offers, however, great resistance to the process of sulphonation. It has, therefore, only been manufactured and sold in the shape of its hydrochloride, which is soluble in spirit. It is sold for dyeing cotton under the name of *Grünlichblau* (Höchst) or 6 *B extra opal blue* (English manufacturers). It has largely gone out of use of late years.

Manufacture of blues. An immense number of prescriptions for blue melts has been published, and a larger number still circulates amongst manufacturers. It would be perfectly useless to reproduce any of them. The principles upon which they are based may be thus briefly stated:—

For the production of good blues a perfectly pure magenta base is the first requirement. For its preparation crystallised fuchsin only should be employed. If crude magenta or any of the magenta residues (*cerise*, *grenadine*, &c.) be used, the base obtained can only be employed for the production of *Blackley blues*. Pure pararosaniline, the base prepared from parafuchsin (*Neu-fuchsin*), should be used for the production of the so-called diphenylamine or methyl-blues (direct blues); whilst crystallised base from ordinary fuchsin forms the starting-point for all the ordinary blues from 4 R to 6 B, as well as for regina purples.

The second condition for the production of good blues is the use of very pure aniline, perfectly free from toluidine. It is in the manufacture of blues that the necessity of operating with pure aniline was first felt. The term *aniline for blue* was, therefore, and is still occasionally, applied to perfectly pure aniline, boiling within one degree, and having a specific gravity of 1·0268–1·0270. Such aniline can only be prepared from pure crystallisable benzene.

If these two conditions—pure magenta base and pure aniline—be fulfilled, the shade of the blue obtained is still dependent upon:

1. The proportions of base and of aniline in the melt. It may be said that greenish blues will only be obtained if a very large excess of aniline be used, whilst reddish blues are produced in melts rich in magenta base.

2. The time and temperature of the melt. The formation of blue begins below 100°. It proceeds quickly at a higher temperature; 120°–140° may be assumed to be the most favourable temperature. From 140°–180° certain impurities (diphenylamine ?) are formed, which impair the tendency of crystallisation of the blue. The temperature of high-class blue melts should therefore not be raised above 140°. The

time required by a blue melt depends upon the proportion of base to aniline, and, to some extent, the quantities operated upon. The process proceeds quickly in highly-concentrated melts. Melts for high-class blues, which contain a large proportion of aniline, require prolonged heating —20 hours, and even more, before being finished. As a rule, the progress of the melt is tested by placing a drop of the melt on filter paper moistened with spirit. The gradual change of colour may thus be observed with great accuracy. When the melt is finished, there should be no reddish rim visible in the spot produced on the paper.

3. The nature and proportion of the acid used in the melt. It has already been said that organic acids only should be used, the action of hydrochloric acid being too slow. Acetic and benzoic acids are now used exclusively. The action of acetic acid is quicker than that of benzoic acid, but it seems impossible to transform all the rosaniline into its triphenyl derivative by the use of acetic acid. Benzoic acid acts more slowly, but it continues its action until all the rosaniline is transformed into the triphenyl derivative. At the same time, the whole of the melt is, even with benzoic acid, not entirely transformed into crystallisable opal. Moreover, acetic acid produces (by its simultaneous reaction on aniline) some acetanilide, which remains in the blue and is apt to prevent its subsequent crystallisation, whilst no benzanilide is formed by heating aniline with benzoic acid. For these reasons acetic acid is employed in the production of low-class reddish-blues (in concentrated melts), whilst benzoic acid is used only for the production of high-class opals. The greater part of the benzoic acid may be recovered from the melt, whilst the recovery of the acetic acid does not pay.

There is no advantage in using other acids instead of acetic and benzoic acid. As a rule, it may be said that the fatty acids (formic, butyric, valeric acids) act similarly to acetic acid, whilst the aromatic acids (toluic, phthalic, cinnamic acids) may take the place of the benzoic acid.

Upon these conditions all the prescriptions for blue melts are based. Taking the quantity of magenta base to be operated upon as unity, the quantity of aniline added varies from four to twenty-five times its weight, the quantity of the organic acid from $\frac{1}{10}$ to $\frac{1}{2}$. The conditions of time and temperature have already been stated.

The apparatus necessary for blue-making is very simple so far as the melt is concerned, enamelled cast-iron pots with a lid and stirrer being always used. In the early times of the manufacture of aniline colours it was believed that blue melts could only be made in glass, and on a very small scale. In the 'Fuchsin' factory at Lyons the blue was therefore manufactured in large numbers of glass flasks heated in a sand-bath. At present it is believed that blue melts are best under control in large quantities; large melting-pots are therefore used as a rule. While the melt is in progress ammonia is given off, which carries a certain amount of aniline away. It is advisable to condense this aniline, and to absorb the ammonia by water or sulphuric acid.

When the melt is finished it must be worked up. This may be done by a variety of methods. Of these the simplest—which is, as a rule, resorted to in the manufacture of low-class and Blackley blues—consists in neutralising the melt with a quantity of caustic soda just sufficient to saturate the acid added to the melt. The excess of the aniline is then driven off with steam and recovered. The blue base remains in the still, and is run out whilst still hot, in a tarry state, together with the water. On cooling, it solidifies into a very brittle mass, which may be powdered, dried, and subjected to the process of sulphonation to be described hereafter.

For the production of high-class blues this simple process cannot be adopted. A separation of the crystallisable opal from the uncrystallisable blue, which invariably accompanies it, must take place, and for this separation the melt requires a special treatment. For this there are two distinct processes, of which one is very complete, although costly, because it requires large quantities of spirit. We may call it the *English process*, because it was worked and carried out chiefly in English factories. The other process, which is now used in most of the German works, is very rapid, and requires but little spirit. On the other hand, it does not give so pure a product; we may call it the *German process*.

The English process is the final outcome of the original French process for working up the blue melts, which consisted in boiling them out with dilute hydrochloric acid. The aniline was dissolved out together with the organic acid present, whilst the blue remained in the shape of its hydrochloride as a fine blue precipitate, which was filtered off and washed. It was then ready for sulphonation. When it was discovered that this blue was a mixture of different colouring matters it became customary to separate these by boiling the crude blue with spirit. This dissolved out the lower-class blues, leaving a better product as a residue. By repeating this process frequently, a residue was obtained at last which was quite insoluble in spirit. This represented the purest opal blue obtainable. It was by this tedious process that the once famous 'Bleu Mavi,' or 'Bleu MAVI' was obtained in France and Switzerland. The improved English process much simplified things, and at the same time gave better yields and a purer colour by producing the opal blue in a crystallised condition, in which it is totally insoluble in spirit. This process consisted in adding to the melt (prepared with benzoic acid and a large excess of aniline), while still hot, a certain quantity of aniline hydrochloride; on cooling, the opal blue, being gradually converted into the hydrochloride, settled out in small glistening crystals, whilst the low-class blue remained dissolved in the aniline. The opal was then filtered off, and washed with spirit until quite pure. If necessary, it could be re-converted into base by treatment with alcoholic caustic soda. The base, re-dissolved in aniline, could again be converted into hydrochloride by again adding aniline hydrochloride. The opal then came out in very fine crystals, which represented the blue in a state of greatest purity. The aniline liquors obtained from these crystallisations had to be distilled in order to recover the spirit. They were then made alkaline in order to decompose the aniline hydrochloride present, the aniline was driven off by steam, and the remaining low-class blue obtained in the shape of base as described. Owing to the large quantities of spirit used for washing the crystallised opal, and the consequent loss of spirit by evaporation, this process (which may be recommended for laboratory experiments) was costly, and unable to compete with the rapid and cheap German process.

The German process is based upon the fact that the crystallisable blue opal is insoluble in a very hot solution of aniline hydrochloride, whilst the common non-crystallisable blues are soluble in this liquid. The solution of the aniline salt must, however, be so concentrated (in order to act properly) that it would solidify into a mass of crystals if cooled in the least degree. It is rather fused aniline hydrochloride that is required, and not an actual solution of the salt in water. In order to operate properly with such liquids, closed vessels must be used. The following is the principle upon which the plant in the majority of German works is constructed.

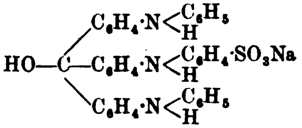
Near the melting-pot a battery of closed iron vessels, lined with lead, is erected. The first of these is filled with a quantity of hydrochloric acid, just sufficient to neutralise the aniline contained in the blue melt. The melt, when finished, is introduced into this vessel by means of air pressure. The vessel is fitted with a stirrer, which stirs up the mixture into a homogeneous mass. This is then pressed into a second vessel, which contains some filtering arrangement, upon which the blue crystals are deposited. The liquid which issues from this vessel is diluted with water, when the common blue hitherto dissolved in it is quickly deposited. The blue crystals remaining on the filter are washed with water, and may be purified by boiling them with spirit.

Blues soluble in water. Very little of the blue that is manufactured is used in the opal state, viz. soluble in spirit. By far the largest proportion of it must be transformed into products soluble in water in order to become a marketable article. For this purpose sulphonation is resorted to.

The sulphonation of triphenylrosaniline takes place very easily, the phenyl radicles attached to the amino groups being readily substituted by the sulpho group SO_3H. As there are three of these phenyl radicles present, three sulpho groups may be introduced into the molecule of the blue. The pure, crystallisable, high-class opal blue is more easily sulphonated than the common blues. The sulphonation takes place in progressive stages, one sulpho group being introduced after the other. It is difficult to introduce more than two sulpho groups by the use of ordinary sulphuric acid. Fuming sulphuric acid must be resorted to in order to produce the trisulpho derivative. As this, however, is hardly ever required, being much too soluble for the purposes of the dyer, common sulphuric acid is invariably used, but the 'extra-strong' quality of 95–97 p.c. H_2SO_4 is, as a rule, preferred.

If this acid be allowed to act upon an aniline blue, the reaction begins at about 30° and results at first in the formation of the monosulpho derivative. The following are its properties:

In the free state triphenylrosaniline monosulphonic acid forms blue flakes, which are quite insoluble in water, in a solution of sodium bicarbonate, or even in weak ammonia. Sodium carbonate dissolves it on boiling; caustic soda in the cold. The solutions are perfectly colourless. They contain, in fact, the sodium salt of monosulphotriphenyltriaminotriphenylcarbinol:



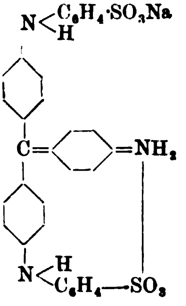
The dry sodium salt is jet black.

This compound has the curious property of combining with wool in an alkaline bath. The wool remains colourless, but after being washed with water it becomes brilliantly blue if immersed in weak sulphuric acid.

This curious property, discovered by Nicholson, has been made use of by wool dyers, who prefer the 'alkaline' or 'Nicholson' blues to all others for the production of bright and brilliant blues.

The alkaline blues originally manufactured by Nicholson and other makers were as nearly as possible the pure sodium salts of the monosulpho derivative. Owing to the difficulty of dissolving them even in boiling water, another kind of alkaline blues was produced later on; these new alkaline blues contain a proportion of the disulpho derivative. They form blue powders, easily soluble in water, giving a solution which is distinctly blue. The use of these new alkaline blues is exactly similar to that of the old quality.

If the sulphonation of the opal blue be carried farther by raising the temperature and allowing the reaction to continue for a longer period, the monosulpho acid gradually disappears and is replaced by the disulpho derivative. This is insoluble in weak sulphuric acid, but rather soluble in pure water, with an intensely blue colour. Its sodium salt forms bright coppery masses soluble in water with a blue colour. This salt contains probably the compound represented by the following formula:



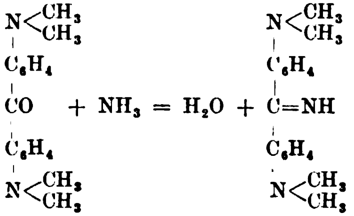
The disulpho derivatives of the various classes of triphenyl-rosanilines are known under the names of *Cotton blue, Water blue, China blue, Navy blue, Guernsey blue,* and many others, which are again sub-divided by the use of the letters R and B. Thus a 6B cotton blue is the disulpho acid of a very high-class, crystallisable Opal blue, whilst a 4R Guernsey or Navy blue would be a reddish-tinted blue, manufactured from an opal prepared with acetic acid and a small excess of aniline in the melt.

The process of sulphonation, though very simple in theory, requires great care and attention on the part of the manufacturer. The sulphonation is carried on in cast-iron pots into which the necessary quantity of sulphuric acid is introduced. The opal blue, which should be finely powdered and perfectly dry, is then stirred in, and the temperature raised gradually. Samples should be drawn from time to time, and the precipitate produced by the addition of water must be examined as to its solubility in water, weak ammonia, sodium carbonate, and caustic soda. When the desired degree of solubility is obtained, the liquid is poured into water, and the blues filtered off and carefully washed. When quite free from acid, they are dissolved in the necessary quantity of caustic soda; the solution is then filtered, and evaporated to dryness in jacketed pans. Cotton blues should be freed from the excess of sulphuric acid by the addition of slaked lime. The solution of the calcium salt is filtered and converted into the sodium salt by double decomposition with sodium carbonate. After another filtration, the solution of the blue is evaporated to dryness. Certain artifices are required to produce porous masses, such as the brand known as *China blue*, which is manufactured for export, and is required to possess a given bulk for a given weight.

Appendix to basic triphenylmethane colouring matters.

Auramine. This dye-stuff, although a derivative of diphenylmethane, is so closely connected with the manufacture of crystallisable violet that it cannot be omitted from this article.

It has been shown that crystal violet, as well as Victoria blue and other dye-stuffs, are manufactured from dimethyl and diethyl diaminobenzophenone. Now, if these ketones be heated with ammonium chloride in the presence of zinc chloride, an interesting reaction takes place at the temperature of 150°–160°. The oxygen of the ketone is replaced by the imino group NH, thus:



$$\begin{array}{c} N{<}^{CH_3}_{CH_3} \\ | \\ C_6H_4 \\ | \\ CO \\ | \\ C_6H_4 \\ | \\ N{<}^{CH_3}_{CH_3} \end{array} + NH_3 = H_2O + \begin{array}{c} N{<}^{CH_3}_{CH_3} \\ | \\ C_6H_4 \\ | \\ C{=}NH \\ | \\ C_6H_4 \\ | \\ N{<}^{CH_3}_{CH_3} \end{array}$$

The imides thus obtained are yellow colouring matters, and have received the name of *auramines*. The auramine of commerce is iminotetramethyl-di-*p*-amino-diphenylmethane hydrochloride, containing one molecule of water of crystallisation:

$$C_{17}H_{21}N_3{\cdot}HCl,H_2O.$$

It forms a yellow powder easily soluble in water. It is exclusively used for dyeing and printing on cotton.

Substituted auramines may be obtained by using the hydrochlorides of primary bases instead of sal-ammoniac. Thus a phenylat auramine of orange colour may be produced by acting with aniline hydrochloride upon tetramethyldiaminobenzophenone.

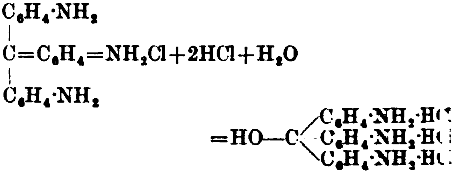
The auramines were discovered by Caro and Kern in 1884. They form the subject of the Eng. Pats. 5512, 1884, and 5741, 1884, and the D.R.PP. 29060 and 31936. (*See* art. AURAMINE, vol. i. 338.)

II. THE AURIN GROUP.

The members of this group contain oxygen in the place of the pentavalent nitrogen of the preceding one. If magenta and its congeners may be considered as quinone-imides, the aurins are the corresponding quinones.

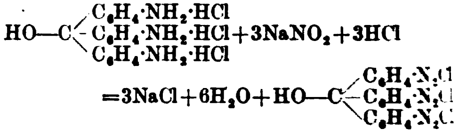
The generic relation between the fuchsin and the aurin groups will be best seen by showing how the typical representative of the former, parafuchsin, may be transformed into the first representative of the aurin group, aurin itself.

We know that parafuchsin, if treated with an excess of acid, is transformed into the triacid salt of triaminotriphenylcarbinol:



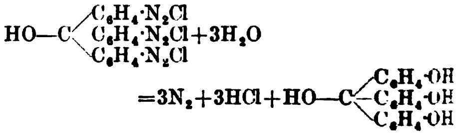
$$\begin{array}{l} C_6H_4{\cdot}NH_2 \\ | \\ C{=}C_6H_4{=}NH_2Cl+2HCl+H_2O \\ | \\ C_6H_4{\cdot}NH_2 \end{array} = HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}NH_2{\cdot}HCl \\ {-}C_6H_4{\cdot}NH_2{\cdot}HCl \\ \diagdown C_6H_4{\cdot}NH_2{\cdot}HCl \end{array}}$$

Now this salt, if treated with nitrous acid, is transformed into the corresponding diazonium compound.



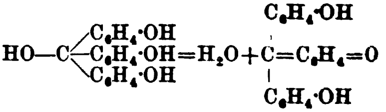
$$HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}NH_2{\cdot}HCl \\ {-}C_6H_4{\cdot}NH_2{\cdot}HCl \\ \diagdown C_6H_4{\cdot}NH_2{\cdot}HCl \end{array}}+3NaNO_2+3HCl = 3NaCl+6H_2O+HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}N_2Cl \\ {-}C_6H_4{\cdot}N_2Cl \\ \diagdown C_6H_4{\cdot}N_2Cl \end{array}}$$

This, on being boiled with water, loses nitrogen and is transformed into trihydroxytriphenylcarbinol



$$HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}N_2Cl \\ {-}C_6H_4{\cdot}N_2Cl \\ \diagdown C_6H_4{\cdot}N_2Cl \end{array}}+3H_2O = 3N_2+3HCl+HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}OH \\ {-}C_6H_4{\cdot}OH \\ \diagdown C_6H_4{\cdot}OH \end{array}}$$

The latter loses, in *statu nascendi*, one molecule of water, being transformed into its inner anhydride, aurin:



$$HO{-}C{\begin{array}{l} \diagup C_6H_4{\cdot}OH \\ {-}C_6H_4{\cdot}OH \\ \diagdown C_6H_4{\cdot}OH \end{array}} = H_2O+\begin{array}{l} C_6H_4{\cdot}OH \\ | \\ C{=}C_6H_4{=}O \\ | \\ C_6H_4{\cdot}OH \end{array}$$

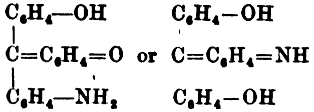
Thus aurin is parafuchsin in which all nitrogen has been replaced by oxygen.

This mode of formation has long been known, not for aurin itself, but for its higher homologue, rosolic acid, which was prepared from the ordinary fuchsin or magenta by the process described. The many co-ordinate points of aurin and rosolic acid were recognised at an early period. On the other hand, chemists were aware of the distinct difference between aurin and rosolic acid, which is just as considerable as that existing between parafuchsin and its higher homologue.

When an insight into the nature of the fuchsin group had been obtained, the knowledge of the constitution of the aurin group followed as a natural consequence.

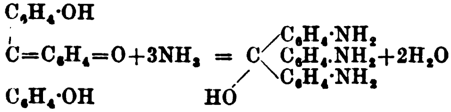
But even before this was the case, another connection was discovered between aurin and fuchsin.

It had long been known that aurin (the mode of formation of which will be given later on) may be modified by heating it with alcoholic ammonia. F. Persoz produced a red dye-stuff, which he called *Pæonine*, by this process. This had, in all probability, the following constitution:



$$\begin{array}{l} C_6H_4{-}OH \\ | \\ C{=}C_6H_4{=}O \\ | \\ C_6H_4{-}NH_2 \end{array} \quad \text{or} \quad \begin{array}{l} C_6H_4{-}OH \\ | \\ C{=}C_6H_4{=}NH \\ | \\ C_6H_4{-}OH \end{array}$$

In 1878, Dale and Schorlemmer, whose researches on aurin are of great importance, showed that aurin, by very prolonged heating with alcoholic ammonia, may be transformed into pararosaniline

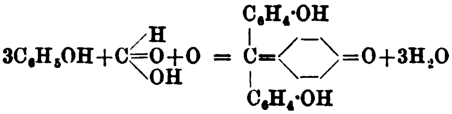


$$\begin{array}{l} C_6H_4{\cdot}OH \\ | \\ C{=}C_6H_4{=}O \\ | \\ C_6H_4{\cdot}OH \end{array} + 3NH_3 = \begin{array}{l} \quad C_6H_4{\cdot}NH_2 \\ C{-}C_6H_4.NH_2 \\ \quad C_6H_4{\cdot}NH_2 \\ HO \end{array} + 2H_2O$$

Thus the connection of the two typical dye-stuffs was definitely established. At present we know that the aurin group contains the acid counterparts of the basic members of the fuchsin group. A considerable number of them are known and described in chemical literature. As, however, almost all of them are of no practical value it would be useless to enumerate them in this article. We will therefore describe only those substances of the aurin group which are of some practical interest. There are very few of them.

1. **Aurin** $C_{19}H_{14}O_3$. The discovery of this substance, or one very nearly related to it, dates as far back as 1834, when F. Runge, the pioneer of the chemistry of coal-tar, observed that crude carbolic acid (containing cresol) was transformed into an acid red dye-stuff by oxidation. Later on (1859), Kolbe and Schmitt and F. Persoz simultaneously observed that pure phenol, when heated with oxalic acid, or with oxalic acid and sulphuric acid, was transformed into a similar red substance. The manufacture of the new dye-stuff was first taken up in Lyons by the firm of Guinon and Marnas. Later on, it was carried out on a large scale by C. Calvert and by C. Lowe; also by Roberts, Dale, & Co., in Manchester. The crude aurin thus obtained is a non-crystallisable, brittle, pitchy mass, of a brilliant green metallic aspect, insoluble in water, but soluble in caustic soda solution, with a magnificent red coloration. It dyes silk and wool from an acid bath, producing an orange shade on these fibres. It was much used on silk in former days, but its use has been abandoned since the introduction of the azo-colouring matters, which produce brighter and faster shades.

The researches of Dale and Schorlemmer, Zulkowski, and others have shown that common aurin consists of a mixture of a number of substances which, in a pure state, are well crystallised. Of these, aurin itself $C_{19}H_{14}O_3$, oxyaurin $C_{19}H_{16}O_6$, methylaurin $C_{20}H_{16}O_3$, and pseudorosolic acid $C_{20}H_{16}O_4$, may here be mentioned. All these substances are produced by the action of nascent formic acid (generated from the oxalic acid) upon phenol. This mode of formation of aurin itself may be represented by the following equation:

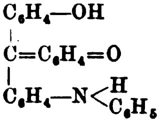


A large number of other reactions have been observed in which aurin is formed to a greater or lesser extent. Thus, for instance, it is obtained by acting with formaldehyde, with iodoform, with chloroform and caustic potash on phenol. These reactions have never attracted the attention of manufacturers, aurin having lost its practical interest.

The sodium salt of crude aurin is known in commerce under the name of *Yellow Corallin*.

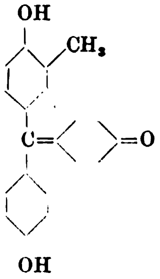
2. **Pæonin**, *corallin red, aurin red* is the sodium salt of the reaction product of alcoholic ammonia upon aurin, which has already been mentioned and the constitution of which is given above.

3. **Azulin** is a similar product, of a dirty violet shade, obtained by heating aurin with aniline. It is probably phenylated pæonin:



$$\begin{array}{l} C_6H_4{-}OH \\ | \\ C{=}C_6H_4{=}O \\ | \\ C_6H_4{-}N{<}^{H}_{C_6H_5} \end{array}$$

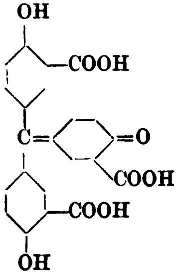
4. **Rosolic acid** is the name which was originally given by Runge to the oxidation product of crude carbolic acid. For a long time it was considered to be identical with aurin. At present this name is reserved for the product obtained from the ordinary fuchsin of commerce by the diazotising process. It forms magnificent blue needles, which, being homologous to true aurin, have the composition $C_{20}H_{16}O_3$:



It dyes silk and wool orange shades, similar to those obtained with aurin. It is of no practical interest (*v.* AURIN AND ROSOLIC ACID, vol. i. 340).

5. **Chrome violet** $C_{22}H_{13}O_9Na_3$ is the only member of the aurin group which is of

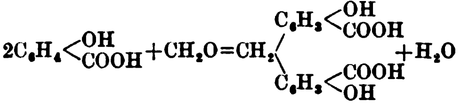
considerable practical value. It is the sodium salt of aurin-tricarboxyl acid:



It was discovered in 1889 by Sandmeyer, and patented (D. R. P. 49970, J. R. Geigy). It is prepared by acting with formaldehyde, or with a mixture of methyl alcohol and sodium nitrite, upon a solution of salicylic acid in sulphuric acid. The carboxyl groups are in the *ortho*-position to the hydroxyl groups. The result of this arrangement is that the dye-stuff combines readily with metallic mordants of the iron group, and especially with chrome mordant, producing violet shades of considerable fastness on cotton. It is chiefly used for printing on cotton.

The process patented for the production of chrome violet is interesting, because it forms a general and excellent synthetical method for the production of the aurins. It is strictly analogous to the synthetical method adopted for the production of 'Neu-fuchsin' by the 'Farbwerke' of Höchst. Two stages may be distinguished in the process:

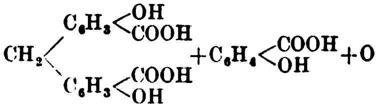
(*a*) In the first stage, formaldehyde (or methylal) acts upon two molecules of the phenol—in the case of chrome violet, salicylic acid—forming the diphenylmethane derivative (methenyl salicylic acid):



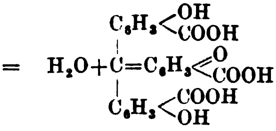
$$2C_6H_4{<}^{OH}_{COOH} + CH_2O = CH_2{<}\begin{array}{l} C_6H_3{<}^{OH}_{COOH} \\ C_6H_3{<}^{COOH}_{OH} \end{array} + H_2O$$

This reaction may be facilitated by the addition of condensing agents, such as hydrochloric acid and others.

(*b*) In the second stage, the diphenylmethane derivative is simultaneously condensed and oxidised with another molecule of the phenol into the corresponding aurin by the mixture of sulphuric acid and sodium nitrite:



$$CH_2{<}\begin{array}{l} C_6H_3{<}^{OH}_{COOH} \\ C_6H_3{<}^{COOH}_{OH} \end{array} + C_6H_4{<}^{COOH}_{OH} + O$$



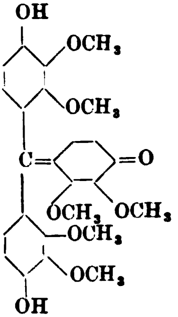
$$= H_2O + \begin{array}{l} C_6H_3{<}^{OH}_{COOH} \\ | \\ C{=}C_6H_3{<}^{O}_{COOH} \\ | \\ C_6H_3{<}^{COOH}_{OH} \end{array}$$

Any phenol, or substitution product of a phenol, may be substituted for the salicylic acid in this process.

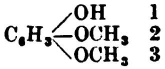
Later on, N. Caro (Ber. 25, 940) prepared a large number of carboxylated aurins by this process, substituting resorcylic, gallic, and cresotinic acid for the salicylic acid in the patented process. The compounds obtained proved to b very similar to chrome violet.

6. Of the large number of aurins prepare only one more need be mentioned here: **pittacal**, a curious substance discovered in 183 by Reichenbach in certain portions of beechwood tar. Liebermann more closely investigated this substance, and gave to it the name o *eupittonic acid* (Ber. 1876, 9, 334; 1878, 11, 1104). Hofmann determined its constitutio (*ibid.* 1878, 11, 1455; 1879, 12, 1371, 2261).

Pittacal is hexamethoxyaurin:

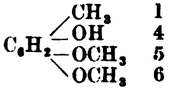


formed by the simultaneous oxidation of dimethylpyrogallol:



$$C_6H_3{<}\begin{array}{ll} OH & 1 \\ OCH_3 & 2 \\ OCH_3 & 3 \end{array}$$

and dimethyl methylpyrogallol:



$$C_6H_2{<}\begin{array}{ll} CH_3 & 1 \\ OH & 4 \\ OCH_3 & 5 \\ OCH_3 & 6 \end{array}$$

which are both contained in wood tar. The methyl group of the second compound yields the central carbon atom, the same as cresol did in the formation of the rosolic acid observed by Runge.

Pittacal is an orange substance, crystallising in beautiful crystals when pure. Its solution in caustic alkalis is of a beautiful blue colour.

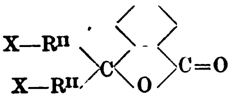
By heating pittacal with ammonia, Grätzel obtained a violet colouring matter, which proved of no practical value (*v.* Eupittonic Acid, vol. ii. 383).

III. The Phthaleïn Group.

The phthaleïns were discovered by Baeyer in his memorable researches on the condensation of phthalic acid with aromatic hydrocarbons and phenols. Their constitution was, however, at first misunderstood. In 1880, when the curious properties of phthalic anhydride became more definitely known, the error was corrected and the phthaleïns were recognised as congeners of the triphenylmethane group.

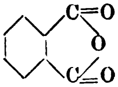
It is a well-known fact that every *o*-dicarboxylic acid is capable of forming, by losing the elements of water, an inner anhydride. These anhydrides act very easily on phenols, in some cases without the addition of condensing agents. Water is again eliminated, and a dye-stuff formed in every instance. Of the many colouring matters thus obtained, only those prepared from phthalic anhydride have, with one exception, become of general and practical interest, and these will here be described.

The central carbon in these dye-stuffs is afforded by one of the carbonyl groups of the anhydride of an *o*-dicarboxylic acid. If we restrict our consideration to phthalic anhydride, the formula may be thus modified :

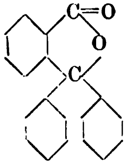


phthalic acid being benzene-*o*-dicarboxylic acid.

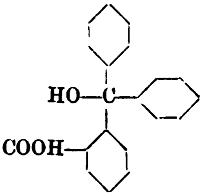
Phthalic anhydride, although perfectly symmetrical in its constitution



acts, in condensations, like an asymmetrical compound, only one of the carbonyl groups being attacked and losing its oxygen. Thus, by being condensed with two molecules of benzene it yields diphenyl phthalide or phthalophenone :



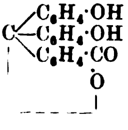
which is the parent substance of all the phthaleïns, just as triphenylmethane is the parent substance of the fuchsin and aurin groups. Diphenyl phthalide, however, is but the inner anhydride of triphenylcarbinol *o*-carboxylic acid :



hence the near relation between the phthaleïn, fuchsin, and aurin groups.

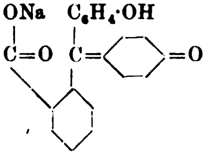
Formerly it was considered as probable that the anhydride structure of phthalophenone was preserved in the dye-stuffs derived from it. At present, almost all chemists are of the opinion that such is not the case, that the carboxyl group becomes free after the condensation has taken place and that it simply serves as a salt-forming group of minor importance. The quinonoid structure is shifted to the pyrone ring which is always present in all the really useful members of this group. Phenolphthaleïn and diaminophthalophenone, which do not contain the pyrone ring, are of no value as dye-stuffs. The constitution of the more important members of this group will be seen from the structural formulæ given for each of them.

1. **Phenolphthaleïn** $C_{20}H_{14}O_4$ was discovered by Baeyer in 1871 (Ber. 1871, 4, 658). Its constitution is



$$C\begin{cases} C_6H_4\cdot OH \\ C_6H_4\cdot OH \\ C_6H_4\cdot CO \\ \quad\; O \end{cases}$$

it may be considered as a substituted phthalophenone, but as in the free state it has no quinonoid structure, it is also colourless. It is easily prepared by heating phthalic anhydride with phenol in presence of sulphuric acid or stannic chloride. It forms pale-yellow crystals, which dissolve with a fine red colour in caustic alkalis. In the salt so formed the quinonoid structure is established and the substance thereby becomes a dye-stuff :



The practical importance of phenolphthaleïn is very small. Its only use is that of an indicator for alkalimetric purposes.

2. *Tetranitrophenolphthaleïn* $C_{20}H_{10}N_4O_{12}$ has been proposed as an orange colouring matter for wool. Its sodium salt $C_{20}H_8N_4O_{12}Na_2$ is sold as an orange powder under the name of *Aurotine*. It was discovered by C. Dreyfus, H. Bull, and T. Hall, and patented in England under 3441 (1889), in Germany under 52211. In a pure state free tetranitrophenolphthaleïn forms orange crystals, melting at 344°.

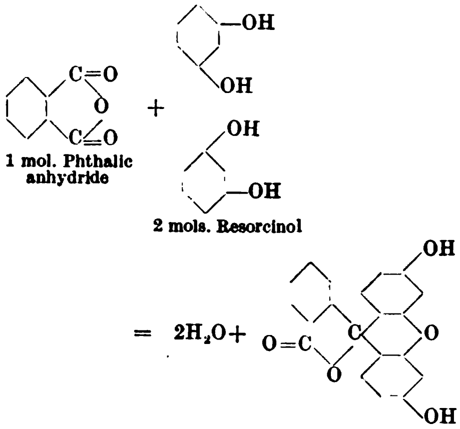
It has long been known that phenolphthaleïn is not a good dye. The same applies to all the ordinary typical phthaleïns. Phthalophenone (diphenylphthalide) is but a poor chromogen, but its properties are at once improved (as has already been shown above) if the two phenyl-radicles in its molecule be linked together by another group, preferably oxygen. We thus come to chromogens containing the pyrone ring combined with the structure of triphenylmethane derivatives, which, by the introduction of auxochromic groups, give rise to some of the most beautiful dye-stuffs yet discovered. As in all cases, the auxochromic groups introduced may be either the hydroxyl or the amino group ; and in the latter hydrogen may be replaced by organic radicles. We thus get phthaleïn colouring matters of either phenolic (acid) or aminic (basic) character. For a long time the former alone were known ; we will, therefore, consider them first.

A. *Acid phthaleïn dye-stuffs.*

The prototype of these is—

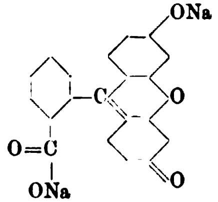
1. *Fluorescein* $C_{20}H_{12}O_5$. This beautiful substance is formed most easily if phthalic anhydride and resorcinol be mixed in molecular proportions and heated to 190°. In the factories this operation is carried out in enamelled cast-iron pots, heated in an oil bath. The ingredients melt, and large quantities of steam are given off. When the reaction is finished the mass solidifies into a cake of dark-brown colour, which consists of almost pure fluorescein.

In this reaction two molecules of resorcinol combine with one of phthalic anhydride. At the same time they interact upon one another, losing one molecule of water, and forming the pyrone ring :



Fluorescein

Fluorescein in a free state has thus a constitution quite analogous to that of phenolphthaleïn, although the presence of the pyrone ring is indicated by the intense brick-red colour of the substance. It is quite insoluble in water, sparingly so in the majority of other solvents. If, however, we dissolve it in alkaline liquids, it assumes, like phenolphthaleïn, its quinonoid nature and this change is marked by the intensity of its colour. In caustic alkalis and in ammonia it dissolves with a brown colour. The solutions have, especially when dilute, a most brilliant and beautiful green fluorescence. Hence the name of the substance.



Sodium salt of Fluorescein, showing quinonoid structure combined with pyrone ring

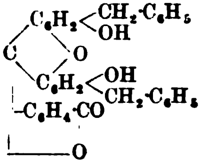
The crude fluorescein obtained in the manufacture, as above described, seems to contain two modifications of the substance (which may be isomerides). By treating the crude cake with boiling spirit, a certain amount of a soluble, non-crystallisable fluorescein is extracted, whilst the greater proportion of it remains undissolved, and is obtained as a crystalline residue on filtering. This process of purification is invariably used in the manufacture of the dye-stuff. Both the soluble and the insoluble part are worked up in the manner to be described hereafter, the insoluble fluorescein giving the better and purer qualities of the dye-stuffs, whilst the low-class qualities are made from the soluble fluorescein obtained by evaporating the alcoholic extract.

A small quantity of the fluorescein manufactured is transformed into its sodium salt

$$C_{20}H_{10}O_5Na_2,$$

which is sold, under the name *Uranin*, in the shape of a yellow powder, very soluble in water. It is used for dyeing pale yellows on silk.

If benzyl chloride and some sulphuric acid be added to the fluorescein melt a substance is obtained which is supposed to be benzyl-fluorescein :



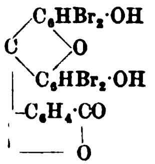
Its sodium salt is sold as a yellow dye-stuff under the name *Chrysolin*. This substance, discovered by Reverdin in 1877, is not of much practical importance.

By far the greater part of the fluorescein produced is transformed into very beautiful red colouring matters by the introduction of halogen atoms into its molecule. The dye-stuffs so prepared are known by the generic name of *Eosins*.

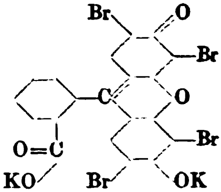
If fluorescein be treated by substituting reagents, it is generally observed that four atoms of hydrogen are replaced by other groups. Further investigations have shown that this substitution takes place in the phenyl radicles, which entered the fluorescein in the shape of resorcinol, whilst the phenyl radicle derived from the phthalic anhydride is never attacked by these reagents.

The most important of the dye-stuffs so prepared is

2. *Eosin* $C_{20}H_6O_5Br_4K_2$, the potassium salt of tetrabromofluorescein. The sodium salt is also occasionally met with, but it does not crystallise so well. The constitutional formula of eosin is :



(In a free state)



(As potassium salt)

Eosin is prepared by acting with four molecules of bromine upon one molecule of fluorescein. The crystallisable modification of the latter is used for the manufacture of a good product. On the small scale a solution of the fluorescein in glacial acetic acid is prepared, and the bromine introduced gradually.

For manufacturing purposes glacial acetic acid is too expensive. The following process, which admits of operating in aqueous solutions, may be used instead.

The bromine is dissolved in exactly the necessary quantity of caustic soda, and the solution is evaporated to dryness. The resulting salt consists of a mixture of sodium bromide and sodium bromate. It is dissolved in water and mixed with a solution of the theoretical quantity of fluorescein in caustic soda. The mixture is then acidified with hydrochloric acid. The bromine generated acts at once upon the fluorescein, and the precipitate obtained is eosin, which need only be dissolved in a solution of potassium carbonate and evaporated to crystallisation.

The quantity of bromine used may be reduced to half (two molecules or four atoms) by using a mixture of potassium bromide and potassium or sodium chlorate, instead of the salt obtained by evaporating the solution of bromine in caustic soda.

This process, although cheap and simple, is not generally used, because the bromine is found to act too energetically. A certain amount of the eosin is destroyed, and the remainder is not so brilliant in colour as it might be.

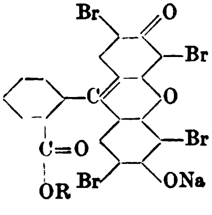
The bromination proceeds much better in an alcoholic solution; alcohol is, therefore, frequently used for the purpose in the manufacture of eosin. The fluorescein is finely ground, and suspended in strong spirit. The necessary quantity of bromine is added. The bromination takes place slowly and gradually, and an excellent product is obtained. The spirit is recovered by distillation.

In order to reduce the bromine in this as in the aqueous process to two instead of four molecules, the addition of a chlorate is necessary. But a chlorate must be used which is soluble in spirit. Cupric chlorate is preferred to any other. It is prepared by mixing concentrated aqueous solutions of sodium chlorate and cupric chloride or sulphate. The solution obtained is added to the operation in progress.

Eosin forms either a dark-brown powder, or dark-brown crystals with a green metallic lustre. The potassium salt may also be obtained in flesh-coloured crystals by re-crystallisation from spirit. These crystals contain alcohol of crystallisation. According to strength and purity of shade, the commercial eosins are distinguished by certain letters and additions, such as 'eosin B,' 'A,' 'GGF,' 'DH,' 'extra,' 'extra-fine,' 'soluble,' and others. All these brands dissolve easily in water, with a scarlet coloration. Dilute solutions show a marked greenish fluorescence.

Eosin is used for dyeing silk and other fibres, also for staining paper, and for preparing red inks of a very fine scarlet colour. Large quantities are used for the last-named purpose, Eosin is not a fast colour, but its brilliancy of shade secures a ready sale for the large quantities produced.

3. **Eosin soluble in spirit** (*Primrose, methyl-eosin*). These names are applied to certain products, which are produced by boiling eosin, dissolved in spirit, with caustic soda and methyl iodide, or ethyl bromide. The carboxyl group is thus alkylated, whilst the hydroxyl group remains combined with alkali. The sodium salts thus obtained form glistening crystals, insoluble in water but soluble in spirit. They have the constitution:



in which R stands for either methyl or ethyl. Small quantities of these substances are prepared and employed as an addition to the vermilion used in cotton printing, in order to increase the brilliancy of its shade. Spirit eosin was formerly also used for silk dyeing, but for this purpose it has been replaced by the bluish eosins soluble in water, to be described later on.

If the hydroxyl group of eosin is also to be alkylated, this can only be effected by acting with alkyl iodide or bromide upon the silver salt of eosin. The dialkyl-ethers thus obtained are colourless.

4. **Eosin scarlet** (*Eosin B, BN, BW, scarlet, J, JJ, V, &c.*). Sodium salt of dinitrodibromofluorescein $C_{20}H_6N_2O_9Br_2Na_2$.

If fluorescein be treated with nitric acid, dinitrofluorescein is obtained, which has found no application as a colouring matter. But by subsequent bromination it yields a brilliant scarlet. The same product (or an isomeride very similar to it) may be prepared by first brominating the fluorescein and then treating it with nitric acid.

This dye-stuff was hailed with enthusiasm when it made its appearance in 1875, but its use was soon much restricted by the introduction of the scarlet azo dyes which are quite as brilliant, and at the same time faster, cheaper, and more easy in their application.

5. **Erythrosin** (*Bluish Eosin, Dianthin, Primrose soluble, Pyrosin B,* and other names).

This is the sodium salt of tetraiodofluorescein $C_{20}H_6O_5I_4Na_2$. The potassium salt is also met with occasionally. It is prepared by iodinating fluorescein with iodine and oxidising agents, such as mercuric oxide, iodic acid, cupric chlorate, &c. It may also be prepared by introducing iodine monochloride into an alcoholic suspension of fluorescein.

Erythrosin dissolves in water, with a fine red colour, and very slight fluorescence. It dyes silk in shades which are much more bluish than those obtained with eosin.

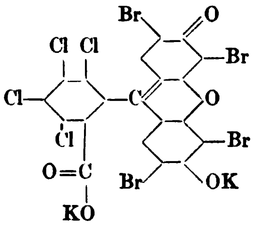
Erythrosin was introduced into the market in 1876 by Bindschedler and Busch. It was well received by the silk dyers. Owing to the high price of iodine, a mixture of eosin and Bengal red is now used for producing the same shades.

There is one application, however, for which pure erythrosin is still required—for producing orthochromatic dry plates for photographic purposes. As a sensitiser of silver bromide, erythrosin holds a prominent place amongst all the colouring matters hitherto tried.

Di-iodofluorescein was sold and used for a very short time as an orange dye-stuff, under the name '*Pyrosine J.*'

6. **Phloxin** (*Potassium salt of dichloro- or tetrachloro- tetrabromofluorescein*).

This colouring matter, discovered in 1876 by Nölting, together with the following ones, formed a new departure in the manufacture of the eosin dyes. The characteristic feature of these substances is the fact that they contain halogen atoms substituted for hydrogen, not only in the resorcinol groups, but also in the phenyl group derived from the phthalic anhydride. Now, it has already been said that a substitution of this kind cannot be effected in ready-made fluorescein. To prepare phloxin, therefore, or any of its congeners, a special fluorescein must be used, prepared not with ordinary phthalic anhydride but with the anhydrides of dichloro- or tetrachloro- phthalic acid. Dichlorophthalic acid is best prepared by oxidising dichloronaphthalene, whilst tetrachlorophthalic acid may be obtained by chlorinating phthalic anhydride in the presence of finely divided iron. Both acids give colouring matters of very similar shades, the tetrachloro derivatives being but very little bluer than the dichloro derivatives. The process of manufacture of the dye-stuffs is identical with that described for eosin. The constitutional formula of phloxin is



if derived from tetrachlorophthalic acid. The phloxin derived from dichlorophthalic acid contains, of course, two atoms of chlorine less.

Commercial phloxin is a red powder, soluble in water, with a red colour and no fluorescence. It dyes beautiful bluish-red shades on silk, which resemble those obtained with erythrosin.

7. **Cyanosin** is the monomethyl ether of phloxin. It is soluble in spirit, and dyes shades still bluer than phloxin.

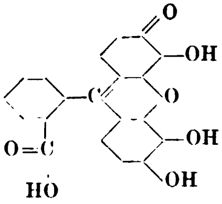
8. **Bengal red** (*Rose Bengale N*)

$C_{20}H_4Cl_2I_4O_5K_2$ or $C_{20}H_2Cl_4I_4O_5K_2$

is the iodo derivative of this series. It is the bluest eosin dye-stuff obtained. It is very expensive, and was formerly used in large quantities to produce the most brilliant bluish-reds on silk. It has now, to a great extent, been replaced by the rhodamines. Its methyl ether, soluble in spirit, received the name of *Cyanosin B*. Its application never became important.

The phthalein derivatives of resorcinol are all very brilliant dyes. There are, however, some other acid phthaleins which, although important as colouring matters, are of much more sober hues. They are derivatives of pyrogallol.

9. **Gallein** $C_{20}H_{12}O_7$. If phthalic anhydride be condensed with pyrogallol, the reaction takes place quite as easily as with resorcinol. The product obtained is, as might be expected, a dihydroxyfluorescein. The constitutional formula now adopted for gallein is



For the manufacture of gallein it is not necessary to prepare pure pyrogallol. Gallic acid may be used instead, which, losing carbon dioxide, is at once transformed into gallein by the action of the phthalic anhydride.

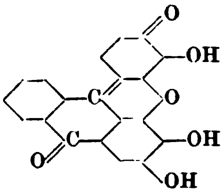
Gallein is generally sold in the shape of a violet paste. It is sparingly soluble in water, easily soluble in caustic alkalis, with a bright-blue coloration. It dyes mordanted wool and cotton. Chrome mordants are used preferably, and dark-violet shades are obtained.

On account of the similarity of the application of gallein to that of alizarin, gallein is also sold under the name of *Alizarin violet* or *Anthracene purple*.

10. **Cœrulein** (*Alizarin green, Anthracene green*) $C_{20}H_8O_6$. This is one of the most important dye-stuffs for wool and cotton, dyeing a beautiful and very fast olive green on chrome mordants. The cotton printer uses it constantly, both pure and mixed, with other dye-stuffs of the alizarin family.

It was discovered in 1871 by A. Baeyer, who obtained it by heating gallein with concentrated sulphuric acid to 200°. By the same process it is now prepared in immense quantities on the large scale.

In this process the substance loses one molecule of water and the carboxyl group forms a new hexagon ring by condensing with the neighbouring benzene ring, thus:



Cœrulein forms a black paste, insoluble in water. It is soluble in caustic alkalis, with a greenish-blue coloration.

11. **Cœrulein S** (*soluble cœrulein*)

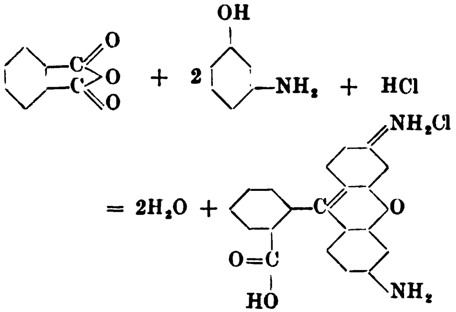
$C_{20}H_{10}O_{12}S_2Na_2$.

This is the product of the reaction of sodium bisulphite upon cœrulein; its manufacture is carried on by the Badische Aniline and Soda works at Ludwigshafen. It forms a black powder, soluble in water, with a brown coloration. It is easily decomposed by the addition of acids or by heat. It is used for the same purposes as cœrulein, and is very convenient, on account of its easy solubility. In dyeing with it, it is, of course, decomposed, the ordinary cœrulein being deposited on the fibre.

B. *Basic phthalein dye-stuffs.*

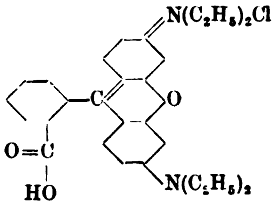
For a long time these were not known. The manner in which they might be obtained had, of course, suggested itself to the consideration of chemists, but the substances required for their synthesis seemed to be quite out of the reach of the manufacturer. In 1887, however, M. Ceresole, of the Badische Anilin- und Soda-Fabrik, successfully effected the synthesis of the first basic phthalein, which proved to be of such value that a thorough search for a good means of preparing the necessary ingredients was made, which led to complete success.

To obtain the basic substance analogous to fluorescein, it is merely necessary to replace one of the hydroxyl groups of resorcinol by an amino- group; or, in other words, to employ *m*-aminophenol instead of resorcinol:



Experience has shown that the compound thus obtained has no practical value. If, however, diethyl *m*-aminophenol is used instead of the *m*-aminophenol, a most beautiful colouring matter is obtained, known under the name of

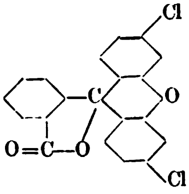
1. **Rhodamin B** $C_{28}H_{31}N_2O_3Cl$. The commercial product is the monohydrochloride :



It forms beautiful needles of a metallic green appearance, easily soluble in both water and spirit. Weak solutions show a most magnificent orange fluorescence, which disappears on heating, and reappears in the cold. This is the most beautiful red colouring matter ever prepared, dyeing silk, wool, and cotton a most brilliant pink of a bluish shade.

The process described for the production of rhodamin is patented by the Badische Anilin- und Soda-Fabrik, Eng. Pat. 15374, 1887; D. R. P. 44002. The diethyl *m*-aminophenol is prepared from diethylaniline by heating it with fuming sulphuric acid to 60°. diethylaniline *m*-sulphonic acid is formed, which yields the phenol by fusion with caustic soda.

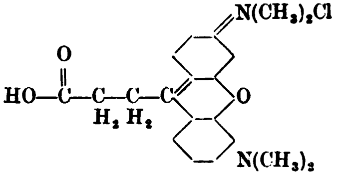
There is, however, another process for the manufacture of rhodamin, discovered by the Farbwerke of Höchst (D. R. P. 48367, 1888). It consists in treating free fluorescein with phosphorus pentachloride, when the fluorescein chloride



is formed. This is transformed into rhodamin if heated with diethylamine under pressure.

2. **Rhodamin S** $C_{20}H_{23}N_2O_3Cl$ and $C_{24}H_{31}N_2O_3Cl$.

These two colouring matters, which are identical in their practical properties and applications, are not, strictly speaking, triphenylmethane derivatives; nor are they derived from phthalic acid. They must, however, be mentioned here, because they are near congeners of rhodamin B. They are obtained by treating dimethyl- or diethyl- *m*-aminophenol, not with phthalic, but with succinic, anhydride. Succinic acid is the typical *o*-dicarboxylic acid of the fatty series. Like phthalic acid, it forms an anhydride, which condenses with resorcinol into fluorescein-like dye-stuffs; these, however, offer no practical interest. The succineines of dimethyl- and diethyl- *m*-aminophenol, however, show a sufficient difference from rhodamin to be manufactured and sold as a special brand. The constitution of the dimethyl compound may be represented by the following formula :



It is, therefore, not a triphenylmethane derivative. It is sold in the shape of its zinc double chloride.

Rhodamin S shows great affinity to unmordanted cotton. It is one of the few members of this group which may be considered to be what is now called a substantive colouring matter.

The properties of rhodamin S are very similar to those of rhodamin B. It forms crystals with a green metallic lustre, easily soluble in water, with a red coloration, and a marked yellow fluorescence. The shades obtained with it are yellower than those produced with rhodamin B.

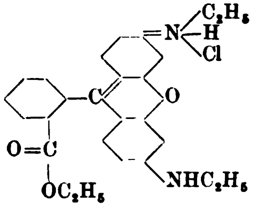
Rhodamin B and S remained for some time the only important members of this magnificent group of dye-stuffs. After a while, however, some new representatives of it made their appearance, of which the more important may be here shortly described.

Rhodamin G $C_{26}H_{27}N_2O_3Cl$ is obtained by heating rhodamin B with aniline hydrochloride. One of the ethyl groups is split off in the shape of ethyl chloride and the recovered dye-stuff is a tri-ethyl-rhodamin which dyes wool and silk in red shades of a much more yellowish tinge than the original rhodamin B.

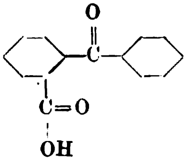
The process of alkylation, which produced such remarkable results in the eosin group, proved equally applicable to the rhodamins. It was carried out at first by using alkyl chlorides, but later on it was discovered that a much cheaper and simpler way to the same end consists in saturating alcoholic solutions of rhodamins with hydrogen chloride. As this is a method which is exclusively applicable to the alkylation of organic acids, the possibility of using it for the rhodamins formed a proof of the presence of a free carboxyl group in the dye-stuffs and went a long way in establishing the modern views about their constitution.

Rhodamin 3B, *Anisoline*, was the first of the alkylated rhodamins. It dyes a more bluish shade of red than rhodamin B, and is, if possible, even more brilliant and pure in its tinge, which strongly resembles that of certain flowers such as the 'Crimson Rambler' rose.

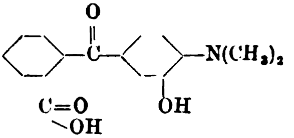
Rhodamin 6G was obtained by the same process from *sym*-diethylrhodamin (produced by the condensation of phthalic acid with two molecules of mono-ethyl-*m*-aminophenol), and has consequently the following constitution :



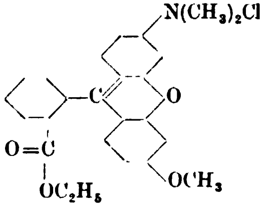
When once the constitution of the rhodamins was recognised, it was clearly seen that they may also be considered as derivatives of *o*-benzoyl-benzoic acid :



Suitable substitution products of this acid may therefore be used for the synthesis of rhodamins. This is important because it enables us to produce asymmetrical rhodamins, whilst the original process was applicable only to the production of symmetrical members of this important class of dye-stuffs. As an example of this method, *Rhodamin* 12 *GM* may be quoted, which is prepared by acting with dimethylhydroxybenzoylbenzoic acid :

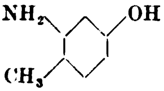


upon monomethylresorcinol and subsequent esterification of the product obtained. This dye-stuff is consequently quite asymmetrical and has the constitution :



It dyes silk, wool, and cotton a beautiful yellowish red.

If in the process given for the production of rhodamin 12 GM the monomethylresorcinol be replaced by *m*-amino-*p*-cresol :



a new and exceedingly beautiful dye-stuff is obtained, which is sold under the name *Irisamin G* or *Rhodin* 3*G*. It dyes silk, wool, and mordanted cotton a flaming, beautiful red.

Several other members of this group have been prepared by various methods, amongst which the reaction of formaldehyde upon ready formed rhodamins may be mentioned. All the rhodamins have also been found applicable not only to the regular dyeing of textile fabrics, but also to the staining processes so largely used for paper, wood and confectionery. Very large quantities of these dyes are used for such purposes.

Few groups of synthetical dye-stuffs have proved so prolific as that of which a short description has here been given. The triphenylmethane group contains some of the oldest artificial colouring matters known, but for more than half a century it has continued to yield new additions to the vast number of such compounds which chemical science has placed at the disposal of our textile industries. O. N. W.

TRIPHYLITE. A manganese lithium phosphate $LiMnPO_4$, occurring naturally as large, rough (orthorhombic) crystals and coarsely cleavable masses. By the isomorphous replacement of manganous oxide by ferrous oxide it passes into the closely allied mineral lithiophilite $(LiFePO)_4$. The colour is grey or bluish, but, the mineral being readily weathered, the masses are usually dark brown on the surface. Triphylite occurs in pegmatite-veins, often in association with spodumene and other lithium-bearing minerals, and sometimes with tin-ore. It is found at Bodenmais in Bavaria, Huréaux and Chanteloube in Haute-Vienne, Branchville in Connecticut, Pala in California, the Black Hills in South Dakota, and King's Mountain in North Carolina. Containing 8·1–9·4 p.c. of lithia it has occasionally been collected, when mining for other minerals, and used as a source of lithium salts. L. J. S.

TRIPOLITE or **TRIPOLI** *v.* KIESELGUHR.

TRÖGERITE *v.* URANIUM.

TROILITE. A name applied by Haidinger to ferrous sulphide FeS, occurring in meteorites.

TRONA, URAO, or **NATURAL SODA.** The sodium carbonates occurring as minerals are : thermonatrite Na_2CO_3,H_2O (orthorhombic) : natron (*q.v.*) $Na_2CO_3,10H_2O$ (monoclinic) ; trona $Na_2CO_3{\cdot}NaHCO_3,2H_2O$ (monoclinic) ; and possibly the anhydrous salt. Of these, trona is by far the most important and constitutes the larger part of the deposits of natural soda. It forms beds of white, cavernous material with acicular or bladed crystals lining the cavities ; and is usually intermixed with more or less earthy matter and sodium chloride and sulphate. It is deposited from the water of soda-lakes and forms an efflorescence on the surface in desert regions. The Natron Lakes of Lower Egypt are well known, and similar lakes and surface efflorescences of soda are met with in many parts of the Sahara and Sudan. Extensive deposits are found in the neighbourhood of Lake Chad, and a large deposit has been opened up at Lake Magadi in British East Africa. Soda-lakes also occur in the western states of North America, viz. in Arizona, California, and Nevada.

The name 'trona' is said to be of Arabic origin ; and 'urao' is a native name for the soda deposited at the bottom of a lake at Lagunilla in Venezuela.

TROOSTITE. A constituent of steel intermediate in characteristics between sorbite and martensite (*q.v.*). It is obtained by quenching highly heated steel in oil or by quenching from the transformation temperature in cold water, and is plentiful in tempered steels.

It acquires a deep brown or black tint when etched with picric acid, and can thus be distinguished under the microscope. Benedicks regards it as a colloidal solution of carbon in iron (J. Iron and Steel Inst. 1905, ii. 352; 1908, ii. 217). The name troostite is also given to a variety of *Willemite* (*q.v.*).

TROPACOCAINE *v.* SYNTHETIC DRUGS.

TROPAEOLINE *v.* AZO- COLOURING MATTERS.

TROPILLENE *v.* KETONES.

TRUFFLES, subterranean fungi, highly prized as food. Many species are known. König divides the edible truffles into two chief classes—

(1) **White truffles,** the best of which is the African truffle, *Tuber niveum* (Desf.) or *Terfezia Leonis* (Tul.), but also including the Italian truffle, *Tuber magnatum* (Pico.) or *Tuber album* (Balb.), with a garlic-like odour, and the German white truffle, *Tuber album* (Bull.) or *Chæromyces meandriformis* (Vitt.), of much less value.

(2) **Black truffles,** which include the highly prized French truffle *Tuber melanospermum* (Vitt.), which is usually in size between a walnut and an apple, of dark brown or black colour, and covered with polygonal warts. It possesses a strong aromatic odour, resembling that of the strawberry; the winter truffle, *T. brumale* (Vitt.) occurs in France and Italy, resembles the French truffle, but has not such an aromatic smell and taste. The summer truffle, *T. æstivum* (Vitt.) is the one most usually found in England, generally in beech, oak, or birch woods, and in marly soils. It is gathered from July to September.

König gives, as the mean composition of truffles—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
77·1	7·6	0·5	6·6	6·4	1·9

Chatin (Compt. rend. 1890, 110, 376, and 435) found the dry matter in French truffles to vary from 20·8 to 25·0 p.c. of the original fresh material, and to contain from 4 to 9 p.c. of its weight of nitrogen, and from 5·6–11·2 p.c. of ash. The ash, in different samples, contained: silica 10–35 p.c., potash 17–28, soda 0·6–2·1, lime 6·0–9·4, magnesia 0·2–3·1, ferric oxide and traces of alumina 3·2–8·4, manganous oxide, traces to 0·05, phosphorus pentoxide 18·4–30·2, sulphur trioxide 2·1–4·6, chlorine with traces of iodine 0·2–0·4 p.c. Much larger proportions of potash and phosphorus pentoxide were found in the ash of truffles by Kohlrausch and Loesecke, quoted by König. The amount of alumina is also apparently very variable, since Pizzi (quoted by König) found, in the ash of black truffles, 5·77 p.c. of alumina, in that of white truffles, 7·17 p.c.

As to the nature of the nitrogenous constituents of truffles, little appears to be known; probably a considerable proportion of it is in the non-proteid form.

In the non-nitrogenous extract, mannitol, trehalose and malic and citric acids have been found.

For an examination of the *tubulane* or Caucasian truffles, and of various species of *Terfezia*, known as 'terfas' and 'kames' in the north of Africa and in Western Asia *v.* Chatin (Compt. rend. 1893, 114, 46; and Revue intern. des falsific. 1893, 14).

Truffles are sold, either in the fresh condition, imbedded in lard, dried, or cooked and preserved in olive oil, or in hermetically sealed cases.

König gives, as the mean of 9 analyses of the air-dried product—

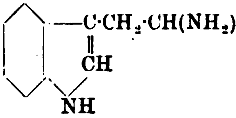
Water	Protein	Fat	N-free extract	Crude fibre	Ash
4·4	33·9	2·0	24·9	27·1	7·7

H. I.

TRYGASE *v.* SYNTHETIC DRUGS.

TRYPSIN *v.* FERMENTATION.

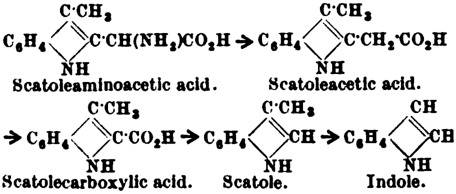
TRYPTOPHAN, *β-indole-α-aminopropionic acid*



It has been known since the researches of Gmelin, Barnard, and others of the earlier physiologists that on tryptic digestion a substance is formed from proteids that gives a reddish-violet coloration with chlorine or bromine. Other methods of decomposing proteids, such as putrefaction or alkali or acid hydrolysis, give rise to the same substance, for which the name *tryptophan* was suggested by Neumeister (Zeitsch. Biol. 1890, 26, 234), and *proteinchromogen* by Stadelmann (*ibid.* 491). The compound itself was not known until 1901 when Hopkins and Cole (J. Physiol. 1901, 27, 418) isolated it from the products formed by the tryptic digestion of casein; they showed that it possessed the formula $C_{11}H_{12}O_2N_2$, yielded scatole and indole when heated, and adopting Neumeister's suggestion named it *tryptophan.*

Tryptophan occurs among the products of hydrolysis of a large number of proteins, both of animal and vegetable origin (*v.* PROTEINS), and is separated by means of the sparingly soluble double salt it forms with mercuric sulphate. It is most conveniently prepared from casein or fibrin, the former yielding 7–8 grms. and the latter 13–14 grms. per kilo (Neuberg, Chem. Zentr. 1906, ii. 892; Neuberg and Popowski, Biochem. Zeitsch. 1906, 2, 357).

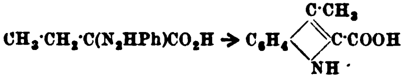
Constitution and synthesis. The formation of indole (Kühne, Ber. 1875, 8, 206; Nencki. *ibid.* 336), of scatole (Brieger, *ibid.* 1877, 10, 1027), of scatolecarboxylic acid (E. and H. Salkowski, *ibid.* 1880, 13, 2217) and of scatoleacetic acid (Nencki, Monatsh. 1889, 10, 506) on putrefaction of proteins was attributed by Nencki to the presence of a scatoleaminoacetic acid in the protein molecule; and when Hopkins and Cole found tryptophan to have the empirical formula $C_{11}H_{12}O_2N_2$ and to yield indole, scatole, scatolecarboxylic acid and scatoleacetic acid on putrefactive decomposition, they regarded their substance as Nencki's hypothetical scatoleaminoacetic acid



Scatoleaminoacetic acid. Scatoleacetic acid.

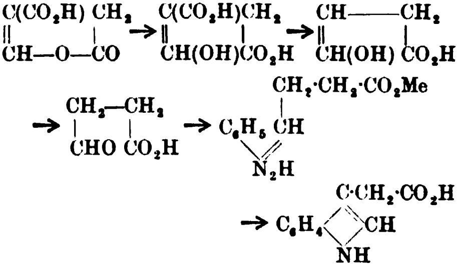
Scatolecarboxylic acid. Scatole. Indole.

Ellinger (Ber. 1904, 37, 1801), however, showed that Nencki's so-called scatolecarboxylic acid was not identical with the synthetic product obtained by Wislicenus and Arnold (*ibid.* 1887, 20, 3394) from the phenylhydrazine derivative of propionylformic acid



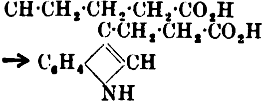
but was in reality the isomeric *indole acetic acid*

, obtained synthetically by condensing β-aldehydopropionic acid (obtained from aconic acid) with phenylhydrazine and subsequent treatment of the ester of the hydrazone with alcohol and sulphuric acid



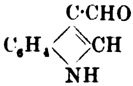
Ellinger (Ber. 1905, 38, 2884) further showed that Nencki's scatoleacetic acid was identical with indole propionic acid obtained by a similar synthetic process from ethyl propionacetalmalonate

$(CO_2Et)_2CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH(OEt)_2$
$\rightarrow CH_2(CO_2H)CH_2{\cdot}CH_2{\cdot}CHO$
$\rightarrow C_6H_5{\cdot}N_2H : CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H$

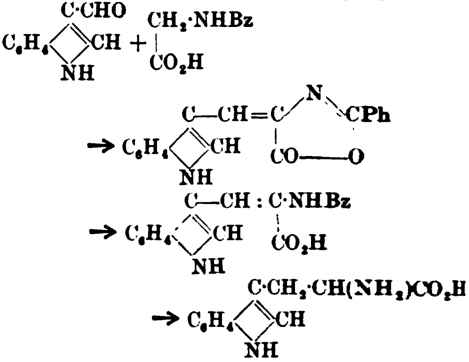


From these considerations it follows that tryptophan must be indole-3-α-aminopropionic acid or indole-3-β-aminopropionic acid, and that it possesses the constitution of the former compound was shown by Ellinger and Flamand (Ber. 1907, 40, 3029), who prepared it synthetically from indole-3-aldehyde and hippuric acid.

Indole-3-aldehyde



is obtained by oxidising tryptophan with ferric chloride (Hopkins and Cole, J. Physiol. 1903, 29, 451; Ellinger, Ber. 1906, 39, 2515), and can also be prepared by the action of chloroform and potassium hydroxide on indole; it condenses with hippuric acid to form an *azlactone*, which on hydrolysis yields *α-benzoylaminoindolylacrylic acid*. This compound on reduction and subsequent hydrolysis yields α-amino-β-indolepropionic acid, identical with *dl*-tryptophan



Properties. The tryptophan obtained from proteids is lævorotatory in aqueous solution. Hopkins and Cole (J. Physiol. 1901, 27, 418) found $[\alpha]_D -33°$, H. Fischer (Zeitsch. physiol. Chem. 1908, 55, 74) found $[\alpha]_D -34{\cdot}5°$ for one specimen, whilst others gave values varying from −29·75° to −40·3°; Abderhalden and Baumann (*ibid.* 412) found $[\alpha]_D^{20} -30{\cdot}33°$. In alkaline or acid solution, *l*-tryptophan is dextrorotatory, having $[\alpha]_D^{20} +5{\cdot}7°$ to $+6{\cdot}3°$ in a 2–3 p.c. solution in N/2NaOH solution, or +6·06° to +6·12° in 10–12 p.c. N/1 NaOH solution (Abderhalden and Kempe, *ibid.* 1907, 52, 207; Abderhalden and Baumann, *l.c.*); lower values were found by Fischer (*l.c.*), $[\alpha]_D +5{\cdot}56°$ to 5·69° in a 2–3 p.c. solution of a N/1 NaOH solution. This is probably due to partial racemisation as Abderhalden and Baumann (*l.c.*) found $[\alpha]_D^{20} +5{\cdot}27°$ for a specimen that had been repeatedly recrystallised; a 6 p.c. solution in N/1 hydrochloric acid gave $[\alpha]_D^{20} +1{\cdot}31°$ (Abderhalden and Kempe, *l.c.*). *l*-Tryptophan crystallises in six-sided and rhombic plates, is sparingly soluble in cold, readily so in hot water and has a slightly bitter taste; it darkens when heated at 240° and melts at 252° (Hopkins and Cole, *l.c.*), at 273° (Neuberg and Popowsky, *l.c.*), at 289° (corr.) (Abderhalden and Kempe, *l.c.*).

dl-Tryptophan is prepared synthetically and also readily formed from *l*-tryptophan which racemises on crystallisation from pyridine, or by the action of ammonia or by heating at 170° with hydrochloric acid (Abderhalden and Baumann, *l.c.*; Allers, Biochem. Zeitsch. 1907, 6, 272; Neuberg, *ibid.* 276); the racemic compound differs from the natural compound only in being optically inactive and in having a sweet taste. For the dissociation constants see Aristides Kanitz (Biochem. Zeitsch. 1910, 29, 126).

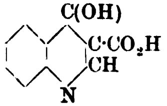
Reactions. The Adamkiewicz or Liebermann reaction given by certain proteins—namely, the formation of a blue violet ring at the junction of the two liquids when concentrated sulphuric acid is added to a mixture of the protein with acetic acid or ether—is due to the presence of tryptophan in the protein and of glyoxylic acid in the acetic acid or ether (Adamkiewicz, Ber. 1875, 8, 161; v. Liebermann, Zentr. Med. Wissensch. 1887, 321, 450; Hopkins and Cole, Proc. Roy. Soc. 1901, 68, 21; J. Physiol. 1901, 27, 418; Cole, J. Physiol. 1903, 30, 311; Osborne and Harris, J. Amer. Chem. Soc. 1903, 25, 853; Bardachzi, Zeitsch. physiol. Chem. 1906, 48, 145; Dakin, J. Biol. Chem. 1907, 2, 289). According to Homer (Proc. Camb. Phil. Soc. 1912, 16, 405), who has studied the behaviour of tryptophan towards certain aldehydes, it is formaldehyde rather than glyoxylic acid that is the substance essential to the formation of the characteristic violet colour in the Adamkiewicz reaction.

For other colour reactions of proteins due to the presence of tryptophan, see Cole (*l.c.*); Dakin (*l.c.*); Fleig (Proc. Soc. Biol. med. 1908, 65, 192); Rosenheim (Biochem. J. 1, 233); Granström (Beitr. Chem. Physiol. Path. 1908, 11, 132); Heimrod and Levene (Biochem. Zeitsch. 1910, 25, 18).

The red-violet colour produced by chlorine or bromine water on tryptophan is only given by free tryptophan, not by its polypeptides. The coloration attains a maximum when the amount of halogen is equivalent to four atoms per gram molecule of tryptophan, and when concentrated solutions are used red amorphous precipitates of the monohalogen derivatives are obtained $C_{11}H_{11}O_2N_2Cl$ and $C_{11}H_{11}O_2N_2Br$. These compounds are soluble in amyl alcohol, ether, or ethyl acetate, and the use of these solvents has been suggested to render the reaction more intense. The addition of excess of halogen converts the red compounds into yellow perhaloids $C_{11}H_{11}O_2N_2Cl_3$ and $C_{11}H_{11}O_2N_2Br_3$ (Neuberg and Popowski, Biochem. Zeitsch. 1907, 2, 357; Neuberg, *ibid.* 1910, 24, 423; Abderhalden and Kempe, *l.c.*).

Tryptophan is decomposed on heating into carbon dioxide, indole and scatole; when fused with potassium hydroxide, scatole, to the extent of 65 p.c. of the calculated amount, is the chief product (Hopkins and Cole, *l.c.*).

In the animal economy, tryptophan chiefly undergoes bacterial decomposition with the formation of indole; in the case of dogs it is partially converted into ***kynurenic acid*** (4-*hydroxyquinoline-3-carboxylic acid*)



(*v.* QUINOLINE) and excreted as such. The administration of tryptophan causes an increased excretion of kynurenic acid. The mechanism of the reaction whereby tryptophan undergoes conversion into kynurenic acid has not been explained (Kretschy, Ber. 1879, 12, 1673; Wein. Akad. Ber. 1881, 83, [ii.] 171; Monatsh. 1883, 4, 156; 5, 16; Solomin, Zeitsch. physiol. Chem. 1897, 23, 497; Capaldi, *ibid.* 1897, 23, 92; Mendel and Jackson, Amer. J. Physiol. 1898, 2, 1; Camps, Ber. 1901, 34, 2703; Mendel and Schneider, Proc. Amer. Physiol. Soc. 1900, ix–x; Amer. J. Physiol. 1901, 5, 427; Gies, *ibid.* 1901, 5, 191; Glaessner and Langstein, Beitr. chem. Physiol. Path. 1901, 1, 28; Ellinger, Ber. 1904, 37, 1801; Abderhalden, London and Pincussohn, Zeitsch. physiol. Chem. 1909, 62, 139).

Salts of l-*tryptophan.* *l*-Tryptophan has an acid reaction towards litmus, and forms salts both with acids and bases; the *copper salt* $(C_{11}H_{11}O_2N_2)_2Cu$, sparingly soluble grey-blue precipitate (Abderhalden and Kempe, Zeitsch. physiol. Chem. 1907, 52, 207); the *silver salt* $C_{11}H_{11}O_2N_2Ag$; the *sodium* salt has $[\alpha]_D + 2{\cdot}50°$ in 2 p.c. solution (H. Fischer, *l.c.*). The *hydrochloride* $C_{11}H_{12}O_2N_2{\cdot}HCl$ has m.p. 251° and $[\alpha]_D - 13{\cdot}44°$ in 2 p.c. aqueous solution (H. Fischer); the *picrate* $C_{11}H_{12}O_2N_2{\cdot}C_6H_3O_7N_3$ forms bright red lustrous needles or plates, m.p. 195°–196° (decomp.); the *picrolonate*

$$C_{11}H_{12}O_2N_2{\cdot}C_{10}H_8O_5N_4$$

forms orange red needles, m.p. 203°–204° (Mayeda, Zeitsch. physiol. Chem. 1907, 51, 261).

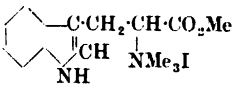
Esters and acyl derivatives. The *methyl ester* $C_{10}H_{11}N_2{\cdot}COOMe$ forms crystalline plates, m.p. 89·5° (corr.); the *hydrochloride*

$$C_{10}H_{11}N_2{\cdot}CO_2Me{\cdot}HCl$$

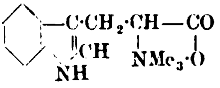
crystallises in microscopic needles, melts with decomposition at 214° (corr.); the *hydrochloride* of l-*tryptophanchloride* $C_{10}H_{11}H_2{\cdot}COCl{\cdot}HCl$ melts and decomposes at 228° (corr.) (Abderhalden and Kempe, *l.c.*). The *phenylcarbimide* derivative $C_{11}H_{11}O_2N_2{\cdot}CONHPh$ crystallises in needles, m.p. 166°; the *naphthylcarbimide* $C_{11}H_{11}O_2N_2{\cdot}CONH{\cdot}C_{10}H_7$, m.p. 159°–160°; the *benzenesulphonic derivative* $C_{11}H_{11}O_2N_2{\cdot}SO_2Ph$ melts and decomposes at 185° and forms a sparingly soluble sodium salt; the β-*naphthalenesulphonic* derivative $C_{11}H_{11}O_2N_2{\cdot}SO_2{\cdot}C_{10}H_7$ melts at 180°, the *sodium salt* at 304° (corr.) (Abderhalden and Kempe, *l.c.*; Ellinger and Flamand, Ber. 1907, 40, 3029).

Other derivatives of tryptophan are *monochlorotryptophan* $C_{11}H_{11}O_2N_2Cl$, an amorphous red precipitate, m.p. 280°, converted by excess of chlorine into the *perchloride* $C_{11}H_{11}O_2N_2Cl{\cdot}Cl_2$, a yellow precipitate decomposing at about 100°; *monobromotryptophan* $C_{11}H_{11}O_2N_2Br$, an amorphous red precipitate with a black reflex, m.p. 270°–280°; the *perbromide* $C_{11}H_{11}O_2N_2Br{\cdot}Br_2$ is yellow and decomposes at 75° (Neuberg and Popowsky, Biochem. Zeitsch. 1906, 2, 357).

The *betaine* of tryptophan is identical with the alkaloid *hypaphorine*, discovered by Greshoff (Mededeelingen uit's Lands Plantentuin, 1890, 7, 29) in the seeds of *Erythrina hypaphorus* (Boerl.). and is of considerable biochemical interest as it is the only naturally occurring simple derivative of tryptophan. The alkaloid can be synthesised from tryptophan by the action of methyl iodide, sodium hydroxide and methyl alcohol, which yields the *iodide* of *methyl-α-trimethylamino-β-indolepropionate*



m.p. 197°, and this on hydrolysis gives *hypaphorine* or *α-trimethylamino-β-indolepropiobetaine*



of which the *nitrate* has m.p. 215°–220° and

$[\alpha]_D+94{\cdot}7°$. Greshoff found $[\alpha]_D$ 91°–93° for the natural base (van Romburgh and Barger, Chem. Soc. Trans. 1911, 2068). M. A. W.

TSCHEN. Chinese coins of a brass or bronze-yellow colour, containing 55–64 p.c. copper, 26–35 p.c. zinc, and from 1–2 p.c. tin, 2–4 p.c. iron, and 1–6 p.c. lead; and occasionally small quantities of antimony, arsenic, and nickel (Pöpplein, Chem. Zentr. 1859, 484).

TSCHERMIGITE. Native ammonium-alum, first found at Tschermig in Bohemia.

TSCHEWKINITE $M''SiO_3M'''TiO_3$. A silicotitanate of iron, cerium, lanthanum, and didymium, of a velvet black colour, found in the Ilmen mountains.

TSE-HONG. A mixture of white lead, alumina, ferric oxide, and silica, used by the Chinese for painting on porcelain.

TSING-LIEN. A red pigment used in porcelain painting. Consists of a mixture of stannic and lead silicates with copper oxide or cobalt and gold.

TULA METAL. An alloy of silver, copper, and lead made at Tula in Russia.

TUNG OIL is obtained from the seeds of *Aleurites cordata* (Muell. Arg.) (*Elæococca cordata* [Bl.]; *Elæococca vernicea* [Juss.]; *E. sinensis* (*Dryandra vernicea* [Corr.]), trees indigenous to China and Japan. Trees belonging to the same species also grow abundantly in Indo-China, Tonkin, Annam, and Cambodja.

The fruits form a nut, in which three seeds, having a hard shell and an oleaginous kernel, are enclosed; hence in China the oil is frequently termed 'nut oil.'

The composition of tung oils varies somewhat according to their source, and the treatment of the seeds in different localities. Three kinds of seeds are distinguished—yellow, drab, and white. In China the seeds are roasted in a flat dish over a naked fire and then broken to powder between stones; finally the mass is expressed in crudely made wooden presses. The kernels contain about 53 p.c. of oil, but the yield of oil amounts to only 40–41 p.c. The cold-drawn oil is pale yellow, and termed white tung oil. This is the variety chiefly imported into Europe. The oil obtained by hot pressing is dark brown, and termed black tung oil. This oil is consumed at home; it has an unpleasant taste, and its odour is more pronounced than that of the white tung oil, which is also somewhat unpleasant. This odour precludes its use for many purposes. The objectionable smell is stated to be absent from oils obtained from seeds freed from all damaged kernels. Tung oil is also expressed in Madagascar, where the oil is known under the name 'Bakoly oil.' This name is most likely a corruption of 'bancoulier' (*Aleurites moluccana*). The Chinese and Japanese oils are not identical. They differ chiefly in their specific gravity (*see Characteristics* under Oils, Fixed, and Fats). The chief shipments of oil are made from Hankow and Wuchow in China; comparatively smaller quantities are exported from Japan (Hokkaido).

Tung oil is stated to consist chiefly of the glycerides of oleic and elæomargaric acids. Hence, although tung oil gives with the bromide test 0·38 p.c. of a precipitate, its fatty acids do not yield any ether-insoluble bromide. In the 'elaidin test' an oily layer is obtained resting on the lower, nearly solid product; when stirred up, the whole mass flows.

The oil is most readily identified by its strong characteristic smell, which it has hitherto not been possible to remove entirely.

The oil is further readily recognised by the manner in which it dries. It is frequently stated that tung oil is a better drying oil than linseed oil, inasmuch as it forms a skin more rapidly than does linseed oil; but the skin it yields, *e.g.* on a glass plate, although dry, is opaque, wax-like, and has no elasticity. Therefore, tung oil cannot replace linseed oil. Nevertheless, tung oil is now largely used as a substitute for linseed oil when the price of the latter is high. A number of patents have been taken out for the manufacture of boiled oils, varnishes, rubber substitutes, and linoleum, in which larger or smaller quantities of tung oil are used in place of linseed oil. *V.* Varnish.

A characteristic property of tung oil is to form a jelly on being heated to 250° for a short time, or even when kept at 180° for an hour or two. On exposure to the light the oil also becomes solid. The jelly-like mass so obtained possesses some elasticity, is insoluble in the ordinary solvents for oils, and shows no tendency to melt on again being heated to 250°. The gelatinisation is not due to oxygen absorption, since the conversion into a semi-solid mass takes place when air is carefully excluded. When heated with lead oxide or red lead, the oil gelatinises within 15 mins. to a light brown mass.

If a saturated solution of iodine in chloroform or any other solvent be dropped on tung oil, the oil is immediately solidified; and if the oil has been previously dissolved in chloroform, a jelly is obtained. Bromine has no such action on the oil.

Concentrated sulphuric acid gives a black clot with the oil. When 1 grm. of the oil is dissolved in 5 c.c. of chloroform, and 5 c.c. of a saturated solution of iodine in chloroform is added, and the mixture stirred, the whole is converted into a stiff jelly after about 2 mins. If 2 grms. of the oil be employed under the same conditions the jelly is so stiff that it can be granulated.

In China and Japan tung oil is used chiefly as a natural varnish for wood, for caulking junks and boats, as a common adulterant of lacquer, and also for lighting. Large quantities are also consumed for water-proofing paper and all kinds of tissues. The oil is further employed in admixture with powdered lime as a mortar. The best kinds of Chinese ink are obtained by burning the oil with a regulated amount of air. The cold-drawn oil is stated to be used in medicine as an emetic and also as a purgative. It should be noted that the raw oil is poisonous.

J. L.

TUNGSTEN. Sym. W. At.w. 184·0. Although found in most of the tin deposits throughout the world, the mineral *wolfram* which furnishes the bulk of the tungsten of commerce and its products, appears to have been regarded, until the middle of the eighteenth century, rather as a constituent of *cassiterite* than as an associated mineral. The term 'wolfram' was, in fact, apparently applied to it on account of its causing loss of tin in smelting, in the same sense that antimony was called 'the wolf' b the alchemist because it devoured the base metals when employed in the refining of gold.

In 1781, Scheele obtained a yellow powder (which he termed tungstic acid) by acid treatment of the aqueous extract from the fusion of a certain heavy lime mineral with potassium carbonate. The production of a yellow colouring matter by direct acid treatment of this mineral (afterwards termed *scheelite*), had been previously noted by Woulfe, who did not, however, explain its nature. Scheele's work was confirmed and amplified by Bergman in 1782, and the following year, his former pupils, the brothers D'Elhuyart, are stated to have shown the presence of tungstic acid in wolfram and to have produced metallic tungsten from it.

Although but little definite work was published on tungsten and its compounds prior to the nineteenth century, it is evident that a considerable amount of knowledge existed, and an interesting short note in Nicholson's journal for 1801, states that Guyton had melted tungsten, but that it was brittle and probably useless except in alloys or for making fixed colours or 'fixing' vegetable colours—three of its present uses. The earliest recognised commercial uses of tungsten ores were, in fact, for the production of sodium tungstate for fireproofing purposes or as a mordant, &c., for the preparation of tungstic acid and other coloured compounds suitable for use as pigments, &c., and for the manufacture of alloys.

As regards the use of tungsten for hardening steel, it is curious that the old Damascus steel, always celebrated for its retention of temper, has been found to contain both tungsten and chromium, although probably not intentionally added. The patents of Mushet (1859) for the manufacture of steel, &c., containing tungsten, following a patent by Oxland (1857) for the production of certain alloys of tungsten with iron and steel, nickel, &c., and the earlier and more important patent of Oxland (1847) for the manufacture of sodium tungstate, tungstic acid and metallic tungsten from tin-wolfram ores, may be considered to form the basis of all present commercial methods of treating tungsten ores and of practically all the technical uses of the metal and its compounds.

Like many other rare heavy metals, tungsten occurs mainly in minerals found in the oldest plutonic rocks and in the alluvium produced by their denudation, a large proportion being obtained in the form of a wolfram concentrate during the dressing of tin ores.

Tungsten is an essential constituent of a considerable number of minerals but, commercially speaking, may be said to be only produced from wolfram and scheelite. The term 'wolfram' or 'wolframite' should, mineralogically, be confined to the tungstate of iron and manganese $FeWO_4 \cdot MnWO_4$, theoretically containing 76·47 p.c. of tungstic acid or 60·7 p.c. of tungsten, but the minerals *ferberite* $FeWO_4$, and *hübnerite* $MnWO_4$, which contain almost the same proportion of tungstic acid as true wolfram, are commonly included under the generic name 'wolfram' for market purposes. The iron and manganese contents of both are, in fact, so variable that it is often difficult to say under which class a so-called 'wolfram' should be placed. No specimen of hübnerite free from iron, or of ferberite free from manganese, has yet been found.

Scheelite $CaWO_4$ (theoretically containing 80·55 p.c. of WO_3) is also an important tungsten mineral, but its common association with rare metals (molybdenum, &c.) and base metals (antimony, &c.), from which it is difficult to effect a separation, has resulted in a smaller output and a lower price as compared with wolfram. Among other minerals may be mentioned *reinite*, a variety of ferberite, $FeWO_4$, *cupro-scheelite* $CaWO_4 \cdot CuWO_4$, *stolzite* or *raspite* $PbWO_4$, and *wolfram ochre* WO_3. The last-named mineral is commonly found as an incrustation produced by the weathering of tungsten minerals, but occasionally occurs massive, and the author has an interesting piece which was sent to England as scheelite, but is almost pure tungstic acid, apparently of colloidal origin.

The principal localities where tungsten minerals are found are England (Cornwall), Spain, Portugal, Bohemia, Saxony, Bolivia, Peru and Argentina, the United States, Canada, the Malay States, Australasia, Nigeria, and South and East Africa. The largest producers are the United States (mainly Colorado) and the Commonwealth of Australia, which respectively produced 1821 and 1789 short tons (2000 lbs.) in 1910, the world's production in that year being estimated at 6950 short tons. These figures have been calculated from the tungstic acid contents reported, on the assumption that the ore, as sold, averaged 60 p.c. of WO_3.

Although their value mainly depends on the amount of tungsten which they contain, at least 90 p.c. of the output being absorbed in the manufacture of the metal and its alloys, the minerals of tungsten are invariably sold on the basis of their tungstic acid content. The best concentrated or hand-picked material contains from 70 to 74 p.c. WO_3, but the usual value of that sold in bulk varies between 60 and 70 p.c., the latter being considered of exceptionally good quality. Material even lower than 60 p.c. is saleable, but is penalised for the impurities. Although the sale of wolfram is commonly a matter of private treaty, schedules covering ores of various percentages and showing the limits allowed for phosphorus, sulphur and other impurities, are published by several firms in the United States, and the demand is increasing more rapidly than the supply.

The composition of selected specimens of the principal tungsten minerals of the nature of wolfram, is shown in the following table compiled from various sources, including Dr. W. F. Hillebrand of the United States Geological Survey and H. E. Wood of the Colorado Scientific Society:

	Wolfram		Ferberite			Hübnerite
	Colorado	Zinnwald	Harz	Spokane	Colorado	Colorado
	p.c.	p.c.	p.c.	p.c.	p.c.	p.c.
WO_3 .	74·10	75·99	76·25	75·0	75·9	75·58
FeO .	11·07	9·62	20·20	18·0	23·0	0·24
MnO .	14·35	13·96	3·96	3·0	0·6	23·40

The analyses are all those of picked specimens, any silica, lime, alumina and other gangue material being ignored. Traces of columbium, tantalum, and other rare metals, as well as of tin and copper, are commonly present in actual combination, even in selected crystals.

Wolfram ore is commonly separated from the gangue by wet dressings but, as any other heavy minerals which may be present in the original material also accumulate in the concentrate, it is usually necessary to carry out a further dressing. Owing to the high price of wolfram, the cost of such treatment is usually justified, especially when tin ore is associated with the wolfram, which is penalised for the presence of tin if more than 2 or 3 p.c. of that metal is present. The usual method of separating wolfram from other minerals in the concentrate, depends on the fact that it is slightly magnetic, and consists in the use of an electro-magnetic separator. Such treatment has proved the salvation of many tin mines, by dividing a concentrate previously almost unsaleable, into two products, tin ore and wolfram, each of which commands a good price in the market. The treatment usually produces four products, one which is valueless (magnetic iron ore, &c.) but the removal of which increases the value of the remainder, a fairly clean wolfram product, an intermediate product known as 'middlings' or 'tinny wolfram,' and a fairly clean tin concentrate ready for sale to the tin smelters. The losses, both in wet dressing to produce the original rough concentrate, and in the magnetic separation, are heavy, especially in the case of reef ore, which constitutes the bulk of the supply and which frequently contains less than 1 p.c. of wolfram and seldom exceeds 5 or 6 p.c.

The treatment of tungsten ores for the manufacture of metallic tungsten or of its oxides or salts, comprises a series of operations which, although chemically and metallurgically simple, require extreme care and experience and, even under the best conditions, result in heavy losses. It is true that ferro-tungsten is now being increasingly made by direct reduction of the ore in the electric furnace, and that the old difficulty, due to the large proportion of carbon formerly always present in directly made ferro-tungsten, has been largely overcome, but metallic tungsten and its alloys are still mainly prepared by the reduction of tungstic acid prepared from sodium tungstate which has been obtained by fusion of wolfram with sodium carbonate.

The 'Oxland' process, patented in 1847 and still used with practically no modification, for the manufacture of sodium tungstate from wolfram ores or from mixtures of wolfram and 'black tin' or cassiterite, consists in heating a mixture of the powdered ore with about 10 p.c. more than the theoretical amount of sodium carbonate (often with the addition of about 10 p.c. of sodium nitrate), in a reverberatory furnace at a red heat. The charge is occasionally stirred and the temperature is regulated so that the mass does not fuse but can be drawn out in a pasty condition when (after about four hours) the reaction is completed. The use of sodium sulphate instead of carbonate was proposed by Oxland but results in irregularity in the furnacing and in the nature of the product, and has met with no general application. The charge is leached with water in superimposed vats in which the weak liquors from the final washing of one charge can be used for the first extraction of another. The solution is crystallised and re-crystallised for the preparation of the pure tungstate, or is evaporated to dryness for the crude salt. The principal impurities in the tungstate thus prepared are sodium sulphate, silicate and arsenate, together with traces of iron and manganese, apparently present as ferrate and manganate. The iron, manganese and arsenic may be precipitated by the addition of a small quantity of caustic soda, whilst the bulk of the sodium sulphate crystallises out prior to the crystallisation of the tungstate and most of the silicate remains in the mother liquor from the tungstate crystals. Hence, almost chemically pure tungstate can be obtained by re-crystallisation, even from the crudest tungstate. Some difficulty is introduced when the wolfram is highly silicious, *i.e.* when it has not been carefully dressed, on account of the tendency towards the formation of silico-tungstates, but their presence merely means the retention of a large proportion of tungstate in the mother liquor, and there is a considerable demand (for fire-proofing purposes, &c.) for the crude salt obtained by evaporation of the liquor to dryness. The tungsten is, however, often precipitated as the calcium salt by addition of milk of lime or calcium chloride, the calcium tungstate thus obtained being afterwards converted into tungstic acid by treatment with hydrochloric acid. The residue from the leaching consists essentially of the oxides of iron and manganese, and is useful as flux in smelting operations. When the wolfram employed was admixed with 'black-tin,' as is commonly the case, the residue is dressed on shaking or other tables and the black-tin separated for sale to the tin smelters.

For the manufacture of tungstic acid, the second step in the production of metallic tungsten, a boiling solution of sodium tungstate is poured into boiling hydrochloric acid diluted with its own bulk of water, the granular tungstic acid thus obtained being filtered and washed in presses. The strength of the solution of both tungstate and acid and the method of admixture, stirring, filtering and washing, require the most careful supervision, and under the best conditions both temporary and permanent losses are heavy, partly from the production of a soluble acid tungstate and partly from the formation of colloidal tungstic acid, both of which pass through the filter or dissolve during the washing. The production of both is minimised by the use of excess of acid, by adding the tungstate to the acid slowly, with constant agitation and at the highest possible temperature and by washing rapidly with dilute acid. The necessity for thorough washing is accentuated by the fact that the retention of a very small proportion of sodium tungstate results in the production of a greenish tinge in the dried tungstic acid, which is supposed to be then less suitable for the preparation of metallic tungsten powder.

The third and last step in the manufacture of tungsten consists in the reduction of tungstic acid by heating in crucibles with carbon, or by reduction at a red heat in producer gas, hydrogen or other reducing gas. The reduction in gas results in the production of the purest metal, but is difficult to control or complete, so that the simpler crucible process is mainly employed. Slightly less than the proportion of carbon theoretically required for the reduction of the metal with production of carbon monoxide is employed, and it is usual to wash the metal and thus remove the free carbon together with the finer particles of tungsten metal and undecomposed oxide. The fine-grained but distinctly granular residual metal is sold, while the amorphous and extremely fine particles which have been washed off are mixed with the next charge for reduction.

Notwithstanding the readiness with which tungsten powder oxidises, it is still mainly used in preference to the fused metal obtained by the alumino-thermic method or in the electric furnace, or to ferro-tungsten obtained by direct reduction from the ore. On account of its high melting-point, it dissolves more readily in steel when added in the form of powder, and its heavier cost in that form is more than counterbalanced by its greater purity, although it is probable that fused tungsten or ferro-tungsten of the necessary purity will shortly be commercially available and will be employed on an increasing scale.

Metallic tungsten may also be prepared by the direct reduction of sodium tungstate with carbon at a heat sufficient to volatilise the sodium which is simultaneously produced, or by similarly reducing calcium tungstate and dissolving out the lime which remains with the resultant powdered metal. The metal obtained by this and many other apparently simple processes is, however, always impure, and the only commercial methods known consist in the reduction of tungstic acid by the processes already referred to. Tungsten powder, as sold to the steel makers, usually contains over 98 p.c. of tungsten together with about 0·5 p.c. each of iron and silicon, under 0·5 p.c. of carbon (commonly 0·1 or 0·2 p.c.) and practically no sulphur or phosphorus. The manufacturing costs, and the losses in each stage of the treatment, are so heavy that, apart from the cost of the ore, the value of the metal ultimately obtained is higher than might be expected. It is found that, although 100 parts of tungsten is theoretically obtained from about 127 parts of tungstic acid, an amount of wolfram containing over 140 parts is required to yield that amount of metal. The costs or 'returning charges' per ton of metal are commonly taken at £80, so that when wolfram ore, containing 60 to 65 p.c. of tungstic acid, sells at about £100 per ton, tungsten powder will command about £300.

Although readily obtained in the massive state in the electric furnace, Moissan found that it could only be produced free from carbon if the heat was not allowed to actually melt it, and although the objection to the presence of carbon is less in the case of steel-making—the principal use of the metal—tungsten or ferro-tungsten containing as much as 1 or 2 p.c. of carbon finds only a limited outlet. High-speed, self-hardening tools, for the manufacture of which the bulk of the tungsten is employed, sometimes contain as much as 10 or even 20 p.c. of tungsten and must be free from more than a small, definite amount of carbon, so that the use of high carbon tungsten or alloy would be impossible. The method now employed for the manufacture of pure tungsten for sheet or wire is not fully known, but is stated to depend upon a final refining *in vacuô* of the purest metal obtainable by reduction of the oxide with carbon. Carbon and occluded gases are removed and, as in the case of tantalum, a metal is obtained which has properties entirely different from those of ordinary so-called pure tungsten.

Tungsten is ordinarily obtained as a powdered or semi-fused, crystalline, brittle metal, harder than glass and having a sp.gr. of between 16 and 17. That obtained by Moissan in the electric furnace had a sp.gr. of 18·7 and was softer than glass. The properties of pure wrought tungsten are entirely different from those of the powdered or ordinary cast metal. It is white, lustrous, tough and non-magnetic, and can be rolled, like steel, into thin sheet, welded at a yellow heat and drawn into wire considerably thinner than one-thousandth of an inch. It melts at about 3000° (3002° according to recent determinations made with the optical pyrometer at the Wisconsin University). Its tensile strength increases as the drawing proceeds. Wire of 5 mm. diameter (*i.e.* $\frac{1}{1000}$ inch) has a tensile strength in pounds per square inch, of 460,000, while that of 1·2 mm. rises to 580,000, hard drawn piano wire of 3 mm. having a tensile strength of 507,000 lbs. The sp.gr. of the pure wrought metal is 18·81, and slightly more when the metal is drawn into wire. It is stated to be as high as 18·92 when heated to 1000° and compressed at 200 atmospheres. Hard drawn tungsten wire has an electrical resistivity of 6·2 microhms per centimetre cube at 25°, the temperature co-efficient for 0° to 170° being 0·0051. The corresponding figure for annealed wire is 5·0.

Tungsten is unaffected by water or air at ordinary temperatures, but both air and steam oxidise it at a red heat. Molten sulphur or phosphorus attack it slowly, while at a red heat their vapours rapidly convert it into the sulphide or phosphide. It does not combine directly with nitrogen. It is readily attacked by fused oxidising salts, such as alkaline nitrates and peroxides. Fused bi-sulphates and alkalis or alkaline carbonates also attack it, but their solutions have no action. At ordinary temperatures, bromine, iodine and sulphuretted hydrogen do not affect it, but chlorine has a slight and sodium hypochlorite a considerable solvent action. Strong or weak hydrochloric acid has no action upon it at ordinary temperatures, but the strong acid slowly attacks it at the boiling-point and produces a coating of black oxide. Boiling dilute sulphuric acid has no action, but the hot strong acid attacks it slowly. Concentrated nitric acid has but little action, but the dilute acid produces a yellow coating of tungstic acid which, as is also the case with *aqua regia*, appears to practically prevent further action. Hydrofluoric acid does not affect the metal, even when hot, but attacks it rapidly when mixed with nitric acid.

There is reason to think that a considerable future use for this metal lies in the manufacture of laboratory and other utensils, as, although not so resistant to certain reagents as platinum or tantalum, there are many purposes for which its special resistance to such reagents, coupled with its greater cheapness, will render it of special value.

Although the production of tungsten minerals may not appear at first sight to justify the statement that tungsten is one of the most important metals other than those commonly spoken of as commercial metals, the saving which has been introduced by its employment in steel manufacture and in the electric-light industry, shows very remarkable figures. In the case of the electric-light industry, in which the use of tungsten has only come into prominence within the last six years (the use of drawn tungsten wire only within about three years), the figures are particularly interesting. Although the actual amount of metallic tungsten used for filament lamps at the present time is measured only in pounds or hundredweights, it is estimated in the Mineral Resources of the United States for 1910 that, assuming the present lamp consumption to require 80 million 25 watt tungsten lamps per annum, the saving in current effected by employing tungsten lamps in place of the old carbon filament lamps would result in an annual saving of between £40,000,000 and £50,000,000 per annum. Economies far greater than the present or any possible saving in electric lighting are effected in engineering work through the use of tungsten for the manufacture of what are commonly called self-hardening lathe tools, drills, &c., which retain their temper even at a red heat, and are practically the only ones now employed in the larger works. Although the value of Mushet steel has been known for over fifty years, it is only within the last twenty years that tungsten steel can be said to have been largely used, but it is stated that Sheffield alone now uses between 1000 and 1500 tons of tungsten powder annually in its manufacture.

Tungsten combines directly with carbon, silicon and boron at or near the melting-point, and may be alloyed with many metals although but few alloys are at present in use. The alloys may commonly be prepared at a considerably lower temperature than the melting-point of tungsten, as it dissolves in other molten metal, the main precaution necessary being the use of a suitable flux to prevent access of air which rapidly oxidises powdered tungsten at the temperatures employed.

Although powdered metal is mainly employed direct in the manufacture of alloys, ferro-tungsten, and tungsten alloys with nickel, chromium and manganese as well as silico-tungsten, are also prepared for use in steel-making or for the production of special tungsten alloys.

Apart from steel-making, which accounts for over 90 p.c. of the metal, tungsten alloys of extremely varied composition are in use or have been suggested for many purposes, including wires for electrical resistances, bronzes, &c., but, although tungsten can be alloyed with most metals, the cost of the alloy is commonly altogether out of proportion to its value.

The following table shows the composition of a number of typical varieties of tungsten powder and ferro-tungsten as employed on the large scale, the former as prepared by reduction of tungstic acid with carbon, and the latter as obtained in the electric furnace :

	Tungsten powder		Ferro-tungsten		
	1	2	1	2	3
W	97·02	98·63	85·15	79·43	71·80
Fe	0·61	0·59	14·12	18·60	24·35
C	0·32	0·12	0·45	1·49	2·58
Si	0·72	0·32	0·13	0·16	0·36
Mn	0·16	—	0·085	0·21	0·78

S	nil	—	0·021	0·016	0·02
Al	0·47	0·21	—	0·001	0·07
Cu	—	—	—	—	0·008
Mg	0·32	—	—	—	—

The principal salts and other compounds of tungsten are described under a separate heading. Although of great theoretical interest, there are few to which any commercial use can be applied, only the yellow oxide WO_3, and the tungstates of the alkalis or alkaline earths being employed as such or as steps in the production of the metal.

C. T. H.

Compounds of Tungsten.

Oxides. Tungsten is said to form a number of oxides the separate existence of which is not definitely settled. Thus, when sulphuric acid acts on metallic tungsten under varying conditions, the blue oxides, WO, W_2O_3, W_4O_3, W_5O_9, are formed ; sulphurous acid acts on tungsten forming the oxide W_5O_{14}, and a beautiful purple oxide with a yellow metallic lustre, W_3O_5, is obtained by heating ammonium metatungstate to a bright red heat or by fusing tungstic acid with potassium iodide (Desi, J. Amer. Chem. Soc. 1897, 19, 213).

The **hydroxide** W_5O_{14},H_2O, a dark blue powder with a purple lustre, is formed when tungstic acid is reduced with stannous chloride and hydrochloric acid, or by heating the acid with hydrogen iodide in a sealed tube at 200°. With ammonia it yields ammonium tungstate and the hydroxide W_3O_8,H_2O (Allen and Gottschalk, Amer. Chem. J. 1902, 27, 328).

The only oxides which are definitely known are WO_2, W_2O_3, WO_3.

Tungsten dioxide WO_2 may be prepared by the reduction of the trioxide or an alkaline metatungstate with zinc and hydrochloric acid (Pfordten, Ber. 1883, 16, 508) or by heating the trioxide to a dull redness in hydrogen (Riche, Ann. Chim. Phys. 1857, [iii.] 50, 29 ; Greenwood, Chem. Soc. Trans. 1908, 1493). It may be obtained crystalline by reducing lithium paratungstate with hydrogen (Hallopeau, Compt. rend. 1898, 127, 512).

Tungsten dioxide may be formed by heating an intimate mixture of tungsten trioxide and $\frac{1}{5}$–$\frac{1}{10}$ its weight of glycerol, ethylene glycol or similar hydroxyl compound, to a bright red heat for some hours (Eng. Pat. 18922, 1907 ; J. Soc. Chem. Ind. 1908, 22).

Tungsten dioxide, prepared in the wet way is of a copper red colour, prepared in the dry way it is a brown powder. It is readily oxidised to the trioxide ; heated in chlorine it yields a yellow oxychloride WO_2Cl_2. When amorphous it is soluble in hydrochloric and in sulphuric acid, but is quite unacted on when crystalline.

Blue tungstic oxide W_2O_3, formed when tungsten trioxide is reduced with hydrogen at 250°–300° (Malaguti, Compt. rend. 1835, 1, 292) or by electrolysing fused sodium tungstate

(Smith, Ber. 1880, 13, 753), is readily oxidised to the trioxide.

Tungsten trioxide (*tungstic oxide or anhydride*) WO_3 occurs naturally as *wolframine* and as *tungstite* or *meymacite* (Walker, Amer. J. Sci. 1908, [iv.] 25, 305), also in the form of tungstates in *wolfram* and *scheelite*. It may be prepared by calcining in contact with air, the lower oxides, the metal, a sulphide or its hydrate (tungstic acid), *v.* below.

Tungsten trioxide forms a yellow powder which may be obtained crystalline by heating the amorphous metal to a very high temperature in air or by fusion of tungstic acid with borax in a porcelain vessel (Nordenskjöld, Pogg. Ann. 1861, 114, 612); or by passing hydrogen chloride over tungstic acid or a mixture of sodium tungstate and sodium carbonate at a white heat (Debray, Compt. rend. 1862, 55, 287). Its sp.gr., when amorphous, varies between 5·27–7·13, when crystalline between 6·30–6·38. It is fusible with difficulty and is insoluble in water. When heated in hydrogen it gives the blue oxide at 250°, the dioxide at a red heat, and the metal if the latter action is prolonged. It is also reduced when heated with zinc and certain other metals (Delépine, Bull. Soc. chim. 1900, [iii.] 23, 675). When heated with chlorine or sulphur monochloride, it is converted into a volatile oxychloride and in the former case also into the hexachloride (Smith and Fleck, J. Amer. Chem. Soc. 1899, 21, 1008; Bourion, Compt. rend. 1908, 146, 1102; Defacqz, *ibid.* 1319).

The oxide is soluble in hydrofluoric acid, but not in hydrochloric or nitric acids or in *aqua regia*. *See* also Ehrenfeld, J. Amer. Chem. Soc. 1895, 17, 381).

Plastic masses of tungsten oxide for incandescent lamp filaments may be prepared by treating the oxide or hydrated tungstic acid with ammonia at −20° or below, or when in alcoholic suspension with gaseous ammonia (Eng. Pat. 14850; J. Soc. Chem. Ind. 1908, 1198, 1104).

Tungstic acids. Tungsten trioxide forms two well characterised acids, WO_3,H_2O or H_2WO_4 and $(WO_3)_4H_2O$ or $H_2W_4O_{13}$. In addition the salts of a number of polytungstic acids are known (Schaefer, Zeitsch. anorg. Chem. 1903, 38, 142).

Tungstic acid H_2WO_4 may be obtained by precipitating a solution of a tungstate with excess of hot acid. If cold acid is used, the white *hydrate* H_2WO_4,H_2O is formed, from which the acid may be obtained by boiling. It is prepared by digesting a tungsten mineral with hydrochloric acid, then with *aqua regia* until the brown powder has become yellow, when the iron and manganese have been dissolved out. The residue is well washed and then shaken with ammonia which dissolves the free tungstic acid. On filtration and evaporation the tungstic acid crystallises out. The finely powdered mineral may be fused with calcium chloride or with alkali carbonates or sodium chloride. The melt is lixiviated and the calcium or other metallic tungstate residue is then decomposed with nitric or hydrochloric acid.

Tungstic acid may be prepared from wolfram or other mineral containing tungsten, by heating the mineral under pressure with a concentrated solution of potassium hydroxide, lime or baryta being added to form insoluble compounds with some of the impurities.

The tungstic acid is then separated from the solution either by fractional precipitation with acid, the impurities separating first, or the whole of the precipitate formed by adding sufficient acid is fractionally redissolved by alkali. The process is said to be economical, convenient, and to give very pure acid (Fr. Pat. 389040, 1908; J. Soc. Chem. Ind. 1908, 939).

Tungstic acid may be purified by treating tungsten trioxide with carbon tetrachloride vapour at a red heat. The resulting volatile chlorine compound is sublimed, condensed and treated with *aqua regia*; the tungstic acid formed is then further purified by solution in ammonia and reprecipitation with dilute nitric acid (U. S. Pat. 926084; J. Soc. Chem. Ind. 1909, 794).

Tungstic acid is a yellow powder insoluble in water and almost so in all acids except hydrofluoric acid, in which it dissolves to the extent of 44·7 p.c. at 25°, 55·3 at 50°, using 50 p.c. hydrofluoric acid (Rosenheim and Bernhardi-Grisson, 7th Inter. Congr. Appl. Chem. 1911, Sect. x. 120). It is readily soluble in alkalis.

Freshly prepared tungstic acid dissolves in aqueous solutions of most aliphatic amines forming substituted ammonium tungstates such as $(NMeH_3)_6W_7O_{24},6H_2O$, which crystallise on evaporation. When heated they are decomposed forming the amine, tungstic acid and the blue oxide of tungsten (Ekeley, J. Amer. Chem. Soc. 1909, 31, 664). It also gives crystalline precipitates with pyridine and quinoline (Rosenheim and Bernhardi-Grisson, *l.c.*).

Colloidal tungstic acid may be prepared by adding hydrochloric acid to concentrated sodium tungstate solution until it has an acid reaction. The white gelatinous precipitate formed, protected from currents of air, is washed by decantation several times at 0° to 5°: 15 parts of the acid are then dissolved in 1 part of concentrated oxalic acid by gently warming, and the liquid is subjected to dialysis. If the outer water is changed frequently, the oxalic acid may be completely removed (Pappadà, Gazz. chim. ital. 1902, 32, ii. 22; see Sabanéeff, Zeitsch. anorg. Chem. 1897, 14, 354).

Colloidal tungstic acid may be obtained by dissolving 5 grms. of tungsten tetrachloride in about 50 c.c. of a mixture containing equal volumes of ethyl alcohol and ether; the filtered solution is diluted to 250 c.c. with alcohol and then mixed with an equal volume of water. The colloidal solution thus obtained behaves as a positive colloid; it may be kept for some days without appreciable opalescence being observed, but coagulation occurs more quickly by adding a larger quantity of water, and immediately when small quantities of neutral salts, hydroxides, or strong acids are added. Weak organic acids or rise in temperature exert no effect. If an electric current is passed through, a deep blue precipitate separates at the cathode (Müller, Zeitsch. Chem. Ind. Kolloide, 1911, 8, 93; Lottermoser, Verh. Ges. deut. Naturforsch. Aerzte, 1910, 11, 70; Wöhler and Engels, Koll. Chem. Beihefte, 1910, 1, 454; Zeitsch. Elektrochem. 1910, 16, 693).

The colloidal acid is also prepared by dialysing a 5 p.c. solution of sodium tungstate to which sufficient hydrochloric acid has been added to combine with the sodium. Colloidal tungstic acid forms a gum-like mass which may be heated at 200° without becoming insoluble and which at a red heat is converted into the trioxide. The colloidal acid has, probably, the constitution of the *meta* acid.

Tungstic acid and sodium tungstate are used in the production of colour resists for aniline black. 200 grms. sodium tungstate dissolved in 1 litre of gum tragacanth paste constitutes a white resist which may be rendered more lustrous and opaque by passing the printed tissue, after steaming, through a solution of barium chloride. The compound thus formed may be coloured by pigments, such as vermilion, ultramarine blue and chrome green, a series of pale resist colours being formed, along with which the usual albumin and tannic acid colour mixtures may be printed (Scheurer, Bull. Soc. Ind. Mulhouse, 1900, 138; *ibid.* 1898, 122).

Tungstic acid may also be employed in the production of resist effects upon *p*-nitraniline red and of discharge effects upon indigo-dyed tissues. In the latter case, the tissue dyed with the indigo is padded in a solution of sodium tungstate, dried and printed with a steam discharge mixture containing barium chlorate, potassium ferrocyanide and a basic dyestuff able to withstand the oxidising action, such as rhodamine 6 G, ultramarine, or chrome yellow. The colours are rendered faster by the addition of albumin together with an alkali citrate or tartrate.

Metatungstic acid $H_2W_4O_{13},7H_2O$, first isolated by Scheibler (J. pr. Chem. 1861, [i.] 83, 310), may be prepared by decomposing the lead salt with hydrogen sulphide or the barium salt with dilute sulphuric acid. It crystallises in small yellow octahedra, very soluble in water, giving a bitter solution, and loses its water of crystallisation at 100°. For its behaviour on electrolysis see Leiser (Zeitsch. Elektrochem. 1907, 13, 690).

Paratungstic acid, the acid corresponding to the salts of the formula $12WO_3,5M_2O,Aq$, has been prepared in dilute solution by mixing barium paratungstate with a quantity of dilute sulphuric acid not quite sufficient for complete decomposition. The solution cannot be concentrated even *in vacuô* without decomposition, and when boiled it yields tungstic acid (Hallopeau, Compt. rend. 1895, 121, 61).

Tungstates. The alkaline tungstates

$$M_2WO_4Aq$$

are prepared by fusing a naturally occurring tungstate with sodium or potassium hydroxide or carbonate, preferably with the addition of a silicious or other flux. The alkali tungstate falls to the bottom and may be tapped off, or, after cooling, the slag may be removed (J. Soc. Chem. Ind. 1885, 116; *ibid.* 1900, 542; *ibid.* 1899, 171; Eng. Pats. 30053, 1897; 6045, 1900).

The *sodium salt* crystallises in thin prisms, soluble in 4 parts of cold, in 2 parts of hot water, the solution having a bitter taste and an alkaline reaction. It has m.p. 698° (Parravano, Gazz. chim. ital. 1909, 39, ii. 55).

The *potassium* salt forms large prismatic crystals. The ammonium salt is very unstable.

Calcium tungstate $CaWO_4$ occurs native as *scheelite* and may be prepared artificially by the interaction of calcium chloride and a normal tungstate. If the amorphous white precipitate so obtained is mixed with lime and heated in a current of hydrogen chloride, it is obtained crystalline. The corresponding *barium tungstate* was prepared by Rousseau for use instead of white lead (Schoen, J. Soc. Chem. Ind. 1900, 740).

Lead tungstate occurs native as *stolzite* and crystallises in red tetragonal pyramids.

Ferrous tungstate occurs as *wolfram*

$$(FeMn)WO_4$$

forming dark grey or brownish-black prisms.

Manganese tungstate is found as *hübnerite*. Granger (Compt. rend. 1898, 127, 106; *ibid.* 1905, 140, 935) has proposed the employment of the tungstates in the ceramic industry.

Ammonio copper tungstate $CuWO_4,4NH_3$, deep blue crystals, are readily decomposed. A similar zinc salt is also known (Briggs, Chem. Soc. Trans. 1904, 675).

The copper compound

$$CuO,4WO_3,6NH_3,8H_2O,$$

has been obtained by the interaction of an ammoniacal solution of copper sulphate and ammonium tungstate. It forms small blue needles (Briggs, *loc. cit.*).

Sodium paratungstate $Na_{10}W_{12}O_{41},Aq$ is known commercially as tungstate of soda and may be prepared on a large scale by roasting wolfram with soda ash and lixiviating the fused mass. The boiling solution is then nearly neutralised with hydrochloric acid and allowed to crystallise when large triclinic crystals of the salt separate. It is sometimes used as a mordant instead of sodium stannate in dyeing and calico printing. It also renders cotton, linen, &c., non-inflammable. The corresponding potassium salt is formed in glistening scales when normal potassium tungstate is boiled with a little water.

For various paratungstates see Hallopeau, Ann. Chim. Phys. 1900, vii. 19, 92; Taylor, J. Amer. Chem. Soc. 1902, 24, 629.

Metatungstates $M'_2W_4O_{13},Aq$ were discovered by Margueritte (Ann. Chim. Phys. 1846, [iii.] 17, 475). The alkali salts are readily formed when the normal tungstates are boiled with tungstic acid until the filtrate no longer gives a precipitate on addition of hydrochloric acid. The other metatungstates are best prepared by double decomposition of the barium salt with the required sulphate or carbonate. The metatungstates have a bitter taste, are generally readily soluble in water and deposit tungstic acid on prolonged boiling. A large number of them are known but there is considerable difference of opinion as to their constitution (Copaux, Compt. rend. 1909, 148, 633; Zeitsch. anorg. Chem. 1911, 70, 297; Rosenheim, *ibid.* 418; *ibid.* 1911, 69, 247; Just, Ber. 1903, 36, 3619).

Pertungstates $M'WO_4,Aq$ are formed by boiling a paratungstate with hydrogen peroxide (Péchard, Compt. rend. 1891, 112, 1060); or by electrolysing a slightly acid solution of sodium tungstate (Thomas, J. Amer. Chem. Soc. 1899, 21, 373). More highly oxidised compounds are formed by treating the pertungstates with hydrogen peroxide (Melikoff and Pissarjewsky, Ber. 1898, 31, 632; Pissarjewsky, J. Russ. Phys. Chem. Soc. 1902, 34, 472).

Tungsten bronzes are compounds of the alkali metals with tungsten and oxygen, which, owing to their colour and insolubility in acids and alkalis have been employed as substitutes for bronze powders. Their exact constitution is not known, although they are generally regarded as compounds of the tungstates with tungsten dioxide. They may be obtained by the reduction of the tungstates heated to redness with hydrogen, coal gas, zinc, iron or tin.

Tungsten bronzes may be prepared electrolytically by fusing tungstic acid with the calculated amount of metallic carbonate and electrolysing the mass. A series of brightly coloured mixed alkali and alkaline earth tungsten bronzes of various compositions are described by Engels (Zeitsch. anorg. Chem. 1903, 37, 125) and Schäffer (*ibid.* 1904, 38, 148).

Four *tungsten sodium bronzes* are known, $Na_5W_6O_{18}$ of a golden yellow colour, $Na_2W_5O_{15}$ of a blue colour, $Na_2W_3O_9$ of a purple red colour, and $Na_4W_5O_{15}$ which forms red-yellow cubes and yields a brown-yellow powder (Philipp, Ber. 1882, 15, 499).

Potassium forms one bronze, $K_2W_4O_{12}$ (Knorre and Schäffer, *ibid.* 1902, 35, 3407).

Blue lithium bronzes are described by Hallopeau (Compt. rend. 1898, 127, 512).

Tungstates of the rare earths are described by Hitchcock (J. Amer. Chem. Soc. 1895, 17, 483).

TUNGSTEN AND THE HALOGENS.

Tungsten hexachloride WCl_6 is prepared by heating metallic tungsten in excess of pure dry chlorine, particular care being taken to exclude all traces of air and moisture in order to avoid the formation of the oxychloride (Roscoe, Annalen, 1872, 162, 349). A small quantity of the latter is formed at the beginning of the reaction, however, in spite of all precautions. It should be driven off beyond the portion of the tube where the chloride is to be collected. Tungsten hexachloride forms dark violet opaque crystals, which are very stable when pure but are readily decomposed by moist air or water, if the slightest trace of the oxychloride is present. It has m.p. 275°, b.p. 346·7°/759·5 mm.

Tungsten pentachloride WCl_5 is formed by the incomplete reduction of the hexachloride in a current of hydrogen. It is volatile and when redistilled forms long, pure black shining crystals, m.p. 248°, b.p. 275·6°. It is hygroscopic and dissolves in water forming an olive-green solution, but most of it decomposes into the blue oxide and hydrochloric acid (Roscoe, *l.c.*).

Tungsten tetrachloride WCl_4 forms the non-volatile residue in the production of the pentachloride. It may also be prepared by the distillation of the latter or of the hexachloride, or better, a mixture of the two chlorides in a current of hydrogen. It forms a greyish-brown crystalline powder (Roscoe, *l.c.*). It is hygroscopic, infusible, is partially decomposed by water and is reduced by hydrogen to the metal.

Tungsten dichloride WCl_2 is best prepared by heating the tetrachloride in a current of carbon dioxide at the temperature of a moderately hot zinc bath. It is a grey non-volatile powder partly decomposed and partly dissolved by water forming a brown solution (Roscoe, *l.c.*).

Tungsten dioxydichloride WO_2Cl_2, obtained by passing chlorine over the dioxide, forms light lemon-yellow scales. Heated with ammonia it forms the compound $W_4O_4N_4H_2$ (Smith and Shinn, Zeitsch. anorg. Chem. 1893, 4, 381).

Tungsten oxytetrachloride, beautiful red needle-shaped crystals, m.p. 210·4°, b.p. 227·5°, is formed by the interaction of the trioxide and phosphorus pentachloride (Schiff, Annalen, 1879, 197, 185); or by passing the vapour of the hexachloride over the heated trioxide.

Tungsten hexabromide WBr_6 obtained by heating tungsten with dry bromine vapour in an atmosphere of nitrogen, forms blue-black needles which decompose when heated to a high temperature, give a colourless solution in aqueous ammonia, fume in air and give a royal blue oxide when treated with water (Schaeffer and Smith, J. Amer. Chem. Soc. 1897, 18, 1098).

Tungsten pentabromide, prepared by passing dry hydrogen bromide over tungsten hexachloride at 300°, or better by the action of excess of bromine on tungsten, forms fern-like aggregates of dark needles with green reflex, m.p. 276°, b.p. 333°. It is very hygroscopic, yields the blue oxide when treated with water and dilute acids and is decomposed by alkalis, alkali nitrates, carbonates and bisulphates (Defacqz, Ann. Chim. Phys. 1901, [vii.] 22, 247).

Tungsten oxybromides WO_2Br_2, $WOBr_4$ and the compounds WCl_3Br_3, WCl_6, $3WBr_6$ are also known (Defacqz, Compt. rend. 1899, 129, 515).

Tungsten tetriodide WI_4, obtained by the action of an excess of liquid hydrogen iodide on tungsten hexachloride at 110°, is a black crystalline substance of sp.gr. 5·2 at 18°, decomposed by water, alkali-hydroxides and carbonates. Soluble in absolute alcohol (Defacqz, Compt. rend. 1898, 127, 510).

Tungsten diiodide WI_2, obtained by the action of hydrogen iodide on tungsten hexachloride at 400°, is an amorphous, insoluble, infusible, non-volatile brown powder of sp.gr. 6·9 at 18° (Defacqz, *ibid.* 1898, 126, 962).

Tungsten hexafluoride WF_6 may be obtained by the interaction of tungsten hexachloride with anhydrous hydrofluoric acid or with arsenic trifluoride, or, best of all, antimony pentafluoride. It has m.p. 2·5° and b.p. 19·5°. Is readily soluble in alkalis, attacks glass and most metals and forms double salts with alkali fluorides. When acted on by water it yields tungstic acid (Ruff, Zeitsch. anorg. Chem. 1907, 52, 256).

Tungsten oxytetrafluoride WOF_4, obtained by the interaction of the oxytetrachloride and anhydrous hydrogen fluoride, forms small colourless hygroscopic plates, m.p. 110°, b.p. 185°–190°, is decomposed by water forming tungstic acid and absorbs large quantities of ammonia in the cold (Ruff, *l.c.*).

Tungsten dioxydifluoride is known in an impure state. For various double fluorides see Marignac (Ann. Chim. Phys. 1863, [iii.] 69, 63); Marchetti (Zeitsch. anorg. Chem. 1895, 10, 66); Miolati and Rossi (Real. Accad. Lincei. 1896, [v.] 5, ii. 223); Ephraim and Heymann (Ber. 1909, 42, 4456).

TUNGSTEN AND SULPHUR.

Tungsten disulphide WS_2 may be prepared by passing hydrogen sulphide over tungsten hexachloride at 375°–550°, or by fusing an intimate mixture of pure dry potassium carbonate, flowers of sulphur and tungsten trioxide. It is a grey-black crystalline powder, insoluble in water, fairly stable, and has sp.gr. 7·5 at 10° (Defacqz, Compt. rend. 1899, 128, 609).

Tungsten trisulphide WS_3, best obtained by treating a sulphotungstate with excess of acid, is a brown powder which becomes black when dried, is slightly soluble in cold water, more so in hot water, and readily in alkali hydroxides and carbonates (Corleis, Annalen, 1885, 232, 244). It has been obtained in the colloidal state by Winssinger (Bull. Assoc. Sci. Belg. 1888, 15, 390).

The compounds, $WCl_6,3WS_3$ (Ann. Chim. Phys. 1901, [vii.] 22, 238) and WO_2S (Winssinger, *l.c.*) and a number of metallic sulpho- or thiotungstates, M_2WS_4 (Corleis, *l.c.*), have been described. A *di-* and *tri-selenide* (Uelsmann, J. 1860, 92) and a *tritelluride* are also known.

Tungsten nitrides W_3N_2, W_2N_3, a number of oxynitrides, nitretamido and oxynitretamido compounds, and also a hydroxylamine tungstate have been obtained (Wöhler, Annalen, 1850, 73, 190; *ibid.* 1858, 105, 258; Rideal, Chem. Soc. Trans. 1889, 41; Wöhler, *ibid.* 1851, 3, 171; Desi, *l.c.*; Allen and Gottschalk, *l.c.*).

TUNGSTEN AND PHOSPHORUS.

Tungsten combines directly with phosphorus when heated to redness, forming a dark green *phosphide* W_3P_4.

Tungsten diphosphide WP_2 produced by heating tungsten hexachloride at 450° in a current of hydrogen phosphide forms a black crystalline mass insoluble in water, sp.gr. 5·8. The phosphorus is readily displaced by the halogens and by sulphur and nitrogen at high temperatures. It may be reduced by heating with hydrogen, zinc or copper (Defacqz, Compt. rend. 1900, 130, 915).

If tungsten diphosphide is heated with a large excess of copper phosphide in a graphite crucible in a wind furnace and the product treated with dilute nitric acid, it yields the *monophosphide* WP, grey lustrous prismatic crystals, sp.gr. 8·5 (Defacqz, *ibid.* 1901, 132, 32).

Another *phosphide* W_2P is formed by reducing a mixture of phosphorus pentoxide (2 mols.) and tungsten trioxide (1 mol.) in a charcoal crucible at a high temperature (Wöhler, Chem. Soc. Trans. 1853, 5, 94).

Phosphotungstic acid. Tungstic acid combines with phosphoric and also with arsenic, antimonic and vanadic acids to form complex compounds of varying composition, $M_2O_5:WO_3 = 1:7$ to $1:24$ analogous to the molybdates. Phosphotungstic acid is used as a reagent for the precipitation of alkaloids, proteins and some of their products of hydrolysis, also for the detection of potassium and ammonium salts with which it gives insoluble precipitates. It may be prepared by acidifying a solution of 4 parts of sodium tungstate and 1 part of sodium phosphate with sulphuric acid and extracting the phosphotungstic acid with ether (Winterstein, Chem. Zeit. 1898, 22, 539).

Literature on phosphotungstic acids and the phosphotungstates (Kehrmann, Zeitsch. anorg. Chem. 1891, 1, 428; Soboleff, *ibid.* 1896, 12, 16; Rogers, J. Amer. Chem. Soc. 1903, 25, 298).

Tungsten arsenide WAs_2, prepared by heating tungsten hexachloride in a current of hydrogen arsenide at 150°–360°, is a black crystalline insoluble powder of sp.gr. 6·9 at 18°.

Tungsten chloroarsenide W_2AsCl_9, obtained by heating the above substances in a sealed tube at 60°–70°, forms hygroscopic bluish-black crystals, decomposed by water and acids (Defacqz, Compt. rend. 1901, 132, 138).

For *arsenictungstic acids* and *tungstates* see Kehrmann and Rüttimann (Zeitsch. anorg. Chem. 1899, 22, 285). *Vanadotungstates* (Friedheim, *ibid.* 1894, 6, 11; Rogers, *l.c.*; Friedheim and Henderson, Ber. 1902, 35, 3242). *Antimoniotungstates* (Hallopeau, Compt. rend. 1896, 123, 1065). *Zirconotungstates* (*ibid.* 1896, 122, 1419). *Alumino-* and *alumino-phospho-* and *arseno tungstates* (Daniels, J. Amer. Chem. Soc. 1908, 30, 1846).

Tungsten boride WB_2, prepared by fusing the two elements together in an electric furnace, crystallises in hard octahedra, sp.gr. 9·6 (Tucker and Moody, Chem. Soc. Trans. 1902, 16).

TUNGSTEN AND CARBON.

When tungsten trioxide is fused with calcium carbide in an electric furnace, it forms an iron-grey *carbide*, CW_2, which is harder than corundum and has sp.gr. 16·06 at 18°. In the presence of a large excess of iron, the *carbide* CW, an iron-grey crystalline powder of sp.gr. 15·7 at 18°, is formed (Moissan, Compt. rend. 1897, 125, 839; Williams, *ibid.* 1898, 126, 1722).

Chromium tungsten carbide $CW_2,3C_2Cr_3$ is formed by heating a mixture of chromic oxide, tungstic acid and carbon in a carbon crucible in an electric furnace for five minutes with a current of 400 ampères at 75 volts and treating the product with warm hydrochloric acid, then with concentrated ammonia solution. It forms small hard stable crystalline grains of sp.gr. 8·41 at 22°. By the addition of tungsten to chromium steels, the formation of this stable hard carbide might give rise to the production of new steels with special qualities (Moissan and Kouznetzow, Compt. rend. 1903, 137, 292).

Iron tungsten carbide $3W_2C,2Fe_3C$, a magnetic substance, sp.gr. 13·4 at 18°, has also been prepared (Williams, *ibid.* 1898, 127, 410; Carnot and Goutal, *ibid.* 1899, 128, 207).

TUNGSTEN AND SILICON.

Tungsten silicide WSi_2 has been prepared by heating copper silicide with amorphous tungsten in an electric furnace, using a current of 800–900 ampères and 50 volts, the resulting product is then washed successively with nitric acid, caustic potash, warm hydrofluoric acid and water. It may also be prepared by reducing a mixture of silica and tungstic anhydride with sulphur and alumina. It forms brilliant, grey crystals, of sp.gr. 9·4, which are not magnetic and are very stable (Defacqz, Compt. rend. 1907, 144, 848; Hönigschmidt, Monatsh. 1907, 28, 1017).

The **silicide** W_2Si_3 is obtained by heating the trioxide with silicon in the electric furnace, after which the mass is suspended in dilute hydrochloric acid (1 in 10) and electrolysed. The excess of metal dissolves and the silicide is removed, washed with *aqua regia*, then with ammonia, and is finally separated from carbon silicide gravimetrically by suspension in methyl iodide

(Vigouroux, Compt. rend. 1898, 127, 393). It forms beautiful steel grey crystals with a metallic lustre, sp.gr. 10·9. *See* also Frilley, Rev. de Metallurgie, 1911, 8, 457; J. Soc. Chem. Ind. 1911, 1018.

Tungsten aluminium silicide forms black hexagonal crystals (Manchot and Kieser, Annalen, 1904, 337, 360).

Silicotungstic acids of the formulæ,

$$H_8W_{10}SiO_{36},3H_2O,$$

$H_4W_{12}SiO_{42},20H_2O$, $H_8W_{12}SiO_{42},29H_2O$, &c., were discovered by Marignac (Ann. Chim. Phys. 1864, [iv.] 3, 5). The acid corresponding to the last formula is formed by precipitating its salts with mercurous nitrate and decomposing the mercury salt with hot hydrochloric acid. It crystallises in large tetragonal prisms, is readily soluble in water, alcohol, and ether, and forms a valuable reagent for alkaloids. The salts, most of which are soluble in water, are prepared by boiling gelatinous silicic acid with metallic polytungstates (Wyrouboff, Bull. Soc. franc. Min. 1896, 19, 219; Friedheim and Henderson, *l.c.*).

ORGANIC SALTS OF TUNGSTEN.

Esters of tungstic acid are described by Smith and Dugan (J. Amer. Chem. Soc. 1899, 21, 1016); *alkali tungsten tartrates* by Henderson and Barr (Chem. Soc. Trans. 1896, 1456); *citrates* by Henderson, Orr and Whitehead (*ibid.* 1899, 547); *tungsten oxalates* by Rosenheim (Ber. 1893, 26, 1191).

Tungsten forms ozosalts which are readily soluble and difficult to obtain free from the normal salts used in their preparation. The following have been described:—

Sodium ozotungsten oxalate

$$NaC_2O_4WO_4,5H_2O$$

and also the corresponding ammonium and calcium salts which have only 1 mol. of water of crystallisation (Mazzucchelli and Inghilleri, Atti. R. Accad. Lincei, 1908, [v.] 17, ii. 30).

Complex compounds of the tungstic acids with organic acids have been obtained by Grossmann and Krämer (Zeitsch. anorg. Chem. 1904, 41, 43); and by Mazzucchelli and Borghi (Gazz. chim. ital. 1910, 40, ii. 241); and additive compounds of the tetra-, penta-, and hexachloride with organic esters by Rosenheim and Loewenstamm (Ber. 1902, 35, 1115).

TURANITE *v.* VANADIUM.

TURANOSE. A sugar $C_{12}H_{22}O_{11}$ obtained by heating melezitose with acetic acid. Is not hydrolysed by any of the ordinary enzymes and is consumed very slowly by yeast. Rotatory power $[\alpha]_D = +71\cdot8$ shows no birotation (Tanret, Compt. rend. 1906, 1424) (*v.* CARBOHYDRATES).

TURF *v.* FUEL.

TURGITE *v. Iron oxides*, art. IRON.

TURKEY-RED OILS *v.* OILS, FIXED, and FATS.

TURMERIC (*Indian saffron; Terra merita*). The so-called turmeric root of commerce is the underground stem or rhizome of *Curcuma longa* (Linn.), or of various species of *Curcuma—e.g. C. tinctoria, C. viridiflora* (Roxb.), &c. These plants, belonging to the *Scitamineæ*, are indigenous to Southern Asia, and are there largely cultivated, being exported from China, Madras, Bengal, Java, Malabar, Batavia, and Barbados. Those varieties which are derived from the central rhizomes are more or less round (*Curcuma rotunda* [L.]), while the lateral rhizomes are long and finger-shaped (*C. longa*). When of good quality these commercial varieties are hard, and of a dull, waxy, resinous fracture, the external colour being yellowish-grey, and internally orange-brown, but producing, when ground, a somewhat bright yellow powder, having a strong characteristic odour and a peppery bitter taste.

The rhizome of *Canna speciosa*, a West African plant, is said to be exactly similar to East Indian turmeric in taste, smell, and chemical reactions (Daniell, Pharm. J. 19, 258). It is cultivated in Sierra Leone, and furnishes the so-called 'African turmeric.'

According to Pelletier and Vogel (Annalen, 44, 297), turmeric contains cellulose, gum, starch, mineral matter, a strong-smelling volatile oil, a brown colouring matter, and a characteristic yellow colouring matter named by them *Curcumin*. Pectin and pectic acid are also present (Schützenberger). Kachler (Ber. 3, 713) found a notable quantity of potassium binoxalate.

Pelletier and Vogel's method of isolating the curcumin consisted in first removing the fatty, resinous, and other impurities by extracting pulverised turmeric with water and carbon disulphide, then dissolving out the colouring matter with boiling alcohol, and purifying it by successive solution in ether and alcohol, precipitation with lead acetate, and subsequent treatment with hydrogen sulphide and extraction with ether. It was thus obtained as an amorphous yellow powder.

Lepage adopted a similar method, but after extraction with carbon disulphide the colouring matter was dissolved in alkali, precipitated with acid, and finally purified by means of ether.

Daube was the first to obtain curcumin in the crystalline state. He removed essential oil by passing a strong current of steam over the coarsely-ground turmeric, then thoroughly extracted it with hot water, and finally treated the dried residue with boiling benzene. On cooling the solution thus obtained, crude curcumin separated as bright orange-red crystalline crusts, which were pressed between blotting-paper, and dissolved in cold alcohol. After filtering off some yellow flocculent substance, the solution was precipitated with an alcoholic solution of neutral lead acetate, adding finally a little basic lead acetate in order to neutralise almost entirely the liberated acetic acid and prevent thereby any solution of the colour-lake. The brick-red precipitate was washed with alcohol, suspended in water, and decomposed with hydrogen sulphide. The liberated curcumin was extracted from the precipitate with boiling alcohol, from which it crystallised on slow evaporation.

Benzene is very suitable for obtaining pure curcumin, for although it is very little soluble in this liquid, the resinous impurities are not dissolved thereby.

Gajewsky (Ber. 3, 265) obtained crystalline curcumin by first extracting turmeric root with carbon disulphide, then dissolving out the colouring matter with ether, and purifying it by fractional crystallisation from ether or benzene. He detected the presence of another colouring matter and also traces of an alkaloid. This chemist obtained an increased yield of colouring matter by washing the dry ethereal extract with dilute ammonia to remove resin, then dissolving the brittle residue in boiling concentrated ammonia solution and precipitating with carbon dioxide; 250 grms. ethereal extract gave 100 grms. flocculent curcumin, m.p. 140°. Jackson (Ber. 14, 485) also obtained crystallised curcumin by first removing the oil by long extraction with carbon disulphide (60 hours), then thoroughly extracting (60 hours) with ether, and after washing the orange-coloured extract thus obtained with cold alcohol or ether, crystallising from hot alcohol.

Perkin (Chem. Soc. Trans. 1904, 85, 63) precipitates an alcoholic turmeric extract with lead acetate, washes the lead compound first with alcohol then with water, and decomposes it with dilute sulphuric acid. From the mixture of lead sulphate and curcumin, the latter is removed with boiling alcohol and the extract evaporated and poured into ether, which causes the separation of tarry impurities. The ethereal solution, after evaporation to a small bulk, is treated with carbon disulphide and allowed to stand, the crystals which separate from time to time being removed. 0·56 p.c. of curcumin was thus obtained from turmeric.

Curcumin crystallises from alcohol in orange-coloured prisms, m.p. 165° (Daube), 172° (Gajewsky), 178° (Jackson), and 183° (Ciamician and Silber, Ber. 30, 192), and is soluble in ether, forming a green fluorescent liquid. Alkaline solutions dissolve it with a reddish-brown colour, which when neutralised passes to yellow, and on this account it is useful in the form of 'turmeric paper' as a reagent for alkalis. Whereas Daube assigned to curcumin the formula $C_{10}H_{10}O_3$, Gajewsky $(C_4H_4O)_n$, probably $C_{16}H_{16}O_4$, Jackson considered that $C_{14}H_{14}O_4$ or $C_{28}H_{28}O_8$ were more reasonable expressions, and of these Jackson and Menke (Amer. Chem. J. 6, 78) preferred the former, and prepared the following derivatives harmonising with this view.

Dihydrocurcumin $C_{14}H_{16}O_4$, brownish-white powder, m.p. 100° *ca.*, *dihydrocurcumin anhydride* $C_{28}H_{30}O_7$, dirty white powder, m.p. 120° *ca.*, *diethylcurcumin* $C_{18}H_{22}O_4$, brownish tar, *p-brombenzyl curcumin* $C_{21}H_{19}BrO_4$, pale yellow crystals, m.p. 76°–78°, *acetylcurcumin* $C_{16}H_{16}O_5$, brownish mass, *diacetylcurcumin* $C_{18}H_{18}O_6$, yellow rhombic crystals, m.p. 154°, *curcumin-tetrabromide* $C_{14}H_{14}O_4Br_4$, powder, m.p. 185° *ca.*, *tetrabromcurcumin* $C_{14}H_{10}Br_4O_4$, red powder, *pentabromcurcumindibromide* $C_{14}H_9Br_5O_4 \cdot Br_2$, red powder, m.p. 120 *ca.*, *potassium curcumin* $KC_{14}H_{13}O_4$, red powder, and *dipotassium curcumin* $K_2C_{14}H_{12}O_4$, red needles. By fusion with alkali curcumin gives *protocatechnic acid*, when oxidised with permanganate *vanillin*, and the diethyl ether by similar treatment yields *vanillic acid ethyl ether*. Jackson and Menke represented curcumin by the following formula

$$C_6H_3(OH)(OCH_3)CH(C_5H_5)CO_2H$$
$$(CH{:}OCH_3 : OH = 1 : 3 : 4).$$

Ciamician and Silber (Ber. 30, 192), as the result of methoxy determinations, assigned the formula $C_{21}H_{20}O_6$ or $C_{19}H_{14}O_4(OCH_3)_2$ to curcumin, and prepared *diacetylcurcumin* $C_{21}H_{18}O_6(C_2H_3O)_2$, needles, m.p. 170°-171°; and *curcumin dimethyl ether* $C_{19}H_{12}O_2(OCH_3)_4$, yellow needles, m.p. 135°. Digested with hydroxylamine hydrochloride in alcoholic solution curcumin gave the compound

$$C_{21}H_{19}NO_5 (i.e.\ C_{21}H_{20}O_5NOH - H_2O),$$

needles, m.p. 178°, whereas phenylhydrazine gave a substance crystallising in colourless needles.

Perkin (Chem. Soc. Trans. 1903, 83, 140, and 1905, 85, 63) by means of alcoholic potassium acetate, obtained from curcumin the monopotassium salt $C_{21}H_{19}O_6K$, fine orange-red needles. A *benzoyl curcumin*, pale-yellow needles, m.p. 176°–178°, was also prepared and gave by the cryoscopic method numbers, harmonising with Ciamician and Silber's formula.

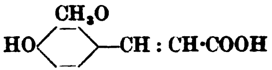
Molecular weight determinations, however, according to Jackson and Clarke (Ber. 1905, 38, 2712), indicated the correctness of the formula $C_{14}H_{14}O_4$, and again (*ibid.* 1906, 39, 2269) these authors pointed out that unless special care is employed Zeisel's method gives erroneous figures with curcumin. When heated with hydriodic acid at 120° a correct result is given, but above this temperature curcumin gives a colourless oil rich in iodine (75·75 p.c.), which reacts with the alcoholic silver nitrate solution.

Von Kostanecki and Lampe (*ibid.* 1910, 43, 2163) consider that Ciamician and Silber's formula $C_{21}H_{20}O_6$ correctly represents curcumin, and describe *dicarbomethoxy-curcumin*

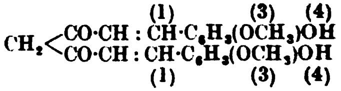
$$C_{19}H_{16}O_2(O{\cdot}COOCH_3)_2(OCH_3)_2,$$

yellow prisms, m.p. 150°, and *dicarbethoxy curcumin*, yellow leaflets, m.p. 149°–150°.

When curcumin is boiled with potassium hydroxide solution, *vanillic acid* and *ferulic acid*

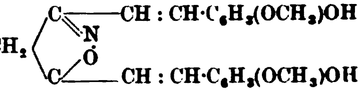


are produced. As a result these authors consider that the constitution of this colouring matter is as follows—



$$CH_2 \begin{cases} \overset{(1)}{CO{\cdot}CH : CH{\cdot}C_6H_3}(\overset{(3)}{OCH_3})\overset{(4)}{OH} \\ \underset{(1)}{CO{\cdot}CH : CH{\cdot}C_6H_3}(\underset{(3)}{OCH_3})\underset{(4)}{OH} \end{cases}$$

Further support for this formula is given by the fact that curcumin, like β-diketones, gives when treated with hydroxylamine an *iso*-oxazole derivative, and the compound prepared by Ciamician and Silber is probably *4·4′-dihydroxy-3·3′-dimethoxy-a : γ-distyrylisoxazole*



It is well known that a mixture of boric and hydrochloric acids imparts to turmeric paper a brown colour which is turned blue by alkalis. This reaction was investigated by Schlumberger (Bull. Soc. Chem. [ii.] 5, 194), who found that when an alcoholic extract of turmeric is heated in a sealed tube with boric acid, a red crystalline boric acid derivative is produced, soluble in alkaline solutions with a purple-violet colour. Boiling water decomposes this compound with elimination of boric acid, and formation of *pseudo-curcumin*, a yellow powder. If the alcoholic solution of the boric acid compound is digested with strong hydrochloric acid, a black substance separates, whereas boric acid remains in the liquid. On extracting the black powder with a mixture of alcohol and acetic acid, the filtrate deposits green iridescent crystals of rosocyanine.

Rosocyanine is readily soluble in alcohol containing a trace of mineral acid and dissolves in ammonia solution with a blue colour. It is according to Schlumberger, an unstable substance, and if boiled for a long time with alcohol, is converted into pseudo-curcumin.

Jackson and Clarke (*l.c.*) prepared rosocyanine by heating a solution of curcumin in dilute alcohol with boric and sulphuric acids, and describe it as a purplish-red powder, closely resembling powdered rosaniline. These authors consider it to be isomeric with curcumin $C_{14}H_{14}O_4$, and describe an *ammonium salt* $C_{14}H_{13}O_4NH_4$, and a *potassium salt* $C_{14}H_{13}O_4K$, both of which possess an intense blue colour. The tinctorial properties of curcumin are of special interest, for not only is it a strong colouring matter towards mordants, but with cotton, wool and silk behaves also as a substantive dyestuff. In the latter case it is only necessary to add the material to a boiling decoction of the colouring matter. Though considerably employed up to within recent years by the wool and silk dyer in the formation of olives, browns, and other compound colours turmeric is now but rarely employed for dyeing purposes in England. In India, however, it appears to be still in vogue.

Cotton is usually dyed in a decoction of turmeric rendered slightly acid by the addition of a little acetic acid, or alum may be employed. The colour does not resist either the action of light or of alkalis, and readily acquires a brownish-red tint. Wool may be dyed without any addition, keeping the temperature about 60°. By previously mordanting with alum a brighter effect is produced, whereas tin mordant gives a more orange colour. Potassium dichromate and ferrous sulphate employed in a similar manner yield respectively olive and brown coloured shades.

Silk is preferably dyed in an acid bath, and is sometimes previously mordanted.

Turmeric oil is the thick orange-coloured aromatic oil present to the extent of 3·23 p.c. in turmeric from which it can be extracted by means of carbon disulphide. Bolley examined the portion distilling over at 230°–250°, and considered it to be identical with carvol, whereas Gajewsky (*l.c.*) found the portion distilling over at 220°–228° contains less carbon and more hydrogen than that which passes over at a higher temperature. On oxidising the latter portion with chromic acid, an acid oil is obtained which contains valeric, caproic, and terephthalic acids. Jackson and Menke (*l.c.*) analysed that portion which distils over at 285°–290°, and gave it the formula $C_{19}H_{28}O$, and the name *turmerol*, and obtained *turmeryl chloride* $C_{19}H_{27}Cl$, *sodium turmerol* $C_{19}H_{27}ONa$, and *turmerol* iso*butyl ether* $C_{19}H_{27}O{\cdot}C_4H_9$. With permanganate turmerol gave *terephthalic acid*, *turmeric acid* $C_{11}H_{14}O_2$, and *apoturmeric acid* $C_{10}H_{12}O_4$ or $C_{10}H_{10}O_4$. According to Rupe (Ber. 1907, 40, 4909) when turmeric oil is boiled with dilute sodium hydroxide solution a substance, b.p. 156°/12 mm., apparently not identical with Jackson and Menke's turmerol, is produced. Stronger alkali yields an optically active ketone $C_{13}H_{18}O$, *curcumone*, b.p. 119°–120°/8 mm., which gives a semicarbazone, m.p. 119·5°–120·5°, an oxime, b.p. 159°/11 mm., and condensation products with aromatic aldehydes. With permanganate the ketone gives p-*methylacetophenone* and *terephthalic acid*, and with alkaline hypobromite the acids $C_{12}H_{16}O_3$, m.p. 150°, and $C_{12}H_{16}O_2$, m.p. 33°–34°. By the further action of permanganate the latter yields a dicarboxylic acid $C_{12}H_{14}O_4$, m.p. 228°. Rupe) Luksch, and Steinbach (Ner. 1909, 42, 1515, were unable to isolate from turmeric oil the turmerol of Jackson and Menke having sp.gr. 0·9388 at 20° and $[\alpha]_D^{20}$ −27·46. By digestion with alcohol and 30 p.c. potassium hydroxide solution the ketone $C_{13}H_{18}O$, *curcumone* was obtained, which has b.p. 121°/10 mm., sp.gr. 0·9566 at 20°, n_D 1·50526, $[\alpha]_D$ 80·55, and yields the p-*bromophenylhydrazone*, m.p. 71°. It condenses with benzaldehyde to form the compound $C_{13}H_{16}O : CH{\cdot}C_6H_5$, m.p. 106°, and with piperonal and anisic aldehyde similar compounds melting respectively at 86° and 77°–78° are produced.

The acid $C_{12}H_{16}O_2$ (*l.c.*), m.p. 33°–34°, is called *curcumic acid*, and appears to be identical with Jackson and Menke's turmeric acid (Rupe and Steinbach, Ber. 1910, 43, 3465). By oxidation with permanganate it gives terephthalic acid, *p*-tolymethylketone, and the acid $C_{12}H_{14}O_4$, m.p. 226°–228° (*l.c.*), and this possibly consists of apoturmeric acid (J. and M.). Although it was considered that curcumic acid might be *γ*-*p*-tolylvaleric acid, the synthesis of this latter compound showed that the two substances are not identical but similar (*ibid.* 1911, 44, 584). Again curcumic acid is not *p*-tolyl-*α*-methylbutyric acid (Rupe and Bürgin, *ibid.* 1218). Rupe and Steinbach (*l.c.*) consider that curcumone is to be regarded as a benzene derivative containing two parasubstituents, one being methyl, and the second, one or other of the groups $\cdot CHMe{\cdot}CH_2{\cdot}CH_2{\cdot}COMe$,

$\cdot CHMe{\cdot}CHMe{\cdot}COMe$, or $.CMeEt{\cdot}COMe$,

whereas in curcumic acid the group COMe is replaced by COOH. *See* also Schimmel & Co. (Bericht, April, 1911). A. G. P.

TURMERIC ACID *v.* Turmeric.

TURMERINE *v.* Primuline and its derivatives.

TURMERYL CHLORIDE *v.* Turmeric.

TURNBULL'S BLUE. A variety of Prussian blue, *v.* Cyanides.

TURNER'S YELLOW. *Patent yellow.* Lead oxychloride $3PbO{\cdot}PbCl_2$.

TURNIP. A biennial, cruciferous plant, producing in the first year a large root stock containing a store of carbonaceous and nitrogenous matter intended for the formation of flower-stem and seeds in the second year. This 'root' is the chief valuable product for which the crop is grown. Many varieties, differing in the shape, size, and colour of the root, are known, but they may all be classed as belonging to two species—the 'white turnip,' or simply 'turnip' *Brassica rapa* (Linn.), or *B. rapa rapifera* (Metzger), and the 'Swedish turnip,' or 'Swede,' known often as 'ruta-baga' in America, *Brassica campestris rutabaga* (Linn.), or *B. napus esculenta* (DC.). There are many varieties of each, but as a rule 'turnips' have rougher leaves, of greener colour, and the root has white, or, in some cases, yellow flesh; whilst 'swedes' possess smoother leaves of a bluish-green colour, and the roots have yellow flesh. The leaves of the turnip spring directly from the root, whilst those of the swede arise from a distinctly marked 'neck.'

Both types grow best in cool, damp climates; in hot, dry countries the roots tend to become very woody and fibrous. Swedish turnips resist frost better, and can be grown in stiffer soils than the white varieties; they also keep better after gathering.

According to König, the following figures represent the average composition of the two types—

	Water	Protein	Fat	Sugar	Other N-free ext.	Fibre	Ash
White turnips	90·67	1·12	0·24	2·55	3·55	1·11	0·76
Swedes .	88·88	1·39	0·18	3·02	4·35	1·44	0·74

Great variations in composition, however, have been observed, the most important factors, in order of importance, being apparently, season, variety, size of root, district, and soil. Even with the same variety, grown under the same conditions, and with roots of approximately the same size, considerable variations in the composition of individual roots are found, especially in the amount of sugar. Thus, Collins (J. Soc. Chem. Ind. 1901, 20, 536) found in 25 individual roots of XL All swedes, the proportion of sugar varied from 4·5 to 7·8 p.c., with an average of 6·27 p.c.

The variation with season is considerable; Collins, as the average of 12 varieties of swedes grown in 1900, found a sugar content of 6·26 p.c., while the same varieties, in 1901, gave an average of only 4·05 p.c. of sugar. Analogous to the effect of season is that of local climate; even in Britain this effect is seen. In 1904 several varieties of swedes were grown simultaneously in Cambridgeshire, Norfolk (2 centres), and Ross-shire (4 centres), and the resulting crops were examined for dry matter and sugar content.

The following figures show the sugar contents of 5 varieties, as grown at the various centres—

Variety	Cambridge	Norfolk 1	Norfolk 2	Norfolk Mean	Ross-shire 1	Ross-shire 2	Ross-shire 3	Ross-shire 4	Ross-shire Mean
Fell's Bronzetop	6·5	6·1	8·0	7·0	7·2	7·3	7·1	8·0	7·4
New Arctic .	6·1	6·0	8·1	7·0	6·9	7·2	7·1	7·9	7·3
Magnum Bonum	6·3	5·7	7·6	6·6	6·8	7·2	6·6	8·1	7·2
XL All . .	6·0	6·0	7·4	6·7	6·8	6·8	6·7	7·5	7·0
Carter's Elephant	6·3	5·6	7·0	6·3	6·7	6·9	6·8	7·4	7·0
Average . .	6·2	5·9	7·6	6·7	6·9	7·1	6·9	7·8	7·2

These results clearly show that the roots grown in the moist, cool climate of Ross-shire were, on the average, richest in sugar, while those grown in the hot, dry climate of Cambridgeshire were the poorest (Guide to Expts. 1906, Dept. of Agric. Univ. of Cambridge).

So, too, Hendrick (Bull. 1, Coll. Agric. Univ. of Aberdeen, 1904) found, as the average of analyses of 21 varieties of swedes, grown in Aberdeenshire, 11·7 p.c. of dry matter, and 5·15 p.c. of sugar, while 9 varieties of turnips yielded an average of 9·48 p.c. of dry matter, and 4·55 p.c. of sugar; and Wood (Guide to Expts. Dept. of Agric. Univ. of Camb. 1906) found as the mean of the analyses of 5 varieties of swedes, grown in Cambridgeshire (1 centre) and Norfolk (2 centres), 10·8 p.c. of dry matter and 6·6 p.c. of sugar, and for 7 varieties of white turnips 7·81 p.c. of total dry matter, and 4·24 p.c. of sugar.

The effect of soil upon the composition of the roots, although perceptible, is not great. That of manuring is very great upon the yield, but is comparatively small upon the composition, except in so far as it affects the size of the roots.

The effect of size of root, in any variety, is considerable, small roots being invariably richer in solid matter, especially sugar, than large ones. This is well seen from the following analyses by Hendrick (J. Soc. Chem. Ind. 1897, 16, 213) of two samples of 'Achilles' turnips—

Average wt. of 1 root	Water	Dry matter	Sugar	Total N	Alb. N	Ash
5lb. 1oz.	92·8	7·2	3·93	0·192	0·108	0·56
2lb. 14oz.	91·3	8·7	4·62	0·148	0·076	0·64

In view of these many circumstances affecting the composition of the roots, it is obviously of little value to attempt to give any representative composition of turnips.

It may, however, be of interest to quote the figures given by Kellner and by Warington as representing the average composition of turnips and swedes.

Kellner gives—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Swedes	87·8	1·5	0·2	8·2	1·3	0·9
Turnips	91·5	0·9	0·1	6·0	0·8	0·7

Warington's figures are—

	Water	Proteids	Amides, etc.	Fat	N-free extract	Crude fibre	Ash
Swedes	89·3	0·7	0·7	0·2	7·2	1·1	0·8
Turnips	91·5	0·5	0·5	0·2	5·7	0·9	0·7

The protein, *i.e.* total N×6·25, in the above analyses, contains a considerable and variable quantity of non-proteid substance. König states that from 35 to 55 p.c. of the total nitrogen is present, partly as amides or amino acids, partly as nitrates. Warington estimates the non-albuminoid nitrogen in turnips at 49 p.c. of the total nitrogen, but gives as the average *digestible* albuminoids 0·2 p.c. in swedes, and 0·1 p.c. in turnips. Collins (*l.c.*) found, in 'Monarch' swedes, the real albuminoids varied from 0·47 to 0·63 p.c., while the amides, &c., ranged from 0·34 to 0·61 p.c. Hendrick (*l.c.*) found the proportion of non-albuminoid nitrogen to total nitrogen varied from 27 to 42 p.c. in yellow turnips, and from 23 to 59 p.c. in 'Best of All' swedes. In the days when the 'nitrogenous substances' or 'albuminoids' in foodstuffs, were estimated by multiplying the total nitrogen by 6·25, turnips, in common with other roots, gave results on analysis which indicated that they possessed greater feeding value than actual experience showed them to have. If, however, distinction is made between true proteids and amino compounds, amides, and nitrates, the nutritive value of turnips, as assessed by analysis, seems, in most cases, to be much less than their actual efficiency as foods (*v.* Ingle, Trans. High. & Agric. Soc. Scotland. 1910, 22, 178; also Hendrick, *ibid.* 150). It would seem, in fact, that either the true albuminoids in turnips are much more digestible than has hitherto been admitted, or, more probably, that the amino compounds may, under certain conditions, behave like albuminoids, in building up animal tissue.

The sugars present in turnips are dextrose, lævulose, and sucrose, the invert sugars largely predominating. The other N-free extractives include pectins, pentosans, and cellulose.

The ash of turnips varies greatly in composition and amount. According to figures compiled by König, the whole ash varies from 4·9 to 14·0 p.c. of the dry matter, while the potash in the ash may range from 26 to 62 p.c., the lime from 5·5 to 15·9 p.c., and the phosphorus pentoxide from 5·5 to 18·9 p.c. The mean of 32 analyses of the ash gave—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
45·4	9·8	10 6	3·7	0·8	12·7	11·2	1·9	5·0

The upper half of a root is richer in solid matter than the lower, and due allowance must be made for this fact in sampling turnips for analysis.

Turnip leaves are sometimes used for feeding purposes; according to Kellner they contain, on the average—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
88·4	2·2	0·5	5·3	1·5	2·1

Turnips, like other plants of the genus *Brassica*, contain thio compounds, and when they decay or even suffer slight decomposition by boiling, they evolve unpleasant-smelling sulphur compounds, among which mercaptans are probably included.

Turnips require liberal supplies of phosphates, and phosphatic manures, generally superphosphates, are almost invariably used for this crop. For a study of the destination of phosphates and nitrogen when applied as a manure to turnips, *v.* Somerville and Smith (J. Soc. Chem. Ind. 1897, 16, 19). H. I.

TURPENTINE *v.* OILS, ESSENTIAL; also TERPENES.

TURPENTINE VARNISH *v.* VARNISH.

TURPETH or **TURBITH MINERAL.** An old name for basic mercuric sulphate $HgSO_4{\cdot}2HgO$, sometimes called Queen's yellow, *v.* MERCURY.

TURPETH or **TURBITH ROOT.** The root of the convolvulaceous plant *Ipomœa Turpethum* (R.Br.) [*Operculina Turpethum* (Peter)], found in India and Australia. It contains a volatile oil and a drastic resin, *turpethin* $C_{34}H_{56}O_{16}$, isomeric with jalapin and scammonin. When treated with dilute mineral acids this substance is hydrolysed into glucose and *turpetholic acid* $C_{16}H_{32}O_4$ (*v.* Boutron-Charlard, J. Pharm. Chim. 8, 131; Spirgratis, J. pr. Chem. [I.] 92, 97).

TURPETHIN *v.* GLUCOSIDES.

TURQUOISE or **CALAITE** (*Türkis*, Ger.). A gem-stone which has often been regarded as a hydrated aluminium phosphate

$$2Al_2O_3{\cdot}P_2O_5,5H_2O,$$

accidentally coloured by copper and iron phosphates. It has been shown, however, by S. L. Penfield (Amer. J. Sci. 1900, 10, 346) that the latter enter into the constitution of the mineral, and he writes the formula as—

$$[Al(OH)_2,Fe(OH)_2,Cu(OH),H]_3PO_4$$

representing a derivative of orthophosphoric acid with the hydrogen atoms largely replaced by the univalent radicles $Al(OH)_2$, &c. In some analyses approximately two-thirds of the hydrogen atoms are so replaced, and the formula becomes $R_2'HPO_4$. The amount of copper ranges from 2·0 to 8·5 p.c. CuO, and the iron from 0·1 to 4·0 p.c. Fe_2O_3. The mineral is soluble in hydrochloric acid without discoloration; when heated it loses water and blackens. It is opaque (or translucent in thin chips) with a sky-blue to green colour, and on the polished surface shows a soft, waxy lustre; sp.gr. 2·6–2·8; H. 6. Turquoise occurs as cryptocrystalline masses, sometimes with nodular or stalactitic surfaces, in crevices in rocks, more especially in those of volcanic origin. The best quality of material has for centuries been mined near Nishapur in Persia, and being exported to the west through Turkey it came to be known as turquoise. Deposits in the Sinai Peninsula were worked by the ancient Egyptians. Ancient mines, worked in prehistoric times, are also known in Mexico and in the state of New Mexico. Considerable quantities (17 tons in 1909, and 8¼ tons in 1910) are now obtained from Nevada, New Mexico, Arizona, California, and Colorado (D. B. Sterrett, Min. Res. U.S., Annual Reports for 1910 and earlier). Recently, minute crystals of turquoise have been described from Campbell Co., Virginia; these are triclinic and isomorphous with chalcosiderite (W. T. Schaller, Amer. J. Sci. 1912, 33, 35).

Turquoise has been imitated by subjecting to pressure a mixture of aluminium and copper phosphates. Very clever imitations are also made of glass; these may be detected by the bright, glassy, conchoidal fracture when chipped at the edges—the fracture of turquoise being dull and finely granular.

Bone-turquoise or *odontolite* is fossil bone or ivory coloured by the iron phosphate vivianite, or perhaps sometimes artificially stained by a copper solution. It can be recognised under the microscope by its organic structure. It effervesces with acid, and gives a smell of burning when heated. L. J. S.

TUTENAG or **TUTENAGUE.** *Chinese silver. Packfong.* An alloy resembling German silver.

TYPE METAL *v.* TIN.

TYRIAN PURPLE *v.* PURPLE OF THE ANCIENTS.

TYROSINE, p-*hydroxyphenylalanine*, p-*hydroxy-β-phenyl-α-aminopropionic acid*

$$HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH_2)CO_2H,$$

was so named by Liebig, who first obtained it by fusing freshly prepared cheese (τυρός) with caustic potash (Annalen, 1846, 57, 127). It occurs widely spread both in the animal and vegetable kingdoms, forming one of the most common products of proteid hydrolysis, and occurring in the free state in the seedlings and young shoots of the vetch (*Vicia sativa*) (Gorup-Besanez, Ber. 1877, 10, 781), the gourd (*Cucurbita pepo*) (Schulze and Barbieri, *ibid.* 1878, 11, 710, 1233); the lupins (*Lupinus luteus*, *L. albus*) (Schulze, *ibid.* 1878, 12, 1924; Wassilieff, Landw. Versuchs Stat. 1901, 55, 45); in the tubers of potatoes (*Solanum tuberosum*) (Schulze, Ber. 1879, 12, 1924), the swede (*Brassica rapa*), the dahlia (*Dahlia variabilis*) (Borodin, Botan. Zeit. 1882, 590; Leitgeb, Chem. Zentr. 1888, 1397; Bertrand, Compt. rend. 1896, 122, 1215); in the tubercules of *Stachys tubifera* (Planta and Schulze, Ber. 1890, 23. 1698); in the juice of sugar beet (*Beta vulgaris*) (v. Lippmann, *ibid.* 1884, 17, 2835), in celery (*Apium graveolens*) (Bamberger and Landsiedl, Monatsh. 1904, 25, 1030); in the unripe seeds of the French bean (*Phaseolus vulgaris*) (Pfenninger, Ber. Deut. bot. Ges. 1909, 27, 227), the pea (*Pisum sativum*) (Schulze and Winterstein, Zeitsch. physiol. Chem. 1910, 65, 431); in the green pods of the broad bean (Bourquelot and Hérissey (J. Pharm. Chim. 1898 [vi.] 8, 385); in the juice of elderberries (*Sambucus nigra*) (Sack and Tollens, Ber. 1904, 37, 4115); in fungi (Winterstein, Zeitsch. physiol. Chem. 1899, 26, 438). In the animal kingdom, tyrosine is found in caterpillars, crabs, spiders, and beetles (v. Lippmann, *l.c.*) and in cochineal (Warren de la Rue, Annalen, 1848, 64, 1); in the larva of *Lucilia Caesar* (Gossard, Compt. rend. 1904, 139, 644); it occurs in Emmenthaler and in Roquefort cheeses (Benecke and Schulze, Landw. Jahrbücher, 1887, 16, 317; Winterstein and Thöny, Zeitsch. physiol. Chem. 1902, 36, 28; Dox, J. Amer. Chem. Soc. 1911, 33, 423). Under normal conditions, tyrosine is not found in the liver or blood of men and animals, but occurs under certain pathological conditions (Frerichs and Staedeler, J. 1856, 702; Hoppe-Seyler, Zeitsch. physiol. Chem. 1881, 5, 348; Neuberg and Richter, Deut. med. Wochensch. 30, 499; Huber, Archiv. Heilkunde, 18, 485; Wyss, Schweiz. Zeitsch. Heilkunde, 1864).

Preparation. Tyrosine is most conveniently prepared from silk by hydrolysing with fuming hydrochloric acid, and evaporating the product under reduced pressure to dryness; the residue is dissolved in water and a stream of ammonia passed through the solution; it is then again evaporated to dryness, and the residue treated with cold water, when the tyrosine is left undissolved; or the whole residue may be boiled with water and animal charcoal, and from the filtrate pure tyrosine crystallises out quantitatively: one kilo of silk yielding 50·65 grms. of tyrosine (Abderhalden, Zeitsch. physiol. Chem. 1912, 77, 75; Abderhalden and Teruuchi, *ibid.* 1906, 48, 528).

Synthesis. Staedeler (Annalen, 1860, 116, 57) was the first to show that tyrosine was an aromatic compound, since it yielded chloranil (tetrachloroquinone) on treatment with chlorine; but its constitution as *p*-hydroxy-*β*-phenyl-*a*-aminopropionic acid was not established until 1882 when Erlenmeyer and Lipp (Ber. 1882, 15, 1544; Annalen, 1883, 219, 161) prepared racemic tyrosine from phenylacetaldehyde by the following series of reactions: *phenylacetaldehyde* on treatment with hydrogen cyanide gave *phenyllactonitrile*; this was converted by ammonia into the *nitrile of phenylalanine* which, on hydrolysis, gave *phenylalanine*; p-*nitrophenylalanine* on reduction gave the corresponding amino compound from which p-*hydroxyphenylalanine* (*r*-tyrosine) was produced by the action of nitrous acid.

$$\begin{aligned}\mathrm{C_6H_5{\cdot}CH_2{\cdot}CHO} &\rightarrow \mathrm{C_6H_5{\cdot}CH_2{\cdot}CH(OH)CN}\\ &\rightarrow \mathrm{C_6H_5{\cdot}CH_2{\cdot}CH(NH_2)CN}\\ &\rightarrow \mathrm{C_6H_5{\cdot}CH_2{\cdot}CH(NH_2)CO_2H}\\ &\rightarrow \mathrm{NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH_2)CO_2H}\\ &\rightarrow \mathrm{NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH_2)CO_2H}\\ &\rightarrow \mathrm{HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH_2)CO_2H}\end{aligned}$$

A more convenient method of synthesis is that due to Erlenmeyer jun., and Halsey (Annalen, 1899, 307, 138), in which *p*-hydroxybenzaldehyde and hippuric acid condense in the presence of acetic anhydride and anhydrous sodium acetate to form the *acetyl derivative* of the *lactimide* of p-*hydroxy-a-benzoylaminocinnamic acid*,  $\mathrm{OAc{\cdot}C_6H_4{\cdot}CH:C}\left\langle\begin{array}{l}\mathrm{NBz}\\ \,|\\ \mathrm{CO}\end{array}\right.$. This, on hydrolysis with alkali, gives p-*hydroxy-a-benzoylaminocinnamic acid*

$$\mathrm{HO{\cdot}C_6H_4{\cdot}CH:C(NHBz)CO_2H}$$

from which by reduction *benzoyltyrosine*

$$\mathrm{HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NHBz)CO_2H}$$

is obtained and converted by hydrolysis with acids into r-*tyrosine.* Another method of synthesis which can also be extended to the preparation of halogenated derivatives of tyrosine is described by Wheeler and Hoffmann (Amer. Chem. J. 1911, 45, 368; *cf.* Wheeler, Hoffmann and Johnson, Bio-Chem. J. 1911, 10, 147; Johnson and Bengis, J. Amer. Chem. Soc. 1912, 34, 1061). This method consists in condensing a suitable aldehyde with hydantoin, reducing and hydrolysing the product; thus hydantoin and anisaldehyde yield *anisylidenehydantoin*  $\mathrm{MeO{\cdot}C_6H_4{\cdot}CH:C}\left\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \qquad\ \ |\\ \mathrm{NH{\cdot}CO}\end{array}\right.$ which, when boiled with hydrogen iodide is converted into *tyrosine* together with a small quantity of 4-p-*hydroxybenzoylhydantoin* (*tyrosinehydantoin*)

$$\mathrm{OH{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH}\left\langle\begin{array}{l}\mathrm{CO{\cdot}NH}\\ \\ \mathrm{NH{\cdot}CO}\end{array}\right.$$

from which tyrosine can be obtained by boiling with baryta water.

Properties. *l*-Tyrosine, the natural product, is also obtained by the resolution of *d*-*al*-benzoyltyrosine through its brucine salt and subsequent hydrolysis of the *l*-benzoyltyrosine. It crystallises in long flexible silky needles, soluble in 2491 parts of water at 17° (Erlenmeyer and Lipp, *l.c.*), more readily soluble in hot water; dissolves in 13,500 parts of cold 90 p.c. alcohol (Staedeler, *l.c.*), insoluble in acetone, ether or absolute alcohol. It melts and decomposes at 314°–318° (corr.) when rapidly heated (Fischer, Ber. 1899, 32, 3638); at 295° (Cohn, Zeitsch. physiol. Chem. 1896, 22, 166); at 272° (Habermann and Ehrenfeld. *ibid.* 1902, 37, 18); 287° (Trans. Guinness Lab. 1903, i. 57). *l*-Tyrosine is lævorotatory both in acid and in alkali solution; the specific rotation varies with the concentration. For a 4 p.c. solution in 21 p.c. hydrochloric acid, the natural product has $[a]_D^{16}=-7{\cdot}98°$ (Mauthner, Monatsh. 1882, 3, 345), $[a]_D^{20}=-8{\cdot}07°$ (Landolt, Ber. 1884, 17, 2838); $[a]_D=-8{\cdot}48°$ (Schulze, Zeitsch. physiol. Chem. 1884, 9, 98); the synthetic product has $[a]_D^{20}=-8{\cdot}64°$ (Fischer, Ber. 1899, 32, 3638). In a 4·6 p.c. solution in 4 p.c. hydrochloric acid, the synthetic compound has $[a]_D^{20}=-13{\cdot}2°$ (Fischer), and the natural product $[a]_D^{16}=-14{\cdot}6°$ to $-16{\cdot}1°$ (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 299); in a 5·8 p.c. solution of 11·6 p.c. potassium hydroxide, the natural product has $[a]_D-9{\cdot}01°$ (Mauthner, *l.c.*). The molecular heat of combustion is 1071·2 Cal., heat of formation 156·4 Cal. (Berthelot and André, Compt. rend. 1890, 110, 884). The affinity constants of tyrosine are: first acid dissociation constant $K_a=4\times10^{-9}$, second acid dissociation constant $Ks=4\times10^{-10}$, basic dissociation constant $Kb=2{\cdot}6\times10^{-12}$ (Kanitz, Pflügers Archiv. 1907, 118, 539). The single band ultra violet absorption spectrum exhibited by solutions of tyrosine, is practically identical with that of proteids containing tyrosine; gelatin, and other proteids that contain no tyrosine show continuous spectra (Blyth, Chem. Soc. Trans. 1899, 1164).

d-Tyrosine, obtained by the resolution of *dl*-benzoyltyrosine through its cinchonine salt and subsequent hydrolysis, has $[\alpha]_D^{20}+8{\cdot}64°$ in 4·6 p.c. solution of 21 p.c. hydrochloric acid (Fischer); the dextrorotatory tyrosine obtained by v. Lippmann from the white shoots of sugar beet gave $[\alpha]_D+6{\cdot}85°$ in 25 p.c. hydrochloric acid; a feebly dextrorotatory tyrosine was found by Winterstein and Thöny (Zeitsch. physiol. Chem. 1902 36, 28) in a very old Emmenthaler cheese.

dl-Tyrosine prepared by hydrolysis of the synthetic benzoyl derivative crystallises in stout needles, melting and decomposing at 316° (corr.) when rapidly heated (Fischer, *l.c.*); its hydrochloride is much less soluble in concentrated hydrochloric acid than are the salts of the optically active forms, and the racemic compound can thus be separated from admixture with *d*- and *l*-tyrosine. By fermentation with large amounts of yeast in the presence of sugar and nutritive salts, tyrosine is converted to the extent of 60–80 p.c. into p-*hydroxyphenylethanol* (*tyrosol*) $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH_2OH$, m.p. 93°, b.p. 310°. The *dibenzoyl derivative* melts at 111°; tyrosol is also obtained by the action of yeast on *p*-hydroxyphenylethylamine (Ehrlich, Ber. 1911, 44, 139; Ehrlich and Pishtschimuka, *ibid.* 1912, 45, 1006).

By putrefactive decomposition, tyrosine is successively broken down into hydro-*p*-coumaric acid $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H$, *p*-hydroxyphenylacetic acid $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CO_2H$, *p*-cresol and phenol (Baumann, Ber. 1880, 13, 279; Zeitsch. physiol. Chem. 1880, 4, 304). The administration of tyrosine to normal animals causes the production of phenol in the urine, but no excess of hydroxy acids (Blendermann, *ibid.* 1882, 6, 234; Bied. Zentr. 1883, 209; Cohn, Zeitsch. physiol. Chem. 1894, 14, 189), except in one case when a man took 50 grms. of tyrosine in 24 hours, and this produced alcaptonuria, homogentisic acid being found in the urine (Abderhalden, *ibid.* 1912, 77, 454). Inactive tyrosine administered to cats undergoes selective decomposition, so that the urine contains more of the dextro- than of the naturally occurring lævo- variety, and on evaporating the neutral or alkaline urine containing the tyrosine, it is converted into the corresponding uramino acid which, on subsequent treatment with acid, readily loses water, yielding tyrosine hydantoin (Dakin, J. Biol. Chem. 1910, 8, 25). In the case of alcaptonurics, the administration of tyrosine or certain derivatives of tyrosine, such as mono-palmyl-*l*-tyrosine, distearyl-*l*-tyrosine, *p*-aminotyrosine, causes an increase in the amount of homogentisic acid excreted (Abderhalden and Massini, Zeitsch. physiol. Chem. 1910, 66, 140; Wolkow and Baumann, *ibid.* 1891, 15, 228).

Detection and estimation. Tyrosine develops a red colour when warmed with Millon's reagent. When tyrosine is dissolved in a few drops of warm concentrated sulphuric acid, and the diluted solution neutralised with barium carbonate the filtrate gives a beautiful violet colour with ferric chloride (Pirea, Annalen, 1852, 82, 252). If a few drops of a solution of tyrosine are added to 2 c.c. of sulphuric acid containing 3 to 5 drops of a solution of aldehyde in twice its volume of alcohol of 90°, the liquid acquires a gooseberry red colour, the intensity of which is proportionate, between certain limits, to the quantity of tyrosine present (Denigés, Compt. rend. 1900, 130, 583). When tyrosine is added to a reagent consisting of 1 part of formalin, 45 parts of water and 55 parts of concentrated sulphuric acid, a green coloration is developed on boiling the mixture (Mörner, Zeitsch. physiol. Chem. 1902, 37, 86).

Tyrosine develops a rose-red colour under the influence of *tyrosinase*, the colour changing to a dirty violet, and finally a black precipitate of *melanin* is deposited (*v. Tyrosinase*, art. FERMENTATION).

Tyrosine is readily estimated by titration with N/5 sodium bromate in the presence of hydrochloric acid and sodium bromide, the liberated bromine being absorbed by the tyrosine with formation of dibromotyrosine (Millar, Trans. Guinness Lab. 1903, I. Part 1; Brown and Millar, Chem. Soc. Trans. 1906, 145).

Salts and derivatives. *l*-Tyrosine forms crystalline salts with mineral acids which dissociate in water, the *hydrochloride* $C_9H_{11}O_3N{\cdot}HCl,2H_2O$, *hydrobromide* $C_9H_{11}O_3N{\cdot}HBr$, *hydriodide*

$C_9H_{11}O_3N.HI$,

nitrate $C_9H_{11}O_3N{\cdot}HNO_3$ and *sulphate*

$C_9H_{11}O_3N{\cdot}H_2SO_4$

are described (Haushofer, J. 1883, 1177; Aloy and Rabaut, Bull. Soc. chim. 1908, [iv.] 3, 391; Staedeler, Annalen, 1860, 116, 64); the *platinichloride* $(C_9H_{11}O_3N{\cdot}HCl)_2PtCl_4$ forms yellowish-brown readily soluble crystals (Gintl, Zeitsch. Chem. 1869, 704); the *picrolonate* blackens and sinters at 260° (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127). The following metallic salts have been prepared, those of the heavy metals and the alkaline earth metals are sparingly soluble: the *copper salt* $(C_9H_{10}O_3N)_2Cu$ dissolves in 1230 parts of cold or 240 parts of boiling water (Hofmeister, Annalen, 1877, 189, 24); the *silver salts* $C_9H_9O_3NAg_2,H_2O$,

$C_9H_{10}O_3NAg,\frac{1}{2}H_2O$ and $C_9H_{10}O_3NAg$;

the *mercury salts*, $C_9H_{11}O_3N{\cdot}2HgO,2H_2O$, $C_9H_{11}O_3N{\cdot}2HgO,H_2O$ and $C_9H_{11}O_3N,3HgO,H_2O$, the *barium salt* $(C_9H_{10}O_3N)_2Ba$; *calcium salt* $C_9H_9O_3NCa$, the *mercury-calcium salt*

$(C_9H_9O_3N)_2CaHg$,

and the *sodium salt* $C_9H_9O_3NNa_2$ (Vintschgau, J. 1869, 985; Baumann, Zeitsch. physiol. Chem. 1880, 4, 320; Causse, Compt. rend. 1900, 130, 1196).

l-*Tyrosine methyl ester* $C_9H_{10}O_3N{\cdot}CH_3$ forms colourless prisms, m.p. 135°–136° (corr.); $[\alpha]_D^{20}+25{\cdot}75°$ in methyl alcohol solution; the *hydrochloride* $C_9H_{10}O_3N{\cdot}CH_3,HCl$ forms colourless needles; l-*tyrosine ethyl ester*

$C_9H_{10}O_3N{\cdot}C_2H_5$,

has m.p. 108°–109°, $[\alpha]_D^{20}+20{\cdot}4°$ in 5 p.c. alcoholic solution; the *hydrochloride*

$C_9H_{10}O_3N{\cdot}C_2H_5,HCl$

has m.p. 166° (Fischer and Schrauth, Annalen, 1907, 354, 21; Fischer, Ber. 1908, 41, 850, Lilienfeld, Archiv. Physiol. 1894, 383, 555; Röhmann, Ber. 1897, 30, 1978; Fischer, *ibid.* 1901, 34, 433). l-*Tyrosineanhydride* $C_{18}H_{18}O_4N_2$, has m.p. 277°–280° (corr.), $[\alpha]_D^{20}-223{\cdot}8°$ in N/1 sodium hydroxide (Fischer and Schrauth). l-*Tyrosineamide* $C_8H_{10}ON{\cdot}CONH_2$ has m.p. 153°–154° and $[\alpha]_D^{20}+19{\cdot}47°$, condenses readily with ethyl chlorocarbonate to form the *monocarbethoxyl* $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH{\cdot}CO_2Et)CONH_2$, m.p. 155°–157°, and the *dicarbethoxyl*

$EtO_2C{\cdot}O{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(NH{\cdot}CO_2Et){\cdot}CO{\cdot}NH_2$

m.p. 185° (corr.). derivatives; the *dinaphthalenesulphonyl derivative* $C_{29}H_{24}O_6N_2S_2$ has m.p. 204° (corr.) (Koenigs and Mylo, Ber. 1908, 41, 4427).

The following *acyl* derivatives of *l*-tyrosine are described: the *benzoyl*

$HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}COC_6H_5$,

m.p. 165°–166° (corr.) $[\alpha]_D^{20}+19{\cdot}25°$ in 8 p.c. alkali solution, the *brucine* salt is crystalline; the *dibenzoyl*

$C_6H_5CO{\cdot}O{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}COC_6H_5$

has m.p. 211°–212° and forms a *potassium* and a *cadmium* salt (Fischer, Ber. 1899, 32, 3638, 2454); the *formyl*

$HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}CHO,H_2O$,

m.p. 171°–174° (corr.) $[\alpha]_D^{20}+84{\cdot}8°$ in 6 p.c. alcoholic solution (Fischer, *ibid.* 1907, 40, 3704); the *palmityl*

$HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}CO[CH_2]_{14}CH_3$

m.p. 133° $[\alpha]_D^{20}+24{\cdot}35$ in 1·8 p.c. alcoholic solution; *palmityl*-l-*tyrosine-palmitylether* $C_{41}H_{71}O_5N$, m.p. 95°–96° $[\alpha]_D^{20}+15{\cdot}28°$ in 1·7 p.c. alcoholic solution; *stearyl*-l-*tyrosine-stearylether*

$C_{45}H_{79}O_5N$,

m.p. 98°–108° (Abderhalden and Funk, Zeitsch. physiol. Chem. 1910, 65, 61); the *β-naphthalenesulphonyl* derivative forms a *hydrochloride* $C_{19}H_{18}O_5NSCl$, m.p. 170°, a *sodium* salt

$C_{19}H_{16}O_5NSNa$

that decomposes at 175°, an *ethyl* ester

$C_{21}H_{21}O_5NS$,

m.p. 140°–143° (Abderhalden and Funk, *ibid.* 1910, 64, 436); the *di-β-naphthalenesulphonyl* derivative

$C_{10}H_7SO_2{\cdot}O{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}SO_2C_{10}H_7$

m.p. about 120°, forms a *sodium*

$C_{29}H_{22}O_7NS_2Na$,

m.p. 252°–254°, an *ammonium* and a *barium* salt (Fischer and Bergel, Ber. 1903, 36, 2592); the *phenylisocyanate* derivative

$HO{\cdot}C_6H_4,CH_2{\cdot}CH(CO_2H)NH{\cdot}CONH{\cdot}C_6H_5$,

has m.p. 104°, and forms a *barium*

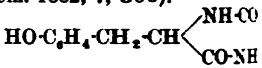
$(C_{16}H_{15}O_4N_2)_2Ba,6H_2O$

and a *silver* salt $C_{16}H_{15}O_4N_2Ag,H_2O$ (Paal and Zitelmann, *ibid.* 1903, 36, 3337); the *α-naphthylisocyanate* derivative melts at 205°–206° (Neuberg and Manasse, *ibid.* 1905, 38, 2359).

dl-*Tryosinylcarbamide*

$CO[NH{\cdot}CH(CO_2H){\cdot}CH_2{\cdot}C_6H_4{\cdot}OH]_2$

decomposes at 240° (Hugounenq and Morel, Compt. rend. 1906, 142, 48); l-*tyrosinhydantoic acid* $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH(CO_2H)NH{\cdot}CONH_2$, m.p. 218°, forms a crystalline silver salt (Jaffe, Zeitsch. physiol. Chem. 1882, 7, 306).



l-*Tyrosinehydantoin* $HO{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH{<}\begin{matrix}NH{\cdot}CO\\CO{\cdot}NH\end{matrix}$ melts and decomposes at 242°–245° (Blendermann, *l.c.*).

The alkaloid *surinamine* or *geoffroyine* from geoffroya bark is a *methyltyrosine*, in which the methyl has replaced one of the hydrogens of the amino group (Hiller-Bombien, Arch. Pharm. 230, 513; Blau, Zeitsch. physiol. Chem. 1908, 58, 153; Walpole, Chem. Soc. Trans. 1910, 97, 94).

Derivatives of *l*-tyrosine containing substituents in the aromatic neucleus are: *nitrotyrosine* $C_9H_{10}O_3N{\cdot}NO_2$, obtained by nitration of *l*-tyrosine, forms yellow needles, m.p. 220°; it is optically inactive and is a mixture of the *o*- and *m*- compounds. The *barium* and *silver salts* have been prepared, also the *hydrochloride*, *nitrate* and *sulphate* (Strecker, Annalen, 1850, 73, 70; Casimir Funk, Chem. Soc. Trans. 1912, 1004). *Aminotyrosine* $C_9H_{10}O_3N{\cdot}NH_2$, prepared by reducing nitrotyrosine, forms grey crystals, m.p. 265°, and is a mixture of the *o*- and *m*-isomerides; by the action of nitrous acid the *o*- compound is destroyed and 2-*aminotyrosine* is left; it forms yellow needles, m.p. 273°, and yields a *tribenzoyl* derivative, m.p. 192°–195° (Casimir Funk, *l.c.*). *Dinitrotyrosine* $C_9H_9O_3N(NO_2)_2$, golden yellow crystalline plates, the *calcium*, *barium*, *potassium*, *sodium*, *ammonium*, *magnesium*, *lead*, and *silver* salts have been prepared (Staedeler, Annalen, 1860. 116, 64).

Tyrosinesulphonic acid

$C_9H_{10}(SO_3H)_3NO,2H_2O$

is strongly acidic and gives a beautiful violet colour with ferric chloride. The *ammonium*, *calcium* and *barium* salts are described (Staedeler, *l.c.*).

3-*Bromotyrosine*

$HO{\cdot}C_6H_3Br{\cdot}CH_2{\cdot}CH(NH_2)CO_2H,H_2O$

has a sweet taste, decomposes at 247°–248°; the *hydrobromide* decomposes at 190°–191°, the *picrate* and *platinichloride* are very soluble in water (Johnson and Bengis, J. Amer. Chem. Soc. 1912, 34, 1061); *dibromotyrosine* (probably the 3 : 5 compound) $C_9H_9O_3NBr_2,2H_2O$ obtained by direct bromination of tyrosine, forms fine needles or rhombic plates, dissolves in 218 parts of water at 16° or 26 parts of boiling water: the *silver* salt, the *hydrochloride*, *hydrobromide* and *sulphate* are crystalline, and it forms an unstable *perbromide* (Gorup-Besanez, Annalen, 1863, 125, 281; Millar, Trans. Guinness Lab. 1903, I. Part 1).

3 : 5-*Dichlorotyrosine*, m.p. 252° (decomp.), prepared by chlorinating tyrosinehydantoin and decomposing with barium hydroxide the resulting 3 : 5-*dichlorotyrosinehydantoin*; the *hydrochloride* has m.p. 260°–265° (Wheeler, Hoffmann and Johnson, J. Biol. Chem. 1911, 10, 147).

3 : 5-*Di-iodotyrosine, iodogorgonic acid*

$HO{\cdot}C_6H_2I_2{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$

is not found free in nature but is one of the constituent amino acids of certain proteids; it was first obtained by Dreschel (Zeitsch. Biol. 1896, 33, 85) from *gorgonin*, derived from the horny skeleton of *Gorgonia cavolinii*. This, on hydrolysis with barium hydroxide, yielded an iodo amino acid, hence name *iodogorgonic acid*. It was shown by Wheeler and Jamieson (Amer. Chem. J. 1905, 33, 365) that iodogorgonic acid is a di-iodotyrosine and can be prepared by the direct action of iodine on tyrosine. That it is the 3 : 5-di-iodotyrosine was shown later by Wheeler and Johns (*ibid.* 1910, 43, 11), for on treatment with methyl iodide and potassium hydroxide it yields the methylether of a di-iodotyrosinetrimethylammonium iodide

$MeO{\cdot}C_6H_2I_2{\cdot}CH_2{\cdot}CH(CO_2H)NMe_3I$,

which on boiling with sodium hydroxide yields 3 : 5-diiodo-*p*-methoxylcinnamate. Iodogorgonic acid occurs in a large number of proteids, and has been isolated from *iodo-albacid*, *iodoglidin*, *iodocasein*, *gorgonin* and *spongin* (Oswald, Zeitsch. physiol. Chem. 1911, 70, 310; 71, 200; 74, 290; 75, 353).

3 : 5-*Di-iodo-d,l-tyrosine*, prepared by hydrolysis of the above-mentioned proteids, crystallises from hot water in glassy right-angled plates, from alcohol in hexagonal plates, dissolves in 2164 parts of water at 15°, melts and decomposes at 200°.

3 : 5-*Di-iodo-*l*-tyrosine*, prepared by the action of iodine on *l*-tyrosine, melts at 204° (Oswald), 196°–205° with decomposition (Wheeler and Jamieson); it has $[\alpha]_D^{20}+2{\cdot}27°$ in 4·5 p.c. solution of 25 p.c. ammonia (Abderhalden and Guggenheim, Zeitsch. physiol. Chem. 1907, 54, 331). The *hydrochloride*

$C_9H_9O_3NI_2,HCl$

forms colourless needles, decomposed by water; the *sulphate* $C_9H_9O_3NI_2,H_2SO_4$ is readily soluble; the *silver salt* $C_9H_7O_3NI_2Ag_2$ and *copper salt* $(C_9H_8O_3NI_2)_2Cu,H_2O$ form amorphous precipitates. The *acetyl* derivative

$C_{11}H_{11}O_4NI_2$

decomposes at 225° (Wheeler and Jamieson, Amer. Chem. J. 1905, 33. 365). The *methyl ester* $C_6H_2OI_2{\cdot}CH_2{\cdot}CH(NH_2)CO_2Me$ decomposes at 192°; its *hydrochloride* forms colourless needles that decompose at 211° (corr.), and yields the *nitrate* on treatment with dilute nitric acid (Abderhalden and Guggenheim, Ber. 1908, 41, 1237). *Palmityl*-3 : 5-*di-iodo-tyrosinepalmityl ether* $C_{44}H_{69}O_5NI_2$ melts at 55°–62° (Abderhalden and Slavu, Zeitsch. physiol. Chem. 1909, 61, 405).

A full account of the chemistry and physiology of tyrosine will be found in Biochemisches Handlexikon, von Abderhalden, vol. iv. part 2, 681–702. M. A. W.

U

UARANA *v.* GUARANA.

ULEXITE (*Boronatrocalcit* of G. L. Ulex, 1849; *Natroborocalcite*). A hydrated borate of sodium and calcium $NaCaB_5O_9,8H_2O$, containing 43·0 p.c. B_2O_3. It forms rounded, white masses, 2–3 ins. in diameter, consisting of a loose aggregates of fine, silky fibres; hence the popular name 'cotton-ball.' It occurs abundantly in the borate deposits of Nevada and California, and forms the main mass of those near Iquique in Chile, and in Jujuy province in Argentina. L. J. S.

ULTRAMARINE. Ultramarine was first artificially made on a commercial scale in 1828, by Guimet, who earned the prize of 6000 francs offered by the 'Société d'Encouragement' of France for its production at a cost not exceeding 90*s.* per lb. About the same time, Gmelin (Ann. Chim. Phys. 1828, [ii.] 37, 409) independently discovered how to prepare ultramarine on a laboratory scale. According to Heintze (J. pr. Chem. 1891, [ii.] 43, 98), ultramarine was being made by Kottig, director of the laboratory of the Konigl. Porzellan-manufaktur in Meissen, at the time when Guimet and Gmelin were claiming the priority of the discovery.

Until 1828 ultramarine was obtained by powdering and washing *lapis-lazuli* (*q.v.*); its composition was first determined by Clément and Désormes (Ann. Chim. Phys. 1806, [i.] 57, 317).

Properties.—Artificial *ultramarine blue* occurs in commerce as a bright, azure blue, impalpable powder, insoluble in water. Its constituent elements are sodium, aluminium, silicon, sulphur, and oxygen. Heated to 200°–300° with water in a sealed tube, it leaves a colourless residue free from sulphur, while sodium sulphide passes into solution. It also loses its sulphur when heated with mercuric oxide (Chabrié and Levallois, Compt. rend. 1906, 143, 222). Ultramarine is quite stable towards alkalis, but is readily decomposed by dilute acids, some sulphur being precipitated and hydrogen sulphide evolved. The preceding reactions seem to indicate the presence of some kind of polysulphide in ultramarine; but it is unaltered by concentrated and fuming sulphuric acid, and also by a mixture of glacial acetic acid and acetic anhydride (Hofmann and Metzener, Ber. 1905, 38, 2482), reagents which instantly decompose polysulphides and thiosulphates. Ultramarine withstands a red heat fairly well, although it loses its brilliancy, and becomes greenish; hence it is difficult to imagine that the blue colour is due to free sulphur, as has been suggested (Paterno and Mazzucchelli, Atti. R. Accad. Lincei, 1907, [v.] 16, i. 465). Ultramarine blue becomes brownish-yellow when strongly heated in hydrogen, and violet when heated to dull redness in chlorine. It possesses hydraulic properties and increases the binding power of cement (Rohland, Zeitsch. angew. Chem. 1904, 17, 609).

When heated with aqueous silver nitrate at 120°–140° in a sealed tube for 15 hours, no silver sulphide is produced, but a dark yellow *silver ultramarine* is obtained, together with silver nitrite and other products (Unger, Dingl.

poly. J. 1874, 212, 232; Heumann, Ber. 1877, 10, 991, 1345, 1888; 1879, 12, 60, 784; Bull. Soc. chim. 1877, [ii.] 28, 570; 1878, 30, 326, 327; 1880, 33, 60, 302; Annalen, 1879, 199, 253; 1880, 201, 262; Philipp, Ber. 1877, 10, 1227; Forcrand and Ballin, Bull. Soc. chim. 1878, [ii.] 30, 112; Chabrié and Levallois, *l.c.*). Silver ultramarine is produced by replacement of the sodium in ordinary ultramarine by silver; when fused with various metallic chlorides or iodides, the silver is replaced by other metals, and in this way have been obtained *potassium* (blue), *lithium* (blue), *barium* (yellowish-brown), *zinc* (violet), *manganese* (grey), *ultramarines*, &c. Heated with the requisite organic iodide, silver ultramarine is decomposed, yielding *ethyl*, *amyl*, *benzyl*, and *phenyl ultramarines*, and silver iodide (Forcrand, Compt. rend. 1879, 88, 30; Bull. Soc. chim. 1879, [ii.] 31, 161). These substances regenerate ultramarine when heated with sodium chloride. They do not evolve hydrogen sulphide when treated with cold hydrochloric acid (Chabrié and Levallois, *l.c.*). *Selenium* and *tellurium* ultramarines have also been produced, in which sulphur is substituted by either selenium or tellurium (Guimet, Ann. Chim. Phys. 1878, [v.] 13, 102; Plicque, Bull. Soc. chim. 1877, [ii.] 28, 518; 1878, 29, 522; 1878, 30, 51; Morel, *ibid.* 28, 522). Light blue *boron ultramarine* has been prepared by fusing together anhydrous borax, boric oxide, and either sodium or potassium sulphide, sulphite, or thiosulphate (Hofmann, Zeitsch. angew. Chem. 1906, 19, 1089; 1907, 20, 568; Chem. Ind. 1911, 34, 699).

Ultramarine blue crystallises in the regular system, isomorphous with the minerals *hauyn*, *sodalite*, and *nosean*.

Green ultramarine is formed as an intermediate product in the manufacture of ultramarine blue, and is converted into the latter by roasting with sulphur. According to Philipp (Ber. 1876, 9, 1109), sulphur is not taken up in the change from green to blue, which can be effected by heating with water in a sealed tube at 100°; a small amount of sodium compound is removed by the water. Heated in chlorine, green ultramarine turns bluish-violet; sodium sulphide solution turns it grey.

White ultramarine is obtained by completely excluding air during the roasting of the materials in the manufacture of ultramarine, and is converted into blue ultramarine when heated in either chlorine, oxygen, or sulphur dioxide (Philipp, Ber. 1876, 9, 1109; 1877, 10, 1227; Böttinger, Annalen, 1876, 182, 311; Hofmann, *ibid.* 1878, 194, 1).

Red ultramarine was first obtained by Scheffer in the course of preparing the ordinary substance, by heating the materials very strongly in a muffle freely exposed to air; it contains less sodium and more aluminium than the blue variety (Scheffer, Ber. 1873, 6, 1450; Büchner, Dingl. poly. J. 1879, 231, 446; Zettner, Ber. 1875, 8, 259, 353).

Red ultramarine has been prepared by passing chlorine and steam over heated ultramarine blue.

Yellow ultramarine is obtained by heating the red variety in air for a short time at 360°, or at a little higher temperature (Hofmann, Annalen, 1878, 194, 1). According to Büchner (Ber. 1874, 7, 990), both the yellow and red forms are produced by heating blue ultramarine to 300°–400° in oxygen or sulphur dioxide; the colour changes to red and then to yellow. If chlorine is passed over ultramarine before the formation of the blue variety is completed, at 410°, the colour goes green and then reddish-yellow (Zettner, Ber. 1875, 8, 259, 353).

Violet ultramarine is obtained when the reddish-yellow product previously mentioned is heated with sodium hydroxide (Zettner, *l.c.*). It becomes blue when heated to dull redness or when further heated with an alkali hydroxide, and nitric acid vapours turn it red.

The violet variety was first prepared by Leykauf in 1859 by allowing moist calcium chloride to react with warm ultramarine blue. In 1872 Wunder prepared it by heating the blue form in chlorine at 300° and treating the product with water. It has been manufactured from ultramarine blue by heating the latter, in thin layers, on earthenware trays at 280°, and passing steam over it to remove sulphur. The temperature was then lowered to 160°, and a mixture of chlorine and steam led over it for 3 hours. For further details, and other methods, v. Wunder, Chem. Zeit. 1890, 14, 1119.

Composition.—The various varieties of ultramarine have not yet been satisfactorily shown to possess uniform compositions. In fact, commercial blue ultramarines are manufactured in three different grades, containing different proportions of silica and sulphur. Moreover, it is not possible to obtain products of identical composition even when, in repeated operations, the relative amounts of the different raw materials are maintained constant and the working conditions duplicated as exactly as possible. The following analyses of different samples of ultramarine blue rich in silica indicate its variable composition :—

	Rawlins			Parry and Coste		
	1	2	3	4	5	6
H_2O .	—	—	—	—	—	0·7
SiO_2 .	38·9	39·6	42·7	42·3	41·7	42·4
Al_2O_3 .	29·5	24·0	24·5	26·8	25·2	24·0
Na_2O .	21·0	19·2	20·0	19·5	18·8	18·7
S . .	10·8	13·1	13·0	12·0	14·2	15·4

The differences in composition between ultramarines of different colours are shown by the following numbers, taken from Jordan (Zeitsch. angew. Chem. 1893, 684) :—

	White (Hofmann)	Green (Philipp)	Blue (Philipp)	Blue (Philipp)	Violet (Wunder)	Red (Wunder)	Light blue (Wunder)
Na	21·5	17·02	15·66	14·66	11·7	8·1	11·9
Al .	16·6	15·81	15·39	12·55	13·1	13·3	13·1
Si .	17·0	17·51	16·87	17·29	19·4	19·3	19·7
S .	6·4	7·91	5·69	11·38	13·3	15·2	12·7
O .	38·4	—	—	—	42·1	43·4	42·0
H .	—	—	—	—	0·4	0·7	0·6

The two analyses of ultramarine blue (Philipp in the table refer to the varieties poor and rich in silica respectively.

The *constitution* of ultramarine is naturally a matter of great uncertainty, in view of what has been said concerning its composition. It is commonly regarded as a combined silicate and polysulphide of sodium and aluminium, but objections to this idea have already been mentioned. For the numerous formulæ that have been proposed for ultramarines, *v.* Rawlins, J. Soc. Chem. Ind. 1887, 6, 791; Szilasi, Annalen, 1889, 251, 97; Guckelberger, *ibid.* 1882, 215, 182; Dingl. poly. J. 1883, 247, 343; Clarke, Amer. Chem. J. 1888, 10, 126; Brögger and Bäckström, Jahresber. Tech. 1891, 454; Rohland, Zeitsch. angew. Chem. 1904, 17, 609; Abegg's Handbuch der Anorganischen Chemie, vol. iii. pt. i.

The similarity in composition exhibited by ultramarines of quite different colours suggests that the actual colouring material may represent only a small fraction of the total mass; it has been supposed that such a small amount of a coloured substance is present, disseminated throughout a colourless body in a state of solid solution (Rohland, *l.c.*). Hofmann (Chem. Zeit. 1910, 34, 823) has suggested that this coloured substance is sulphur; the comparative stability of ultramarine at a red heat does not lend support to this assumption. It is noteworthy, however, that were it not for the presence of sulphur, ultramarine would be expected to be colourless.

Uses.—Ultramarine is extensively used in a variety of manufactures. Its large consumption is due to two characteristics: brilliancy as a body colour, and high colouring power. As a body colour it is used in calico-printing, and wall-paper printing, for colouring writing paper and printing-ink, preparing blue pigments, and blueing mottled soap. As a 'whitening' agent it is very valuable, its great strength and purity of tone correcting the yellow tinge in writing and printing papers, cotton and linen goods, paper pulp, whitewash, soap, starch, and even sugar. It is extensively used in the manufacture of square and ball blue for laundry use.

Tests and analysis. (i.) Dilute 0·1 grm. of a standard sample of ultramarine with 0·6 grm. of pure powdered chalk, and determine the amount of chalk that must be added to 0·1 grm. of the sample under examination in order to match the colour of the diluted standard; this gives an indication of the value of the sample. (ii.) Heat a sample in hydrogen to 400°. A good ultramarine becomes grey and then green, the change taking about half an hour; a bad specimen changes in a few minutes. (iii.) Stir a little of the powder under examination in a cold saturated solution of alum, and note the length of time required for decolorisation; compare with a standard sample ground equally fine. (iv.) Shake up with water and alcohol to detect adulteration with coal-tar dyes.

For the quantitative analysis, the substance may be treated as a silicate readily attacked by dilute hydrochloric acid (*v.* ANALYSIS); in the filtrate from the aluminium the sodium may be determined as the sulphate. The determination of sulphur should be effected on a separate portion, by oxidation to sulphuric acid with *aqua regia* or fuming nitric acid, and subsequent estimation as barium sulphate. *See* also Andrews, Analyst, 1910, 35, 157.

MANUFACTURE OF ULTRAMARINE.

The only ultramarines prepared on a large scale are the blue and green sodium-sulphur ultramarines. Three chief varieties of ultramarine blue are found in commerce:—

Glauber salt or *sulphate ultramarine*, the palest variety. It has a slight greenish tinge, small covering power, and is the form most readily attacked by alum.

Soda ultramarine low in sulphur, a pure blue variety, darker than the preceding, and having more covering power.

Soda ultramarine rich in sulphur and silica, the darkest variety, with a reddish tinge. It has high covering power, and is the form most resistant towards alum; consequently it finds extensive use in paper blueing.

Ultramarine is produced when aluminium silicate is calcined with sodium sulphide; the silicate is employed in the form of china clay, or a similar material, with the addition of silica if necessary; sodium sulphide is produced during the manufacture, either from sodium carbonate, carbon, and sulphur, or from sodium sulphate, carbon, and sulphur. The relative proportions of the ingredients is an important factor in the manufacture of ultramarine, but different authorities recommend different mixtures. With materials of the best quality, the following mixtures are said to be the best for producing the three varieties mentioned above:—

Ultramarine blue	Pale	Medium	Dark
China clay . .	100	100	100
Soda . . .	9	100	103
Glauber salt .	120	0	0
Carbon . . .	25	12	4
Silica (Kieselguhr) .	0	0	16
Sulphur . . .	16	60	117

If the clay employed differs in composition from china clay, the relative proportions of clay and silica must, of course, be suitably adjusted.

The manufacture of ultramarine blue is carried out either by (i.) the *direct* or (ii.) the *indirect* process. All ultramarines rich in silica and a certain amount of the other varieties poorer in silica are made by the former method; but the majority of the ultramarines poor in silica are prepared by the latter method, in which ultramarine green is formed as an intermediate product. Both these are dry processes; wet methods have been described and patented, but do not seem to have been adopted on a large scale (Knapp, J. pr. Chem. 1885, [ii.] 32, 375; 1888, 38, 48; McIvor, Eng. Pat. 9200, 1890; McIvor and Cruickshank, Eng. Pat. 19411, 1892).

For general accounts of the manufacture of ultramarine, *v.* Rawlins, J. Soc. Chem. Ind. 1887, 6, 791; Pichot and Grangier, *ibid.* 1888, 7, 573; Röhrig, Chem. Zeit. 1883, 567; Wunder, *ibid.* 1890, 14, 1119; Jordan, Zeitsch. angew. Chem. 1893, 684.

Raw materials.—*China clay*, and French, German, and Bohemian *pottery clays* are used, and always require levigation. The clay must be very finely divided, and free from excessive amounts of iron and manganese oxides. For *soda*, the best soda ash, known as carbonated ash, is employed; it must be stored in a dry place. The *Glauber salt* must be free from acid and iron, and well calcined; it should be ground in stone edge-runner mills before use. Rod or stick *sulphur*, containing very little non-volatile matter, is usually employed, since poorer forms of sulphur produce dirty shades of colour; like the Glauber salt, it is reduced to a fine powder before use. *Carbon* should not contain more than 4 p.c. of moisture; that made from pine trunks is preferred, and is ground in ball mills and stored in a dry place. Charcoal is sometimes replaced by pitch, tar, colophony, &c. If coal is used, it must be of good quality, and free from sand, stones, and pyrites. *Silica* is usually employed in the form of kieselguhr, but sometimes quartz is used; the latter is ignited and then quenched in water to cause it to break up, being finally dried and ground to powder. Silicious carbon, such as charred rice husks, may partly or wholly replace the carbon and silica (Cross, Eng. Pat. 5174, 1903).

Direct process. The formation of ultramarine blue by this process is effected by roasting the well-mixed raw materials, allowing access of air during the operation. The successive operations involved are mixing, roasting, lixiviating, wet-grinding, levigating, pressing, drying, and sifting.

The most intimate and cheapest mixture is obtained when the various raw materials have been ground first in edge-runner mills, and then in balance mills. With mixtures containing much sulphur, the other ingredients should first be well mixed, the sulphur then added, and further mixing effected. The mixtures should, in any case, be calcined as soon as they are prepared.

The 'mass' oven, so called from the mixture being treated in a mass, produces directly very good ultramarine if carefully managed. Fig. 1 gives an idea of the arrangement. The raw materials, well mixed and ground, are shovelled on to the floor of the oven, pushed up to the end with a broad rake, and, after being piled up to nearly the level of the bridge, are nearly flattened, and covered with thin tiles, the joints being filled in with a very thin mortar made with china clay and sand. The oven having been thus filled with about 1 ton of raw material, the front is built up, leaving a hole just above the level of the tiles for observation, fitted with a loose brick. A small hole below this and about opposite the centre of the mass, fitted with a clay stopper, affords a means of taking samples as the burning proceeds. The heat is slowly raised to a bright red, and as it rises small jets of sulphur dioxide are seen to come from the cracks between the covering tiles and burn with feathery flames, increasing in length as the heat becomes greater, and gradually dying away as the reaction is completed. The heat is maintained at its highest point for from 12 to 18 hours, or until the process appears to be finished, when a sample is taken through the small hole by means of a long auger inserted right into the middle of the mass. The sample presents, if sufficiently burnt, a greenish-blue appearance, gives off sulphur dioxide freely without actually burning, and on being spre upon a clean tile quickly loses its heat, an appears a blue colour with a tinge of gree The changes experienced by the mixture ar interesting and remarkable. As introduced it i a yellowish-grey, and becomes successively brow green, and blue. The brown, a dark rich colou is very unstable, and burns on exposure to ai to a greenish half-formed ultramarine, and. eve if not exposed, slow combustion goes on unti oxidation has taken place. The green is almos equally unstable.

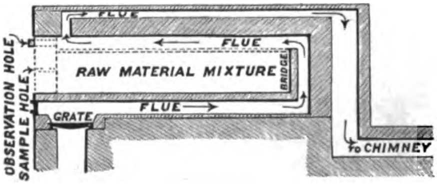


Fig. 1.

When the drawn sample is found to b sufficiently burnt, the operation is concluded b closing the oven, plastering up cracks, an excluding the air as far as possible. It is the left to cool down, which takes a week or 10 days On opening, the mass should appear dark blu the bottom portion not being quite equal i brilliancy to the top owing to the greater degre of heat to which it has been subjected. A los of about one-third of the original weight occurs and the mass shrinks considerably.

Charges amounting to 5 tons are treated in stone troughs, 17–20 ft. long and 10–13 ft. wide, placed in a furnace in such a way that they can be reached on all sides by the flame. The troughs are filled to a depth of 12–16 ins. covered with firebricks, and calcined for about 3 weeks.

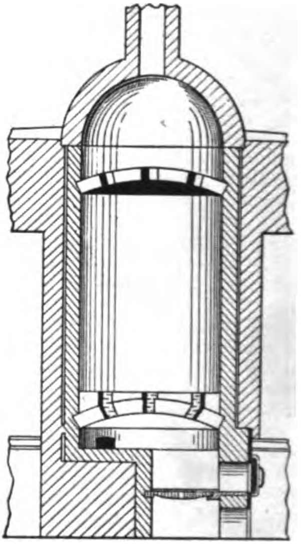

Fig. 2.

Ultramarine blue is also prepared directly in shaft furnaces (Fig. 2), described later on (p. 583). Various special furnaces have been patented (Fr. Pats. 410055, 1909; 407089, 403247, 399211, 400103, 1908; 403077, 1909; 425585, 1910).

A rapid process for the direct preparation of the blue has been patented (Fr. Pats. 391779, 391780, 1908). A mixture of china clay (35 parts), carbon (10 parts), sodium alum (40 parts), rosin (8 parts), and sulphur (7 parts) is heated rapidly to 600°–700°, and maintained at that temperature for about 3 hours; the temperature is then raised to 900°, and the mass stirred well for an hour to oxidise it. Powdered sodium chlorate is then added and the mass stirred for 15 mins.; a further 30 mins. heating then follows. Ultramarine of very superior quality is said to be thus obtained.

Curtius has patented a continuous process. Cast-iron retorts, similar to gas retorts, are employed, lined inside with fire-proof cement. They are set in brickwork, and connected with flues for removing the gases and receivers for condensing sulphur vapour. The charged retorts are closed back and front, but arrangement is made for the admission of air from behind, in order to quickly convert the green ultramarine initially formed into blue. In a modified form of the process, green ultramarine is first produced, discharged into brickwork receptacles beneath the retorts, and directly oxidised to blue (Eng. Pat. 18527, 1890).

The lixiviating, &c. is described later (p. 584).

Indirect process.—The successive stages in this process are mixing, calcining for ultramarine green, crushing, roasting to ultramarine blue, and lixiviating, &c., as in the direct process.

The preparation of the ultramarine green is carried out in either a *crucible* furnace or a *shaft* furnace. The former is a kind of muffle furnace, similar to those used in porcelain works, of square (seldom round) section and lined with firebrick. The ground mixture is filled into tapered crucibles of 12–16 ins. high, the lids are fixed on with a mortar of clay, and the crucibles piled in regular rows in the furnace. A furnace will hold several hundred crucibles, the aggregate charge being 6–8 cwt. of mixture. The temperature is slowly raised until the crucibles are at a bright-red heat, and this temperature is then maintained until the formation of ultramarine green is completed; from 7 to 10 hours are required. It is essential to maintain a uniform temperature throughout the furnace.

When the reaction is finished all openings into the furnace are shut tightly and the furnace allowed to cool down, a process that takes several days.

Shaft furnaces are used for calcining larger quantities, up to 2 tons, of material. These are large, cylindrical, vertical furnaces, lined with firebrick. The furnace is situated at the bottom of the shaft; it is covered in by a firebrick vault, the flat top of which forms the floor upon which the bottom layer of crucibles rests. Numerous openings in the vault allow the heating gases from the furnace to pass up into the shaft. The shaft is filled with crucibles charged with the ground mixture, and arranged layer upon layer. Another vault forms the roof of the shaft proper, and through openings in this the gases pass into a dome and thence into the chimney. Fig. 2 shows such a furnace. These furnaces possess many advantages; they require no special fuel, accommodate large charges and permit the heat to be equally distributed in a very satisfactory manner. Soda mixtures low in sulphur must be heated slowly at first in these furnaces, a bright-red heat being only attained in 4 hours.

The green ultramarine thus produced exhibits a blue tinge on the surface, and if required to be sold as such, the blue outer portions must be removed. This is unnecessary if the product is to be directly converted into blue; it must, however, be crushed and ground to powder.

The material is crushed in roller mills to pieces about the size of peas. Glauber salt greens are then ground in dry mills to a degree of fineness that must be determined by preliminary trials, since if ground beyond a certain degree, the brightness of the final ultramarine blue suffers. Soda greens are much softer than Glauber salt greens, and the application of further pressure during the final grinding must be avoided as much as possible. They are usually ground in ball mills, which may be so constructed as to render the preliminary crushing of the raw green superfluous.

The crushed ultramarine green is converted into blue by roasting it with sulphur; the change is completed in a shorter time by this process than if ammonium chloride, hydrochloric acid, chlorine, &c., are used in the place of sulphur. During the process part of the sodium contained in the green becomes converted into sodium sulphate. Two types of furnace are in extensive use (i.) *cylindrical* or *retort furnaces*, and (ii.) *muffle* furnaces.

The former type consists of an arrangement of strong cast-iron tubes, not exceeding 80 in. long by 16 in. diameter, generally arranged in sets of three, so that the flame entirely surrounds them. They project about 2 in. from the furnace, both at the back and front, and the ends are closed by tight-fitting sheet-iron caps. The arrangement adopted in large works is indicated in Fig. 3; the furnaces are mounted in pairs, back to back. All the gaseous products pass into the narrow corridor A, closed at both ends by doors; through openings in the roof they pass into the flue B, and thence to the chimney.

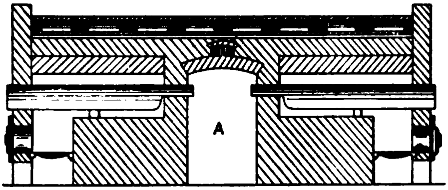

FIG. 3.

In the other type of furnace, the muffle is built into the furnace. The hearth is made of strong fireclay plates with lap joints, luted together, the whole surface being then smoothed. The hearth of the muffle forms the cover of the heating chamber; the products of combustion pass from the grate upwards through flues arranged on the sides of the muffle-walls, thence over the arched roof to the chimney. If the muffle is constructed entirely of fireclay, it is built in completely at the back, and a semicircular hole left in the front, the base of which is on a level with the hearth. This opening, through which the muffle is charged and discharged, can be closed when necessary by a counterpoised iron slide; and since sulphurous gases escape from this opening, it is arched over with a hood for leading these gases to the chimney, an arrangement that is far less convenient and safe than that employed in the cylindrical furnaces. Sometimes the muffle is built with an iron top, and the front of the muffle closed with an iron cap.

The actual roasting process is carried out either (i.) by adding sulphur to the ultramarine green before heating, or (ii.) by heating the green and gradually adding the sulphur during the process. The requisite amount of sulphur is 7 p.c. with soda green, and 9–10 p.c. with Glauber salt green, of the weight of the crude green taken. In carrying out process (i.), the empty retorts or muffles are heated to a medium red heat for soda green, or to bright redness for Glauber salt green. The mixture of green and sulphur is then quickly introduced, and the containing vessels closed. After half an hour, the product is thoroughly mixed and levelled down, a process that is repeated at half-hourly intervals, until all the sulphur has been burnt off. This is indicated by the manner in which the green colour changes to blue. A further 45 mins. heating is given, and then the fire slowly reduced. The retorts and muffles are then tightly closed and allowed to cool. When method (ii.) is employed, the retorts or muffles are charged with ultramarine green, which is raked over and levelled. The successive portions of sulphur added amount to about 1½ lbs. each with retorts (½ cwt. charge), and 4½ lbs. each with muffles (1½ cwt. charge). The first addition of sulphur may be made when a lump of that substance ignites as soon as it is thrown on the ultramarine; the charge is then raked over, and the sulphur allowed to burn away. This operation is repeated until a bright blue product is obtained; samples are withdrawn at intervals and spread out with a steel spatula to examine the colour. The product is then cooled as described under (i.).

The filtering boxes employed in the *lixiviating* process are made of pine, 5–7 ft. long, and 40–60 in. wide. About 6 or 8 in. above the solid bottom a false bottom is mounted, perforated with many ⅜-in. holes, and covered with strong cotton filtering cloth. The cold, calcined ultramarine blue is mixed with a small quantity of hot water (75°–80°) in a vat, thoroughly mixed, and transferred to a filtering box. In this manner all the numerous filtering boxes are charged. The clear filtrates are united, and if sufficiently concentrated (15°B. or more) the liquid is run into crystallising tanks for the recovery of sodium sulphate. Weaker solutions, and the first two or three washings, are concentrated by utilising waste heat from the furnaces. The ultramarine is washed with hot water until quite free from soluble sulphate, of which the crude blue contains about 15 p.c. It is then ground wet in upright mills between hard stones until the requisite fineness is obtained. During this operation sodium silicate passes into solution, and it is therefore necessary to use soft water for the grinding. The whole is then run into a large wooden vat and allowed to settle for 36–48 hours.

The *levigating process* follows next. The top blue liquor is baled out into another vat and left until the extremely finely divided particles of colour have settled; the product is afterwards added to other preparations. The paste remaining in the large vat is distributed in quantities of about 2 cwt. into levigating tanks, three-fourths filled with soft water, and the colour equally distributed throughout the water. The larger particles settle rapidly, and after 2 hours standing the liquids are run into other tanks. The next deposition of ultramarine takes 5 or 6 hours; the liquid is then baled into other tanks, and a further settling of colour for 12 hours is allowed. The liquid now baled off contains extremely finely divided particles: they are precipitated in a fourth series of tanks by the addition of alum, dilute mineral acid, milk of lime or other saline solutions, and the resulting blue paste is pressed. Passing from the first to the fourth series of tanks, the ultramarine becomes successively lighter, finer, bluer, and stronger. The different grades of product are then dried in sheds exposed to air, or on drying hearths heated by waste furnace heat, or in special drying rooms, &c.

The product dries in hard lumps, which must be powdered and sifted; for this purpose ball mills fitted with a continuous sifting device are employed. Very fine brands of ultramarine are sifted in centrifugal sifters or else in a Jasse sifter. It then remains to mix together the various shades and sorts in order to produce the standards of sale; this part of the work is of great importance, as the tinctorial power, fineness of division, depth and purity of colour in each standard, have to be exactly reproduced in bulk.

In making the cheaper brands of ultramarine blue, the pure material is mixed with from 10 to 50 p.c. of gypsum. The latter has an extremely bad effect upon the brightness of certain kinds of ultramarine, which is minimised by incorporating a little glycerol or vaseline into the mixture.

The development of the manufacture of ultramarine has been remarkable. The price in the year of its discovery was about 16*s.* per lb., but competition soon brought this down, and created a demand. Guimet commenced the manufacture in 1828. Between 1830 and 1840 manufactories were established at Cologne and Nuremberg; between 1840 and 1850 nine more were started; 1850–1860 saw nine more; 1860–1870 at least a dozen, and from 1870–1888 four or five, while an equal number of the others had closed down. At the present day (1913) there are about a hundred factories, mainly in Germany and France, although a few are in England, Austria, and the United States, and the annual production of ultramarine is between ten and fifteen thousand tons. The average price is under 30*s.* per cwt.

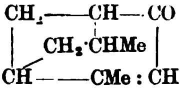
For futher information on ultramarine, *v.* Zerr and Rübencamp's Treatise on Colour Manufacture, translated by Mayer (Griffin & Co.); Bersch's Mineral and Lake Pigments, translated by Wright (Scott, Greenwood & Son); and Hoffmann's Ultramarine (Vieweg u. Sohn, Braunshweig).

ULTRAMARINE, GREEN, *v.* Ultramarine; also Chromium.

ULTRAMARINE, YELLOW. *Barium Chromate v.* Barium; also Chromium.

UMBELLIFERONE *v.* Gum resins.

UMBELLULARIA CALIFORNICA (*Nutt*). An evergreen tree indigenous to California, known locally as 'California Laurel,' 'Mountain Laurel,' 'California Bay-tree,' 'Spice-tree,' 'Pepper-wood,' &c. The essential oil is an aromatic liquid possessing a peculiar pungency due to the presence of a ketone *umbellulone* $C_{10}H_{14}O$



which forms 60 p.c. of the essential oil; the other constituents are eugenol, 1·7 eugenol methyl ether, 10; *l*-pinene, 6·0; cineol 20·0 p.c.; safrole and fatty acids, traces (Power and Lees, Chem. Soc. Trans. 1904, 85, 629; Tutin, *ibid.* 1906, 89, 1104; 1908, 93, 252).

UMBELLULIC ACID *v.* Hendecatoic acids.

UMBER. A brown pigment, consisting of a mixture of the hydrated oxides of iron and manganese, mechanically associated with a large proportion of earthy matter of variable character. The material is prepared for the market by grinding and levigation. Raw umber is exported from Cyprus, Turkey, and Italy; while it is also worked to a limited extent in the United States.

Church (The Chemistry of Paints and Painting, 1890) gives the following analysis of a choice sample of raw umber from Cyprus: water, given off at 100°C., 4·8 p.c.; water expelled at a red heat, including organic matter, 8·8; Fe_2O_3, 48·5; MnO_2, 19; CaO, 1·4; MgO, 0·5; Al_2O_3, 2·1; P_2O_5, 0·9; SiO_2, 13·7; CO_2, &c., 0·3. Part of the manganese probably exists as Mn_3O_4.

For other analyses of umbers, siennas, and ochres, *v.* G. H. Hurst in Chem. News. 1889, 59, 172. He found crude Derbyshire umber to yield the following results: hygroscopic water, 13·47 p.c.; combined water, 5·17; $BaSO_4$, 30·10; SiO_2, 4·43; $CaSO_4$, 2·15; $CaCO_3$, 2·61; Al_2O_3, 8·08; Fe_2O_3, 22·50; MnO_2, 11·53. Hurst regards most ochres as alteration products, formed mainly by the oxidation and hydration of pyrites *in situ*, and mechanically mixed with silica, clay, and other earthy matter. Umbers may have been washed as a fine sediment from deposits of iron and manganese ores. The pigment termed *burnt umber* is merely umber which has been exposed to heat, whereby its colour becomes somewhat reddened.

Ref.—G. P. Merrill, The Non-Metallic Minerals, 2nd ed., New York, 1910, 104; *v.* Ochre.

F. W. R.

UNDECATOIC ACIDS and **UNDECYLIC ACID** *v.* Hendecatoic acids.

UPAS ANTIAR *v.* Antiar resin.

UPAS TIEUTE *v.* Nux vomica.

URACIL *v.* Pyrimidines.

URALITE. A name proposed by G. Rose in 1831 for pseudomorphs of hornblende after augite from the Ural Mountains. (For a *résumé* of the literature, *v.* A. Wilmore, Geol. Mag. 1910, [v.] 7, 357.) Also used as a tradename for a preparation of serpentine-asbestos, made into the form of boards for fire-proof partitions (*v.* Asbestos). L. J. S.

URAMIL *v.* Pyrimidines.

URANINITE *v.* Pitchblende.

URANITE. An early name for the 'uranium micas' in use before these had been separated into the species autunite (calco-uranite) and torbernite (cupro-uranite) (*qq.v.*).

URANIUM. Sym. U. At.wt. 238·5. In 1789 Klaproth prepared from *pitchblende* some compounds of a new element, which he called *uranium* (Crell's Ann. 1789, [ii.] 400). The compounds of uranium were studied by Richter, Arfvedson, Berzelius, and others. In 1840 Péligot showed that what had previously been thought to be uranium was really one of its oxides; he prepared the metal by reducing uranous chloride with potassium (Ann. Chim. Phys. 1842, [iii.] 5, 5). The work of Péligot was confirmed and extended by Ebelmen (*ibid.* 1842, [iii.] 5, 189), Wertheim (*ibid.* 1844, [iii.] 11, 49), Rammelsberg (Pogg. Ann. 1842, 55, 318; 56, 125), and Hermann (Ueber einige Uranverbind. Göttingen, 1861).

Occurrence.—Uranium is not very abundant; its chief ore is *pitchblende* or *uraninite*, which consists of impure U_3O_8, and is found in Cornwall, at Joachimsthal (Bohemia), and other localities. It contains from 40 to 90 p.c. of U_3O_8 (Hermann, J. pr. Chem. 1859, [i.] 76, 326; Ebelmen, Ann. Chim. Phys. 1843, [iii.] 8, 498; Whitney, Amer. J. Sci. 1849, [ii.] 7, 434; Genth, *ibid.* 1857, 23, 421; Zimmermann, Annalen, 1886, 232, 300). *Clevite* and *bröggerite* are varieties of pitchblende rich in rare earths. *Carnotite* is a vanadate of potassium and uranium, found in Utah and Colorado (Friedel and Cumenge, Bull. Soc. chim. 1899, [ii.] 21, 328). *Samarskite* is a uranotantalite of iron and yttrium, found in Siberia (Miask) and North Carolina (Rammelsberg, Pogg. Ann. 1877, 160, 658); *fergusonite* is a complex columbate of yttrium, cerium, uranium, calcium, and iron (Rammelsberg, *ibid.* 1873, 150, 200).

Nearly all the phosphates, silicates, and zirconates of the rare earths contain small quantities of uranium, notably *xenotime*, *æschenite*, *columbite*, *cerite*, and *monazite*. *Thorianite* (*v.* Thorium) contains from 10 to 20 p.c. of uranosouranic oxide. *See* also Szilárd, Le Radium, 1909, 6, 233.

Naturally occurring uranium minerals are radioactive; it was from the pitchblende of Joachimsthal that radium was first prepared, whilst helium was originally obtained from clevite.

Treatment of uranium minerals; preparation of uranium. The chief source of uranium compounds is pitchblende, which, after a preliminary roasting, is heated in a reverberatory furnace with sodium carbonate. The product is extracted with warm dilute sulphuric acid and filtered, the residue being used in the preparation of radium salts. The filtrate is worked up commercially for uranium compounds as described under sodium diuranate (p. 588). The following method is due to Wöhler; the liquid is treated with hydrogen sulphide to remove arsenic, antimony, copper, lead, and bismuth, and after oxidising the filtrate with nitric acid, excess of ammonia is added. The washed precipitated iron hydroxide and ammonium uranate are digested at 100° with concentrated ammonium carbonate, containing ammonia in excess, to dissolve the ammonium uranate. The double salt, ammonium uranyl carbonate, crystallises out on cooling the filtered liquid. From the mother liquor a quantity of ammonium uranate can be obtained by precipitating any zinc, nickel, and cobalt with ammonium sulphide, and evaporating the filtrate. Both ammonium uranate and ammonium uranyl carbonate leave the green oxide U_3O_8 when ignited in the air.

Carnotite is fused with potassium hydrogen sulphate and the mass extracted with water; from the solution the double sulphates of uranium and vanadium with potassium sulphate are crystallised out. The crystalline product is reduced with zinc and sulphuric acid, and the vanadium then precipitated with ammonia and ammonium carbonate. From the filtrate the uranium is thrown down as ammonium uranate by boiling (Gin, Chem. Zentr. 1906, ii. 1172; *cf.* Haynes, Mines and Minerals, 1909, 30, No. 3, 139).

Metallic uranium was first prepared by Péligot (*l.c.*) by reducing the tetrachloride with potassium. Zimmermann (Annalen, 1883, 216, 1) replaced the potassium by sodium. It is better to employ the double chloride of uranium and sodium, and magnesium may be used in place of potassium (Moissan, Compt. rend. 1896, 122, 1088). These methods are unsatisfactory, since uranium tetrachloride is extremely hygroscopic. Uranium is best prepared by heating 500 parts of the oxide U_3O_8 with 40 parts of sugar carbon in the electric furnace in a carbon tube. The product, which contains a little carbon, is purified by heating it in a crucible brasqued with uranium oxide, and embedded in another crucible brasqued with titanium, to prevent access of nitrogen to the uranium (Moissan, Compt. rend. 1893, 116, 349). Reduction of uranium dioxide by carbon begins at 1500° (Greenwood, Chem. Soc. Trans. 1908, 93, 1492). The oxides of uranium may also be reduced by heating with aluminium powder (Aloy, Bull. Soc. chim. 1901, [iii.] 25, 153; Stavenhagen, Ber. 1899, 32, 3065; Stavenhagen and Schuchard, *ibid.* 1902, 35, 909; Giolitti and Tavanti, Gazz. chim. ital. 1908, 38, ii. 239). Uranium may also be prepared by the electrolysis of the fused double chloride of uranium and sodium, in an inert atmosphere, using carbon electrodes (Moissan, Compt. rend 1896, 122, 1088); and is obtained in the pyrophoric state by heating its amalgam in a vacuum (Férée, Bull. Soc. chim. 1901, [iii.] 25, 622).

Properties.—Pure uranium is a white metal, which takes a high polish; its density is 18·7, and its specific heat 0·02765 (Zimmermann, Annalen, 1886, 232, 310; Ber. 1882, 15, 851). It melts at a white heat, and can be distilled in the electric furnace (Moissan, Compt. rend. 1906, 142, 425; *cf. ibid.* 1893, 116, 1429; 1896, 122, 1088). The most prominent lines in the emission spectrum are in the yellow (Thalén, Ann. Chim. Phys. 1869, [iv.] 18, 239; Hasselberg, K. Svenska. Vet-Akad. Handl. 1910, 45, 3; Pollok, Sci. Proc. Roy. Dubl. Soc. 1909, 11, 331). Most uranium compounds possess marked absorption spectra (Morton and Bolton, Chem. News. 1873, 28, 47, 113, 164; Jones and Strong, Phil. Mag. 1910, [vi.] 19, 566; Strong, Zeitsch. physikal. Chem. 1910, 11, 668) and are fluorescent, the fluorescence spectra having been studied by E. Becquerel (Ann. Chim. Phys. 1872, [iv.] 27, 539) and H. Becquerel (Compt. rend. 1885, 101, 1252; 1907, 144, 459); *v.* also Becquerel and Kamerlingh-Onnes (*ibid.* 1910, 150, 647) for phosphorescence at low temperatures.

Uranium in the form of powder is unaltered in dry air at ordinary temperatures; it burns in oxygen at 170°. It unites directly with fluorine in the cold, and with chlorine, bromine, and iodine when gently heated. At 500° it combines with sulphur and selenium, and at 1000° unites readily with nitrogen. It forms a crystalline carbide (Moissan, Compt. rend. 1896, 122, 1088).

Uranium powder decomposes water slowly at ordinary temperatures, more rapidly at 100°. It dissolves readily in hydrochloric, sulphuric, and nitric acids.

Uranium is closely allied to the elements chromium, molybdenum, and tungsten; they all exhibit a maximum valency of six, yield acidic trioxides, and form numerous halogen derivatives in which their valencies vary from two to six. These halogen derivatives in general bear little resemblance to well-defined salts, as is indicated by their volatility, solubility in numerous organic media, and the ease with which they are hydrolysed by water. There are two principal series of uranium salts: (i.) the *uranous* compounds, corresponding to the basic oxide UO_2; and (ii.) the *uranyl* compounds, in which the group UO_2 functions as a bivalent metallic radicle. Besides these, there exist *uranates*, *diuranates*, and *peruranates*, analogous to the corresponding chromium derivatives (*v.* O. de Coninck, Bull. Acad. roy. Belg. 1909, 175). The *uranous* salts are usually green or blue, and in solution are readily oxidised to uranyl compounds, even by air, the rate of oxidation being proportional to the concentration of the solution and inversely proportional to the square of the concentration of the hydrogen ions present (McCoy and Bunzel, J. Amer. Chem. Soc. 1909, 31, 367). They are obtained by the reduction of uranyl compounds (*v.* Aloy and Auber, Bull. Soc. chim. 1907, [iv.] 1, 569; Colani, Ann. Chim. Phys. 1907, 12, 59). The *uranyl* salts are generally yellow, with a greenish fluorescence. They are highly sensitive to light, and are employed in photography (Niepce de Saint Victor, Compt. rend. 1858, 46, 448, 489; Titlestad, Zeitsch. physikal. Chem. 1910, 72, 257; Bacon, Philippine J. Sci. 1910, 5, 281). They are somewhat analogous to basic salts, but they are stable in solution, being only hydrolysed to a slight extent. On electrolysis the uranyl ion UO_2 migrates to the cathode. Uranyl salts form numerous complex derivatives, especially with salts of organic acids (Dittrich, Zeitsch. physikal. Chem. 1899, 29, 449; Ley, *ibid.* 1900, 30, 193; Ber. 1900, 33, 2658; Kohlschütter, Annalen, 1900, 311, 1).

Uranium salts are radioactive, emitting *a* rays, and producing a new radioactive element called *Uranium-X* (*v. infra*, Uranium-X and Radioactivity).

Atomic weight. This was taken as *circa* 120 until Mendeléeff pointed out the similarity of uranium to chromium, molybdenum, and tungsten, and proposed the value 240 (Annalen, Suppl. 1872, 8, 178; Chem. News. 1880, 41, 39), which assigned to uranium a position in the Periodic Classification in the same Group as the elements just mentioned. The determination of the specific heat of the metal and the vapour densities of uranous chloride and bromide (Zimmermann, Annalen, 1882, 216, 1) confirmed the views of Mendeléeff. The actual value at present adopted (238·5) rests mainly on the work of Zimmermann (Annalen, 1886, 232, 299), Aloy (Ann. Chim. Phys. 1901, [vii.] 24, 418), and of Richards and Merigold (Proc. Amer. Acad. 1902, 37, 365; Zeitsch. anorg. Chem. 1902, 31, 235).

OXIDES AND OXYACIDS.

Uranium dioxide or *Uranous oxide* UO_2 is obtained by heating the green oxide or uranyl oxalate in a stream of hydrogen (Berzelius, Péligot, Ebelmen); or by electrolysing uranyl nitrate solution (O. de Coninck and Camo, Bull. Acad. Roy. Belg. 1901, 321); these methods yield a brown pyrophoric powder. The reduction of uranyl chloride solution with magnesium or aluminium yields uranous oxide as a black powder (de Coninck, *ibid.* 1909, 744). It is obtained as black, microscopic crystals by reducing crystalline uranic hydroxide in hydrogen (Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368); and as jet black octahedra by fusing the amorphous form with borax, and washing the product with dilute hydrochloric acid (Hillebrand, Zeitsch. anorg. Chem. 1893, 3, 249). It is a basic oxide, and dissolves in concentrated acids to form green uranous salts. It combines directly with chlorine and bromine, forming uranyl chloride and bromine, and burns when heated in air, the green oxide U_3O_8 being produced.

Uranous hydroxide $UO_2,2H_2O$ is precipitated by adding an alkali to a solution of a uranous salt and boiling; it forms black flakes, and readily dissolves in dilute acids (Aloy, Bull. Soc. chim. 1899, [iii.] 21, 613).

Uranium trioxide, *uranic oxide, uranic anhydride,* or *uranyl oxide* UO_3 is a chamois yellow powder, obtained by heating uranyl nitrate to 250°; also by heating the hydroxide or double uranyl ammonium carbonate to 250° (Ebelmen Ann. Chim. Phys. 1842, [iii.] 5, 199; de Coninck, Compt. rend. 1901, 132, 204; Bull. Acad. Roy. Belg. 1904, 363, 448). It oxidises to the green oxide when heated in air, and is reduced by hydrogen to uranous oxide.

This oxide is slightly basic, but only one-third of its oxygen can be replaced by acidic radicles; the salts thus produced are of the type $UO_2R^I_2$, and are called *uranyl* compounds. Towards strong bases, uranic oxide behaves as an acid anhydride, similar to chromic anhydride.

Uranic hydroxide or *uranic acid* UO_3,H_2O is best prepared by heating a solution of uranyl nitrate in alcohol until no more brown fumes are evolved, and washing the yellow precipitate with boiling water (Malaguti, Ann. Chim. Phys. 1843, [iii.] 9, 463). It may also be obtained, mixed with the dihydrate, by evaporating a solution of uranyl nitrate to complete dryness (de Coninck, Compt. rend. 1909, 148, 1462). The *dihydrate* $UO_3,2H_2O$, which is obtained as a yellow precipitate by boiling the double uranyl ammonium carbonate with water, loses water at 100°, and yields the hydroxide UO_3,H_2O (Ebelmen, *l.c.*; for other methods, *v.* Jacquelin, Ann. Chim. Phys. 1842, [iii.] 5, 199; Riban, Compt. rend. 1881, 93, 1140; Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368). Uranic hydroxide has a sp.gr. of 5·9; it does not alter in air, and when heated to 300° it is dehydrated. For the preparation of the colloidal hydroxide, *v.* Szilárd, J. Phys. Chem. 1907, 5, 488, 636.

Uranosouranic oxide or *Green oxide of uranium* $U_3O_8(=UO_2{\cdot}2UO_3)$ occurs more or less pure as *pitchblende.* It can be obtained by heating any of the other oxides to a red heat in air, also by igniting ammonium uranate or any uranium salt of a volatile acid. It forms a dark-green, lustrous powder of sp.gr. 7·2, insoluble in water; in concentrated acids it dissolves, forming a mixture of uranous and uranyl salts. This oxide is employed for producing a black glaze on porcelain. It is radioactive, and has been suggested as a suitable standard of α-ray radioactivity (McCoy and Ashman, Amer. J. Sci. 1908, 26, 521).

A violet hydroxide can be obtained by the action of light on aqueous uranyl oxalate or alcoholic uranyl acetate (*v.* Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368).

Uranium pentoxide $U_2O_5(=UO_2{\cdot}UO_3)$ is formed by the strong ignition of uranium nitrate in air, and is a black powder, used for producing a black glaze on porcelain. According to Zimmermann (Annalen, 1886, 232, 273) it is a mixture of U_3O_8 and UO_2.

Uranium peroxide UO_4 is only known in the hydrated form as *peruranic acid* $UO_4,2H_2O$. It is obtained by adding hydrogen peroxide to a mixture of uranyl and uranous sulphate in aqueous solution, and drying the precipitate over concentrated sulphuric acid (de Coninck, Bull. Acad. Roy. Belg. 1909, 692; *cf.* Fairley, Chem. Soc. Trans. 1877, 31, 133; Zimmermann, Annalen, 1886, 232, 273; Alibegoff, *ibid.* 1886, 233, 123). It forms a yellow powder, which loses oxygen when heated; when treated with alkali hydroxides it yields a mixture of alkali uranate and peruranate.

URANATES.

The alkali uranates are formed by precipitating uranyl salts with alkali hydroxides; those of the other metals by adding ammonia to a mixture of a uranyl and a metallic salt. They are yellow, insoluble in water, but soluble in acids. The majority are of the type $M_2O{\cdot}2UO_3$, analogous to the dichromates (*v.* Drenkmann, J. 1861, 255; Patera, J. pr. Chem. 1850, 51, 125; Debray, Ann. Chim. Phys. 1861, [iii.] 61, 451; Grandeau, *ibid.* 1886, [vi.] 8, 224; Zimmermann, Annalen, 1882, 213, 290; Ditte, Compt. rend. 1882, 95, 988; de Coninck, Bull. Acad. roy. Belg. 1909, 173, 835).

Ammonium uranate. This is obtained as a yellow, voluminous precipitate by adding ammonia to a solution of a uranyl salt. It is prepared by boiling a solution of uranyl sodium carbonate with ammonium sulphate; or by boiling sodium diuranate (*q.v.*) with concentrated ammonium chloride solution, and forms a fine, deep yellow-coloured powder, that is sometimes used commercially, under the name *uranium yellow,* in the preparation of uranium glass (*v.* Stolba, Zeitsch. anal. Chem. 1864, 3, 74, and sodium diuranate).

Potassium uranate K_2UO_7, obtained by fusing uranyl chloride with a mixture of potassium and ammonium chlorides (Zimmermann, *l.c.*), forms yellow, rhombic crystals.

Potassium diuranate $K_2U_2O_7$ is obtained in the form of a trihydrate by precipitating a uranyl salt with potassium hydroxide and drying the product at 100° (Patera, *l.c.*).

Sodium uranate Na_2UO_4 may be obtained by fusing the green oxide with sodium chloride and sodium carbonate (Ditte, *l.c.*; Zimmermann, *l.c.*).

Sodium diuranate $Na_2U_2O_7$ is prepared commercially from pitchblende, which is powdered and roasted to remove the greater part of the sulphur, arsenic, and molybdenum. The ore is then heated in a reverberatory furnace with sodium carbonate and a little sodium nitrate. The product is washed with water, when soluble arsenate, molybdate, tungstate, and vanadate of sodium are removed; sodium uranate is insoluble in water. The insoluble residue is dissolved in dilute sulphuric acid, the solution evaporated to remove excess of acid, diluted and filtered from silica, lead sulphate, and basic sulphate and arsenate of bismuth, and an excess of sodium carbonate solution added. A solution of uranyl sodium carbonate is thus obtained, while the basic carbonates of iron, aluminium, nickel, and cobalt are precipitated and removed. The uranium is then precipitated as sodium diuranate by adding sodium hydroxide, or by neutralising with sulphuric acid and boiling. The yellow precipitate is thoroughly washed, dried, and pulverised (Patera, J. pr. Chem. 1849, [i.] 46, 182; 1850, 51, 122; Giseke, J. 1852, 779; Anthon, J. 1860, 698; Kessler, J. 1857, 199; Hofmann and Strauss, Ber. 1900, 33, 3126; *cf.* Metzger and Heidelberger, J. Amer. Chem. Soc. 1909, 31, 1040).

Sodium diuranate is found in commerce as the hexahydrate $Na_2U_2O_7,6H_2O$. It is a fine yellow powder, known as *uranium yellow*, and is used in painting and staining glass and porcelain, and for making the fluorescent 'uranium glass.'

PERURANATES.

These salts are formed by the action of hydrogen peroxide and alkali hydroxides on uranyl salts, and are usually precipitated by means of alcohol as orange-yellow crystals. The sodium salt has the formula $Na_4UO_8,8H_2O$. These compounds have been studied by Fairley (Chem. Soc. Trans. 1877, 31, 134) and Melikoff and Pissarjewsky (Ber. 1897, 30, 2092; Zeitsch. anorg. Chem. 1898, 18, 59; J. Russ. Phys. Chem. Soc. 1902, 34, 472).

A red potassium peruranate $K_2UO_5,3H_2O$ is obtained when peruranic acid is added to hydrogen peroxide containing alcohol, and the solution treated with potassium hydroxide (Aloy, Bull. Soc. chim. 1903, [iii.] 29, 292). The formation of this substance may be employed as a delicate colorimetric test for the presence of uranium (Aloy, *ibid.* 1902, [iii.] 27, 734).

URANIUM COMPOUNDS.

Uranium tetrafluoride or *Uranous fluoride* UF_4 is the main product of the action of fluorine on uranium. It is prepared by adding hydrogen fluoride to a solution of uranous chloride, and forms a green powder, insoluble in water and dilute acids (Smithells, Chem. Soc. Trans. 1883, 43, 125; Bolton, J. 1886, 209). It leaves a residue of oxide when heated in air; and forms double fluorides with the alkali fluorides.

Uranium hexafluoride UF_6 is best obtained by the action of fluorine on the cooled pentachloride—

$$2UCl_5+5F_2=UF_6+UF_4+5Cl_2.$$

It forms colourless, monoclinic prisms, which sublime at ordinary temperatures under diminished pressure. It melts at 69·2° under a pressure of two atmospheres, and boils at 56·2°. The solid has a density of 4·68; the vapour gives a value 11·7 (air=1). It is very hygroscopic, and highly reactive (Ruff and Heinzelmann, Zeitsch. anorg. Chem. 1911, 72, 63: *cf.* Ber. 1909, 42, 492).

Uranium trichloride UCl_3 is obtained by heating the tetrachloride in hydrogen (Péligot, Ann. Chim. Phys. 1842, 5, 20), and is a reddish-brown substance, which easily dissolves in water, forming a red solution that slowly evolves hydrogen and becomes green.

Uranium tetrachloride or *Uranous chloride* UCl_4 is produced when uranium is heated in chlorine, and is prepared by passing chlorine over heated uranium carbide or a mixture of any oxide of uranium with carbon (Péligot, Annalen, 1842, 43, 258; Zimmermann, *ibid.* 1882, 213, 320; 1883, 216, 8; Roscoe, Chem. Soc. Trans. 1874, [ii.] 12, 933; Aloy, Bull. Soc. chim. 1899, [iii.] 21, 264). It forms dark-green octahedra, is volatile at a red heat, and the vapour has a density (air=1) of 13·33 (Zimmermann). In molten bismuth chloride as solvent the molecular weight is 373 (theory=380·3) (Rügheimer and Gonder, Annalen, 1908, 364, 45). It is extremely deliquescent, fumes in the air, and readily dissolves in water with evolution of heat; the solution is a powerful reducing agent. The solution reacts acid, and on evaporation, leaves an oxychloride. Boiling water completely hydrolyses the chloride.

It forms double chlorides with the chlorides of the alkali and alkaline earth metals (Moissan, Compt. rend. 1896, 122, 1088; Aloy, Bull. Soc. chim. 1899, [ii.] 21, 264).

Uranium pentachloride UCl_5 is obtained by the direct union of the tetrachloride and chlorine. It exists in two forms: (i.) long, dark needles which are green by reflected, and ruby-red by transmitted, light, and (ii.) a light-brown, mobile powder. It is very hygroscopic, and is decomposed by water. It cannot be volatilised without decomposition; in an atmosphere of carbon dioxide, dissociation into the tetrachloride and chlorine is complete at 235° (Roscoe, Chem. Soc. Trans. 1874, 12, 933).

Uranium tetrabromide or *Uranous bromide* UBr_4 is obtained by heating the green oxide of uranium with excess of sugar charcoal, and passing bromine vapour over the heated mixture of uranous oxide and carbon thus produced (Zimmermann, Annalen, 1883, 216, 2; Alibegoff, *ibid.* 1886, 232, 132; Richards and Merigold, Zeitsch. anorg. Chem. 1902, 31, 250). It forms lustrous, dark-brown tablets of sp.gr. 4·838 at 21°/4°. At a red heat it is volatile; the vapour density (air=1) is 19·46 (Zimmermann). It closely resembles the tetrachloride in properties.

Uranium tetraiodide or *Uranous iodide* UI_4 is prepared by passing the vapour of iodine over powdered uranium heated to 500° in the absence of air (Guichard, Compt. rend. 1907, 145, 921). It forms black, crystalline needles, which melt at about 500°, and have a sp.gr. of 5·6. The aqueous solution is dark green and closely resembles the chloride in properties.

Uranous oxyfluoride UOF_2 is obtained by the action of hydrofluoric acid on uranosouranic oxide—

$$U_3O_8+6HF=UOF_2+2UO_2F_2+3H_2O.$$

It is a fine green powder, insoluble in water (Giolitti and Agamennone, Atti. R. Acad. Lincei, 1905, 14, i. 114).

Uranyl fluoride UO_2F_2 is formed in the preceding reaction, and is a yellow soluble mass. It also exists, according to Smithells (Chem. Soc. Trans. 1883, 43, 125) in a white crystalline form, which can be sublimed; this modification is prepared by carefully heating the tetrafluoride in air. It is hygroscopic and forms a yellow solution in water. Both forms unite with potassium fluoride forming a lemon-yellow crystalline double salt $UO_2F_2\cdot3KF$, which can also be obtained from uranyl acetate and an excess of potassium fluoride. This salt is trimorphous (Baker, *ibid.* 1879, 35, 763). The corresponding double salts of other metals are also known, and are converted into deep yellow-coloured peroxyfluorides by hydrogen peroxide Lordkipanidzé, J. Russ. Phys. Chem. Soc. 1900, 32, 283).

Uranyl chloride UO_2Cl_2 is obtained by heating uranous oxide to redness in a stream of chlorine. It is a yellow crystalline mass, stable in dry air; it is reduced by hydrogen at a red heat to the dioxide. Uranous chloride is soluble in water, alcohol, and ether, and its aqueous solution yields the monohydrate UO_2Cl_2,H_2O on evaporation. A solution of uranyl chloride may be prepared by oxidising uranous chloride with nitric acid or by dissolving uranium trioxide in concentrated hydrochloric acid (Mylius and Dietz, Ber. 1901, 34, 2774; de Coninck, Compt. rend. 1909, 148, 1769; Bull. Acad. roy. Belg. 1909, 836). For a table of specific gravities of its aqueous solutions, *v.* de Coninck, Ann. Chim. Phys. 1904, [viii.] 3, 500.

Uranyl bromide UO_2Br_2 may be obtained in an impure state by heating uranous oxide in bromine vapour. It is obtained in aqueous solution by acting on uranous oxide with bromine water, or by dissolving uranic oxide in hydrobromic acid. Yellow needles of the hydrated compound separate on concentrating the solution; they decompose when heated (de Coninck, Bull. Acad. roy. Belg. 1902, 12, 1025).

Uranyl iodide UO_2I_2 is obtained by adding barium iodide in slight excess to an ethereal solution of uranyl nitrate. It separates from ether in red deliquescent crystals, and is not very stable (Aloy, Ann. Chim. Phys. 1901, [vii.] 24, 412).

Uranium monosulphide US is a black, amorphous powder formed by heating the sesquisulphide in hydrogen (Alibegoff, Annalen, 1886, 233, 131, 135).

Uranium sesquisulphide U_2S_3 is a greyish-black substance formed by heating the tribromide of uranium in hydrogen sulphide (Alibegoff, *l.c.*).

Uranium disulphide US_2 is formed by the direct union of its elements at 500° (Moissan); at a higher temperature uranium burns vividly in sulphur vapour. The sulphide is best prepared by heating the double chloride of uranium and sodium in a current of hydrogen laden with the vapour of sulphur; or the double chloride may be fused with sulphide of sodium, aluminium, magnesium, antimony or tin (Colani, Compt. rend. 1903, 137, 382; Ann. Chim. Phys. 1907, [viii.] 12, 59). It forms large, slender, pearly crystals; the amorphous powder, obtained by heating uranous chloride in hydrogen sulphide, is greyish-black in colour. It oxidises in the air to uranyl sulphide, and with nitric acid is rapidly converted into uranyl sulphate.

A black, hydrated disulphide is obtained by precipitating a uranous salt with ammonium sulphide; it rapidly oxidises in the air to uranyl sulphide.

Uranyl sulphide UO_2S is obtained by adding ammonium sulphide to an alcoholic solution of uranyl nitrate, washing the precipitate with alcohol and drying *in vacuô*. By precipitating in aqueous solution a brown hydrated form is obtained (Remelé, Compt. rend. 1864, 58, 716). It rapidly decomposes by heating to 180°; warm water converts it into hydrated uranous oxide and sulphur. It dissolves in dilute acids and in ammonium carbonate. When digested for 48 hours with cold ammonium sulphide exposed to air, a deep-red solid is obtained, soluble in acids with the evolution of hydrogen sulphide and deposition of sulphur. This substance is called *uranium-red* (Patera, J. pr. Chem. 1850, [i.] 51, 122; Remelé, Pogg. Ann. 1865, 124, 158; Hermann, J. 1861, 14; Zimmermann, Annalen, 1880, 204, 204). A complicated substance of the formula $5UO_3\cdot2K_2O\cdot KHS_2,xH_2O$ is obtained by precipitating uranyl nitrate with potassium sulphide and treating the precipitate with potassium carbonate (Kohlschütter, Annalen, 1900, 314, 311). This is also called *uranium-red*; acids decompose it, liberating sulphur and hydrogen sulphide.

Uranyl sulphide is formed in black, tetragonal needles by heating uranosouranic oxide with sulphur and potassium thiocyanate (Milbauer, Zeitsch. anorg. Chem. 1904, 42, 448).

The *oxysulphide* $2US_2\cdot UO_2$ has been described by Hermann (J. 1861, 260).

Uranium selenides USe_2 and U_2Se_3 are obtained in the crystalline state by heating the double chloride of uranium and sodium in a current of hydrogen containing the vapour of selenium (Colani, Compt. rend. 1903, 137, 382; Ann. Chim. Phys. 1907, [viii.] 12, 59).

Uranyl selenide is produced by heating uranosouranic oxide with selenium and potassium cyanide (Milbauer, Zeitsch. anorg. Chem. 1904, 42, 450).

Uranium telluride U_2Te_3 is prepared by fusing the double chloride of sodium and uranium with sodium telluride in an atmosphere of hydrogen (Colani, *l.c.*).

Uranium nitride U_3N_4 is a stable, greyish-black powder, prepared by heating uranous chloride in ammonia, and igniting the product mixed with ammonium chloride, once more in a stream of ammonia (Kohlschütter, Annalen, 1901, 317, 158). Uranium unites directly with nitrogen at 1000°, a yellow nitride being produced, the composition of which is not known (Moissan, Compt. rend. 1896, 122, 274).

Uranium phosphide U_3P_4 is obtained by fusing sodium uranous chloride with aluminium phosphide in a stream of hydrogen (Colani, *l.c.*) The *arsenide* U_3As_4 and *antimonide* U_3Sb_4 are similarly prepared. All three compounds are obtained as black crystalline powders; they are easily oxidised by nitric acid.

Uranium carbide U_2C_3 is prepared by strongly heating a mixture of 500 parts of uranosouranic oxide and 60 parts of carbon in the electric furnace. It is a lustrous, crystalline solid of sp.gr. 11·28 at 18°, and is harder than quartz, although not so hard as corundum. It is decomposed by fluorine when gently warmed; chlorine readily attacks it at 350°, whilst it reacts with oxygen at 370°. Uranium carbide is decomposed by water, a very complex change occurring. About one-third of the carbon is evolved in combination with hydrogen, mainly as methane, but mixed with a little ethylene and traces of acetylene; the gaseous mixture contains about 15 p.c. of free hydrogen. The remainder of the carbon is converted into a mixture of solid and liquid hydrocarbons (Moissan, Compt. rend. 1896, 122, 274). A shower of brilliant sparks is produced when two pieces of the carbide are rubbed together.

Uranium silicide USi_2 is obtained from a mixture of silica and uranosouranic oxide by the aluminothermic process (*v.* THERMIT PROCESS). It crystallises in the cubic system, and has a density of 8·0. At 500° it reacts with chlorine giving a mixture of uranous and silicon chlorides (Defacqz, *ibid.* 1908, 147, 1050).

SALTS OF URANIUM.

Uranyl acetate $UO_2(C_2H_3O_2)_2,2H_2O$ is prepared by dissolving in warm acetic acid the yellowish-red mass produced by heating uranyl nitrate until evolution of oxygen commences. It crystallises in yellow, monoclinic needles, and is used in photography and also for the volumetric estimation of phosphates.

Uranous arsenate $UH_2(AsO_4)_2,2H_2O$ (Aloy, Bull. Soc. chim. 1899, [iii.] 21, 613; Rammelsberg, Pogg. Ann. 1842, 55, 318; 56, 125).

Uranyl arsenate $UO_2{\cdot}H(AsO_4)_2,4H_2O$, a yellow powder, insoluble in water and acetic acid, is obtained by double decomposition (Werther, Annalen, 1848, 68, 313). Several arsenates occur as minerals, *e.g.* *trögerite* $(UO_2)_3(AsO_4)_2,12H_2O$; *walpurgite*, a basic bismuth uranyl arsenate; and *uranospinite*, a calcium uranium arsenate.

Uranyl bromate $UO_2(BrO_3)_2,xH_2O$, *v.* Rammelsberg, Pogg. Ann. 1842, 55, 77.

Uranous carbonate and **uranyl carbonate** are not known (Parkman, Amer. J. Sci. 1862, [ii.] 34, 326). Numerous double carbonates exist. *Potassium uranyl carbonate* $UO_2(CO_3),2K_2CO_3$ is obtained by dissolving potassium uranate in potassium bicarbonate and evaporating the solution at a moderate temperature; the corresponding ammonium and sodium salts are prepared in a similar manner (Ebelmen, Ann. Chim. Phys. 1842, [iii.] 5, 189; Anthon, J. 1860, 698; de Coninck, Bull. Acad. roy. Belg. 1904, 363, 448). They form yellow, rhombic prisms, which are not very soluble in water, but much more soluble in alkali carbonate solutions. The ammonium salt loses ammonia on keeping. Another ammonium compound $2UO_2{\cdot}CO_3{\cdot}3(NH_4)_2CO_3,4H_2O$ has been obtained by mixing uranyl nitrate and ammonium carbonate (Giolitti and Vecchiarelli, Gazz. chim. ital. 1905, 35, ii. 170). *Uranyl calcium carbonate* $UO_2CO_3{\cdot}CaCO_3,10H_2O$ occurs as the mineral *liebigite* in apple-green warty masses.

Uranyl chlorate $UO_2(ClO_3)_2,xH_2O$ is a very soluble substance, which readily decomposes when heated (Rammelsberg, *l.c.*).

Uranyl chromate $UO_2{\cdot}CrO_4$ is obtained by adding uranic oxide to boiling chromic acid solution; it crystallises, on cooling the solution, in yellow needles, containing $5\frac{1}{2}H_2O$ (Formánek, Annalen, 1890, 257, 108), or $3H_2O$ (Orloff, Chem. Zeit. 1907, 31, 375). The double salt

$$K_2CrO_4{\cdot}2UO_2{\cdot}CrO_4,6H_2O$$

is obtained as yellow monoclinic crystals by treating potassium uranate with chromic acid. The ammonium salt is isomorphous with the preceding salt; the sodium salt contains $10H_2O$ (Formánek, *l.c.*).

Uranyl iodate $UO_2(IO_3)_2$ is precipitated on mixing boiling solutions of uranyl nitrate and sodium iodate in dilute nitric acid; it forms yellow prisms, slightly soluble in water. A hydrate $UO_2(IO_3)_2,5H_2O$ is also known (Ditte, Thèse de doctorat ès Sc. Paris, 1870).

Uranous nitrate has not yet been prepared in the solid form (Isambert, Compt. rend. 1875, 80, 1087).

Uranyl nitrate $UO_2(NO_3)_2$. The anhydrous salt is not known, but numerous hydrates have been prepared. The trihydrate $UO_2(NO_3)_2,3H_2O$ crystallises in yellow, monoclinic forms, and melts at 121·5°; the dihydrate is rhombic and melts at 179·3° (Vasilieff, J. Russ. Phys. Chem. Soc. 1910, 42, 570). The commercial salt is the hexahydrate $UO_2(NO_3)_2,6H_2O$. It is formed when any of the oxides of uranium are dissolved in nitric acid, and is prepared commercially by heating ammonium uranate and dissolving the residue in nitric acid (Janda, Oester. Zeit. Berg-Hütt. 1901, 49, 325). For methods of preparation from pitchblende, *v.* Péligot, Ann. Chim. Phys. 1844, [iii.] 12, 557; Ebelmen, *ibid.* 1842, [iii.] 5, 186. The hexahydrate forms lemon-yellow, fluorescent, rhombic prisms, which melt at 60·2° and deliquesce in the air (Vasilieff, *l.c.*; de Coninck, Compt. rend. 1900, 131, 1219, 1303; 1901, 133, 90, 204; Bull. Acad. roy. Belg. 1901, 222; 1909, 743). Water at 18° dissolves twice its weight of the salt. It is very soluble in alcohol and ether, and is best purified by crystallisation from the latter solvent. The aqueous solution is slightly hydrolysed, and has an acid reaction (Ley, Zeitsch. physikal. Chem. 1899, 30, 193; Ber. 1900, 33, 2658; Dittrich, Zeitsch. physikal. Chem. 1899, 29, 449).

Double nitrates of the type $RUO_2(NO_3)_3$, where R may be potassium, ammonium, thallium, rubidium, or cæsium, but not sodium or lithium, are obtained by crystallising solutions of the mixed salts in nitric acid. Water decomposes them into their components (Meyer and Wendel, Ber. 1903, 36, 4055; Rimbach, *ibid.* 1904, 37, 461).

Uranyl nitrate is used in photography, and also for the volumetric estimation of phosphates and arsenates.

Uranous phosphate $UH_2(PO_4)_2,5H_2O$ (Aloy, Bull. Soc. chim. 1899, [iii.] 21, 613).

Uranyl phosphate $UO_2{\cdot}HPO_4$. This is precipitated in an amorphous form by adding a soluble phosphate to uranyl nitrate solution. When this precipitate is continuously boiled with dilute hydrochloric acid for a long time, it is converted into $UO_2{\cdot}HPO_4,4H_2O$, which crystallises in tetragonal plates (Bourgeois, *ibid.*

1897, [iii.] 19, 733). The *dihydrogen phosphate* $UO_2(H_2PO_4)_2,3H_2O$ is obtained by heating uranic oxide with dilute phosphoric acid, and concentrating the solution. It separates in small yellow crystals (Werther, J. pr. Chem. 1848, [i.] 43, 321). *Uranyl ammonium phosphate* $UO_2(NH_4)PO_4.xH_2O$ is a greenish-yellow precipitate formed by the addition of a soluble phosphate to a mixture of a uranyl and an ammonium salt. It is obtained in the volumetric estimation of phosphates. The precipitate is insoluble in acetic acid. Upon ignition it leaves a yellow residue of *uranyl pyrophosphate* $(UO_2)_2P_2O_7$.

Various phosphates occur in nature, *e.g.* *chalcolite* or *torberite* $(Cu(UO_2)_2(PO_4)_2.10H_2O)$ and *autonite* or *uranite* $(Ca(UO_2)_2(PO_4)_2.8H_2O)$.

Uranous sulphate $U(SO_4)_2.8H_2O$ is prepared by dissolving the green oxide in dilute sulphuric acid, adding alcohol and allowing the solution to crystallise. The mother liquor contains uranyl sulphate; on exposure to light it is reduced to uranous sulphate, and another crop of crystals is obtained. A large number of other hydrates are known, *e.g.* di-, tri-, tetra-, penta-, hexa-, hepta-, and nonohydrates (Orloff, J. Russ. Phys. Chem. Soc. 1902, 34, 381; de Coninck, Bull. Acad. roy. Belg. 1901, 483; Kohlschütter, Ber. 1901, 34, 3628; Giolitti and Bucci, Gazz. chim. ital. 1905, 35, ii. 151, 162; Giolitti and Liberi, *ibid.* 1906, 36, ii. 443). The tetrahydrate is a stable substance, and the nonohydrate $U(SO_4)_2,9H_2O$ crystallises from aqueous solution in green monoclinic prisms that frequently exhibit twinning and are isomorphous with thorium sulphate

$$Th(SO_4)_2,9H_2O$$

(Rammelsberg, Zeitsch. Krystall. 1889, 15, 640). Uranous sulphate forms double salts with sulphates of the alkali metals, *e.g.*

$$U(SO_4)_2\cdot K_2SO_4,2H_2O$$

(Kohlschütter, Ber. 1901, 34, 3619). Aqueous solutions of uranous sulphate are readily hydrolysed, basic sulphates being precipitated.

A sulphate of the composition $UH(SO_4)_3$, which is supposed to contain trivalent uranium, has been described (Rosenheim and Loebel, Zeitsch. anorg. Chem. 1908, 57, 234).

Uranyl sulphate $UO_2\cdot SO_4$ is obtained by dissolving the hydroxide of uranium trioxide in concentrated sulphuric acid and crystallising the solution (Schultz-Sellack, Ber. 1871, 4, 13); or by drying either of its hydrates at 300°. It forms yellow fluorescent crystals. The hydrate $UO_2\cdot SO_4,3\frac{1}{2}H_2O$ is obtained by concentrating a solution of uranic hydroxide in dilute sulphuric acid; the solution does not crystallise readily. Another method is to dissolve uranosouranic oxide in concentrated sulphuric acid, dilute, and boil with nitric acid to oxidise the uranous sulphate present. The hydrate forms citron yellow prisms, which effloresce in air, losing water and leaving the trihydrate $UO_2\cdot SO_4.3H_2O$. This dissolves in twenty times its weight of water at ordinary temperatures (de Coninck, Bull. Acad. roy. Belg. 1901, 222, 349; 1902, 94, 161). Dried *in vacuô* or at 100° it retains 1 molecule of water. When dissolved in moderately concentrated sulphuric acid, a beautiful yellow, fluorescent, crystalline acid sulphate

$$UO_2\cdot SO_4\cdot H_2SO_4$$

crystallises out. The pyrosulphate $(UO_2)_2S_2O_7$ crystallises from a solution of the anhydrous sulphate in pyrosulphuric acid (Schultz-Sellack, Ber. 1871, 4, 13).

Uranyl sulphate forms a double sulphate with hydroxylamine sulphate (Rimbach, Ber. 1904, 37, 461); a salt $Tl_2SO_4\cdot UO_2SO_4,3H_2O$ with thallous sulphate (Kohn, Zeitsch. anorg. Chem. 1908, 59, 111); and combines with equimolecular quantities of the sulphates of ammonium, potassium, lithium, cæsium, and magnesium, forming double salts which crystallise with from 2 to 5 molecules of water (de Coninck, Bull. Acad. roy. Belg. 1904, 1171; 1905, 50, 94, 151, 182; de Coninck and Chauvenet, *ibid.* 1908, 50).

A number of *basic sulphates* occur naturally, *e.g.* *zippéite* $(UO_2\cdot SO_4\cdot UO_2)$ and *uraconite* $(UO_2\cdot SO_4\cdot 2UO_3,14H_2O)$, which are alteration-products of pitchblende.

Uranyl sulphite. The crystalline precipitate obtained by evaporating a solution of uranic oxide in aqueous sulphurous acid, or by passing sulphur dioxide into an aqueous solution of uranyl acetate, has the empirical composition $UO_2\cdot SO_2,4H_2O$ (Girard, Compt. rend. 1852, 34, 22). According to Kohlschütter (Annalen, 1901, 314, 311) it is really uranyl sulphurous acid $SO_2H\cdot UO_2\cdot OH,3H_2O$ (*cf.* Ley, Ber. 1900, 33, 2659).

Tungstates, *v.* Rammelsberg, Pogg. Ann. 1843, 59, 31; Lefort, Compt. rend. 1878, 87, 748.

Detection and estimation. In qualitative analysis uranium is obtained together with iron. All the uranyl salts of weak acids, *e.g.* carbonate, sulphide, phosphate, &c., are soluble in ammonium carbonate and the other alkali carbonates. The ferrocyanide, a brown precipitate, insoluble in dilute acids, is characteristic; alkalis turn it yellow. Uranium is usually weighed as uranosouranic oxide, or else as uranyl pyrophosphate; uranous salts may be titrated with permanganate. *V.* ANALYSIS, and Finn, J. Amer. Chem. Soc. 1906, 28, 1443; McCoy and Bunzel, *ibid.* 1909, 31, 367; Giolitti, Gazz. chim. ital. 1904, 34, ii. 166; Mazzucchelli, Atti. R. Accad. Lincei. 1906, [v.] 15, ii. 429, 494; Campbell and Griffin, J. Ind. Engin. Chem. 1909, 1, 661; Ibbotson and Clark, Chem. News. 1911, 103, 146.

URANIUM MICA *v.* AUTUNITE; TORBERNITE; URANITE.

URANIUM X. Estimated at.wt. 230·5. A radioactive element produced by the disintegration of uranium. It emits two kinds of β- rays, and also γ- rays, and its presence in ordinary uranium salts is responsible for the penetrative rays they emit. Uranium salts, when freed from uranium X, only emit α-rays.

Uranium X may be separated in a number of ways. When a concentrated solution of uranyl nitrate (sp.gr. of solution 2·05) is allowed to cool, the mother liquor left after removing the crystals formed contains about 85 p.c. of the uranium X present (Soddy and Russell, Phil. Mag. 1909, [vi.] 18, 620). If crystals of hydrated uranyl nitrate are shaken with ether, two layers are formed; the aqueous (lower) layer retains the uranium X. In the purification of a uranyl solution from iron, aluminium, &c., by pouring into excess of ammonium carbonate, the precipitated impurities contain all the uranium X.

If this precipitate is dissolved in concentrated hydrochloric acid, and the solution extracted with ether, saturated with hydrogen chloride, the ferric chloride is removed, but not the uranium X, which remains in the aqueous layer (Lloyd, J. Phys. Chem. 1910, 14, 509; Soddy, Phil. Mag. 1909, [vi.] 18, 861). It has been recommended to add a thorium salt to a uranyl salt, and then precipitate the thorium in acid solution as fluoride; the precipitate contains the uranium X (Keetman, Jahr. Radioaktivitat, 1909, 6, 269; Ritzel, Zeitsch. physikal. Chem. 1909, 67, 725). By using a lanthanum salt containing a very little thorium, converting the precipitated fluorides into sulphates and then precipitating by boiling with sodium thiosulphate, a precipitate is obtained, consisting mainly of sulphur, which on ignition leaves a very slight residue containing all the uranium X originally present (*cf.* Antonoff, Phil. Mag. 1911, [vi.] 22, 431).

Chemically, uranium X seems to resemble thorium very closely; for its radioactive properties, *v.* RADIOACTIVITY.

URANIUM YELLOW *v.* URANIUM.

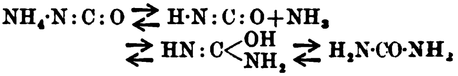
URAO. A native form of sodium sesquicarbonate $Na_4H_2(CO_3)_3,2H_2O$, found in South America, Africa and other places.

URARI *v.* CURARA.

p-**URAZINE** *v.* HYDRAZINES.

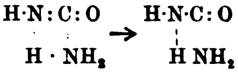
UREA, *carbamide*, $CO{<}\genfrac{}{}{0pt}{}{NH_2}{NH_2}$ occurs in human urine to the extent of 1·5 p.c. to 2 p.c.; in the urine of other mammalia, especially the carnivora; in small quantities in the blood, bile, milk, perspiration, the aqueous humour of the eye, and other animal fluids (Würtz, Compt. rend. 1859, 49, 52; Popp, Annalen, 1869, 151, 88; Argutinsky, Pflüger's Archiv. 1891, 46, 594; North, Proc. Roy. Soc. 1886, 39, 443; Pautz, Zeitsch. biol. 1894, 31, 212); in the liver, muscle and blood of the dog-fish, the blood containing 2·78 p.c. (v. Shroeder, Zeitsch. physiol. Chem. 1890, 14, 576; Baglioni, Beitr. chem. Physiol. Path. 1906, 9, 50); in the bile and blood of other fish (Hammarsten, Zeitsch. physiol. Chem. 1898, 24, 322; Baglioni, *l.c.*). In the vegetable kingdom urea has been found in *Lycoperdon bovista*, *Psolliota campestris* and other higher fungi to the extent of 4·3 p.c. of the dry weight, and is present in minute quantities in the juice from the washed leaves of a number of plants and also in seedlings of wheat, barley, maize, peas, clover, and beans (Bamberger and Landseidl, Monatsh. 1903, 24, 218; Gaze, Arch. Pharm. 1905, 243, 78; Goris and Mascré, Compt. rend. 1908, 147, 1488; Fosse, *ibid.* 1912, 155, 851; 1913, 156, 567).

Urea was first obtained synthetically by Wöhler in 1828 from ammonium cyanate, which undergoes a spontaneous transformation into its isomeride urea when an aqueous solution is evaporated at the temperature of boiling water. The mechanism of the reaction has been exhaustively studied by Walker and others (Chem. Soc. Trans. 1895, 67, 746; 1896, 79, 193; 1897, 71, 489; 1900, 77, 30), who have shown: (1) that the reaction is a reversible one, equilibrium being reached in a decinormal solution when ere is about 95 p.c. of urea and 5 p.c. of am-ium cyanate present; (2) that the reaction bimolecular one; (3) that the velocity of the reaction is thirty times as great in 90 p.c. ethyl alcoholic as in aqueous solutions; and (4) that pure dry ammonium cyanate passes rapidly into urea when heated at about 80°. These authors suggest that the active molecules in the reaction are ammonium ions and cyanic acid ions, $NH_4^{\cdot}+CNO'=CO(NH_2)_2$; and that the increased velocity of the reaction in alcoholic solution is due to the effect of the alcohol in increasing the rate at which the dissociated ions interact, and this more than counterbalances the diminution in the velocity due to the diminished degree of electrolytic dissociation of the cyanate. Another explanation of the reaction offered by Chattaway (Chem. Soc. Trans. 1912, 101, 170) is that ammonium cyanate dissociates into ammonia and cyanic acid, that these interact to form *iso*urea, which rapidly undergoes molecular rearrangement



$$NH_4{\cdot}N{:}C{:}O \rightleftarrows H{\cdot}N{:}C{:}O+NH_3 \rightleftarrows HN{:}C{<}\genfrac{}{}{0pt}{}{OH}{NH_2} \rightleftarrows H_2N{\cdot}CO{\cdot}NH_2$$

Wheeler and others (J. Amer. Chem. Soc. 1912, 34, 1269) offer a somewhat simpler explanation of the interaction between the cyanic acid and ammonia by introducing the idea of partial valency



$$\begin{matrix} H{\cdot}N{:}C{:}O \\ \vdots \quad \vdots \\ H \cdot NH_2 \end{matrix} \rightarrow \begin{matrix} H{\cdot}N{\cdot}C{:}O \\ \vdots \\ H\,NH_2 \end{matrix}$$

Urea can be obtained from lead cyanate by direct hydrolysis with boiling water (Cumming, Chem. Soc. Trans. 1903, 83, 1391); by heating ammonium sesquicarbonate or ammonium carbamate at 130°–135° under pressure (Bourgeois, Bull. Soc. chim. 1897, [iii.] 17, 474; Fichter and Becker, Ber. 1911, 44, 3473); by passing a mixture of ammonia and carbon dioxide through a red hot tube (Mixter, Amer. Chem. J. 1882, 4, 35); by the action of carbonyl chloride on ammonia (Hofmann, Quart. J. Chem. Soc. 1850, 2. 44); by passing a stream of air charged with ammonia and benzene vapour or acetylene over a heated platinum spiral (Herroun, Chem. Soc. Trans. 1881, 39, 471); by heating a solution of carbon monoxide in ammonium cuprous chloride at 105° under pressure (Jouve, Compt. rend. 1899, 128, 114); by the decomposition of copper or ammonium fulminate with sulphuretted hydrogen (Gladstone, Quart. J. Chem. Soc. 1849, 1, 228); by the decomposition of an aqueous solution of prussic acid (Campani, Gazz. chim. ital. 1871, 1, 472), or by the oxidation of potassium cyanide with potassium permanganate or sodium hypochlorite (Volhard, Annalen, 1890, 259, 377; Reychler, Bull. Soc. chim. 1893, [iii.] 9, 427). Urea is also obtained by the hydrolysis of guanidine (Flemming, Chem. Zeit. 1900, 24, 56), arginine (Schulze and Likiernik, Ber. 1891, 24, 2701) or lysatine (Drechsel, *ibid.* 1890, 23, 3096) with barium hydroxide solution: and is a constant product of oxidation with acid potassium permanganate of a large number of organic compounds containing nitrogen: for example, acid amides and amino acids (Hofmeister, Chem. Zentr. 1896, ii. 389; Jolles, Ber. 1900, 33, 2834; J. pr. Chem. 1901, [ii.] 63, 516), and proteins (Ritter, Compt. rend. 1872, 73, 1219; Hofmeister, *l.c.*; Hugounenq, Compt. rend. 1901, 132, 1240; Jolles, Ber. 1901, 34, 1447; Fosse, Compt. rend. 1912, 154, 1187, 1819).

Urea is usually obtained from urine by treating the concentrated filtered liquid with a hot saturated solution of oxalic acid and decomposing the sparingly soluble urea oxalate thus obtained with powdered chalk; the filtrate is decolorised with animal charcoal and evaporated until the urea crystallises out on cooling. Another method consists in extracting the urea with alcohol from the syrup obtained by evaporating the urine, precipitating the urea as the sparingly soluble nitrate by the addition of concentrated nitric acid, and decomposing the salt by boiling with barium carbonate and alcohol; the urea is obtained by crystallisation from the filtrate.

Carbamide can be prepared on a large scale by passing dry ammonia into fused phenyl carbonate until the odour of ammonia is persistent. The product is poured into hot water, when it separates into two layers consisting respectively of phenol and a solution of carbamide; 5 kilos. of phenyl carbonate yield 1 kilo. of carbamide and the whole of the phenol is recovered. The phenyl carbonate is obtained in an almost theoretical yield by passing dry carbonyl chloride into a solution of phenol in its equivalent quantity of dilute caustic soda (Hentschel, Ber. 1884, 17, 1286). By a similar reaction, guaiacol carbonate is rapidly converted into carbamide and guaiacol when an alcoholic solution is saturated with ammonia (Cazeneuve, Compt. rend. 1896, 122, 999).

Urea crystallises in needles, or in four-sided rhombic anhydrous prisms; it is readily soluble in water, 1 grm. of water dissolving 0·779 grm. of urea at 5·5°, 1·00 grm. at 17·1° and 1·094 grm. at 20·92° (Krummacher, Zeitsch. biol. 1905, 46, 302). It dissolves in five parts of cold alcohol, is soluble in methyl and in amyl alcohol, and is insoluble in ether, ethyl acetate or chloroform. The heat of combustion is 2·532 cal., and the heat of solution 3·57 cal. (Krummacher, *l.c.*).

Urea melts at 130°–132°, and sublimes readily when heated under reduced pressure at 120°–130° (Bourgeois, Bull. Soc. chim. 1892, [iii.] 7, 45). Urea decomposes when heated above its melting-point; at 150°–160° it loses ammonia forming *biuret* $NH_2\cdot CO\cdot NH\cdot CO\cdot NH_2$, which on further heating decomposes into ammonia, ammonium cyanate, melanuric acid.

$$C_3N_3(OH)_2NH_2$$

and cyanuric acid $C_3N_3(OH)_3$ (Drechsel, J. pr. Chem. 1874, [ii.] 9, 284). When urea is sublimed in a vacuum at 160°–190°, the sublimate consists of ammonium cyanate (Escales, Chem. Zeit. 1911, 35, 595). When an aqueous solution of urea is boiled, it is partially converted into ammonium cyanate. The reaction is a reversible one, equilibrium being reached in a N/10 solution, when there is about 5 p.c. ammonium cyanate present (Walker and Hambly, Chem. Soc. Trans. 1895, 67, 746; Fawsitt, Zeitsch. physikal. Chem. 1902, 41, 602). When heated with water in a sealed tube at 180°, urea undergoes complete hydrolysis, forming ammonium carbonate. Urea is decomposed by the action of nitrous acid, yielding nitrogen and carbon dioxide (Claus, Ber. 1871, 4, 140). It is oxidised by a hot acid solution of potassium permanganate, yielding two vols. CO_2 and 1 vol. N (Wanklyn and Gamgee, Chem. Soc. Trans. 1868, 21, 25). By the action of sodium hypochlorite or hypobromite, urea is converted into carbon dioxide, nitrogen and water. For an explanation of the course of this reaction, compare Schestakow (J. Russ. Phys. Chem. Soc. 1905, 37, 1), Dehn (J. Amer. Chem. Soc. 1910, 31, 1220). Urea is decomposed by bromine, yielding cyanuric acid, ammonium bromide and nitrogen: chlorine has a similar reaction on fused urea (Smolka, Monatsh. 1887, 8, 64). Urea is converted into cyanamide $NC\cdot NH_2$ by the action of sodium (Fenton, Chem. Soc. Trans. 1882, 41, 262) or of sulphuryl chloride (Moureu, Bull. Soc. chim. 1894, [iii.] 11, 1068).

Urea readily undergoes bacterial fermentation with production of ammonium carbonate (Miguel, Compt. rend. 1890, 111, 397; Frankland, Chem. Soc. Trans. 1885, 47, 175; Hatton, *ibid.* 1881, 39, 256); a ferment present in urine is particularly active in causing this decomposition, and if this ferment is collected on paper by filtration, washed and dried at 35°–40°, its activity revives when brought into contact with water; and such papers, when previously coloured with turmeric, form a convenient test for urea, becoming deep brown when dipped into a solution containing even $\frac{1}{10000}$ part of urea (Musculus, Compt. rend. 1874, 78, 132).

Detection. Urea can be detected by the formation of its sparingly soluble nitrate or oxalate. In the case of the latter salt, the precipitation is facilitated by using an amyl alcoholic solution of the urea and of the oxalic acid (Brücke, Monatsh. 1881, 3, 195). The *biuret* test is the commonest test for urea. It consists in heating gently the urea until it ceases to evolve ammonia freely, dissolving the residue in a little water and adding a few drops of very dilute copper sulphate solution, on the subsequent addition of a drop of concentrated potassium hydroxide, a beautiful violet colour is developed. If the urea is in solution, it may be detected by evaporating to dryness with hydrochloric acid, heating the residue until it ceases to evolve thick white fumes and then dissolving in ammonia; on adding barium chloride solution and stirring, crystals of barium cyanurate separate on the lines of friction made by the rod; or copper sulphate may be added to the ammoniacal solution of the residue, when violet crystals of cuprammonium cyanurate separate out (Bloxam, Chem. News, 1883, 47, 285). Other colour reactions that can be used for the detection of urea are (1) the formation of a fine purple violet colour, when a solution of urea is treated with a concentrated solution of furfurol and a few drops of concentrated hydrochloric acid (Schiff, Ber. 1877, 10, 773); (2) the development of an intense blue colour when minute quantities of urea (or other compounds containing the $\cdot NH\cdot CO\cdot NH_2$ group) and methylfuril ($C_4H_3O\cdot CO\cdot CO\cdot C_4H_2O\cdot CH_3$) are mixed on a filter paper and treated with a drop of fuming hydrochloric acid (Fenton, Chem. Soc. Trans. 1903, 83, 187; Proc. Camb. Phil. Soc. 1911, 16, 64); (3) the development of the characteristic red colour of the sodium violurate when the urea (or its mono- or sym. di-substituted derivatives) is condensed with malonic acid by cautiously heating the mixture moistened with phosphoryl chloride, the resulting barbituric acid dissolved in water, neutralised with solid sodium carbonate, and then treated with a crystal of sodium nitrite and a drop of acetic acid (Whiteley, *private communication*); (4) urea condenses with *o*-nitrobenzaldehyde when heated in alcoholic solution. The *o*-nitrobenzodiureide

$$NO_2{\cdot}C_6H_4{\cdot}CH(NH{\cdot}CO{\cdot}NH_2)_2$$

thus obtained melts at 200°, and if present in very small amount may be readily detected by decomposing it with dilute hydrochloric acid and testing for *o*-nitrobenzaldehyde by the red colour it gives with phenylhydrazine (Lüdy, Monatsh. 1889, 10, 295).

Estimation. The determination of the amount of urea present in urine, blood serum or other animal liquids, is a problem of great physiological importance. Of the large number of methods that have been described for the estimation of urea, only those are now in use that involve the conversion of urea into ammonia, under such conditions that other nitrogenous substances that may be present in the specimen are not simultaneously hydrolysed. The most important methods are those of Folin and of Benedict, Mörner and Sjöquist and of Pflüger and Bleibtreu.

I. Folin's method is based on the fact that urea is quantitatively converted into ammonia and carbon dioxide when heated with fused magnesium chloride $MgCl_2,6H_2O$. In using this method for the estimation of urea in urine, 3 c.c. of the sample are boiled for half an hour with 20 grms. of hydrated magnesium chloride and 2 c.c. concentrated hydrochloric acid in a small reflux apparatus supplied with a special 3-bulb safety tube. After careful dilution, 7 c.c. of 20 p.c. sodium hydroxide are added to liberate magnesium hydroxide and the ammonia distilled over into a known volume of N/10 acid, the distillation being prolonged until the contents of the flask are almost dry. Allowance must be made for the ammonia present in the magnesium chloride (Folin, Zeitsch. physiol. Chem. 1901, 32, 504; 1902, 36, 333). In this method, creatinine yields traces of ammonia and allantoin yields all its nitrogen as ammonia. Benedict (J. Biol. Chem. 1910, 8, 405) modifies the method by adding to the urine potassium hydrogen sulphate, zinc sulphate, a little powdered pumice, and a piece of paraffin to prevent frothing; the mixture is boiled to dryness, the residue heated at 162°–165° for an hour, then mixed with sodium hydroxide and the liberated ammonia distilled into standard acid.

II. In the Mörner-Sjöquist method of estimating urea in urine, uric acid, purine bases, tyrosine, allantoin, &c., are removed by precipitation with barium chloride and hydroxide in a mixture of alcohol and ether. The filtrate and washings are evaporated at 55° to about 25 c.c., a little water and magnesia added and the distillation continued until the steam has no longer an alkaline reaction. The volume is then concentrated to 10–15 c.c. and the nitrogen present estimated by the Kjeldahl method (Chem. Soc. Abstr. 1891, 758; compare Braunstein, Zeitsch. physiol. Chem. 1900, 31, 381).

III. In the Pflüger-Bleibtreu method for the estimation of urea in urine, the nitrogenous compounds other than urea are precipitated by means of a mixture of hydrochloric and phosphotungstic acids; the urea decomposed in the neutralised filtrate by heating it with phosphoric acid, and the ammonia estimated. For working details of this and the other methods, see Abderhalden's Handbuch der Biochemisches Arbeitsmethoden, vol. iii. part 2, 776–782.

Derivatives. *Salts.* Urea forms salts with metals; *silver urea* $CO(NHAg)_2$ (Mulder, Ber. 1873, 6, 1019); *monopotassium urea* CON_2H_3K, colourless needles; *dipotassium urea* $CON_2H_2K_2$, gelatinous mass (Franklin and Stafford, Amer. Chem. J. 1902, 28, 83). It also forms salts with acids, some of which combine with metallic salts to form stable crystalline double salts. The *nitrate* $CO(NH_2)_2{\cdot}HNO_3$ forms sparingly soluble monoclinic crystals that decompose at 140° (Gaubert, Compt. rend. 1907, 145, 378); the *hydrochloride* $CO(NH_2)_2{\cdot}HCl$ dissociates in aqueous solution (Datta, Chem. Soc. Trans. 1912, 101, 166); the *phosphate* $CO(NH_2)_2{\cdot}H_3PO_4$, large rhombic crystals, readily soluble in alcohol or water; *acetate* $CO(NH_2)_2,C_2H_4O_2,2H_2O$ large deliquescent crystals (Matignon, Compt. rend. 1891, 112, 1367); *glycine urea*

$$CO(NH_2)_2{\cdot}NH_2{\cdot}CH_2{\cdot}CO_2H,$$

large crystals (Matignon, Bull. Soc. chim. 1894, [iii.] 11, 575); the *salicylate* (*ursal*)

$$CO(NH_2)_2{\cdot}C_7H_6O_3$$

has m.p. 122°; the *acid* salt $CO(NH_2)_2{\cdot}2C_7H_6O_3$ has m.p. 115°; the *quinate* (*urol, urocol*)

$$[CO(NH_2)]_2C_7H_{12}O_6$$

m.p. 107°; the *picrate* $CO(NH_2)_2{\cdot}C_6H_3O_7N_3$ decomposes at 142° (Smolka, Monatsh. 1885, 6, 915); the *oxalate* $[CO(NH_2)_2]_2C_2H_2O_4$ forms rhombic plates or prisms, sparingly soluble in water (1 : 23), less so in alcohol (1 : 62), amyl alcohol, and insoluble in ether. With hydrogen peroxide urea forms the *compound*

$$CO(NH_2)_2{\cdot}H_2O_2$$

crystallising in large transparent crystals (Tanatar, J. Russ. Phys. Chem. Soc. 1908, 40, 376). Urea forms crystalline *compounds* with *sodium chloride* $CO(NH_2)_2{\cdot}NaCl,H_2O$ rhombic plates or prisms, m.p. 60°–70°; with *ammonium chloride* $CO(NH_2)_2{\cdot}NH_4Cl$ quadratic plates or needles that readily dissociate; with *calcium bromide* (*ureabromin*) $4CO(NH_2)_2{\cdot}CaBr_2$, m.p. 186°, which has therapeutic properties resembling those of the alkali bromides (Biltz, Pharm. Zentr. 1912, 53, 245); with *mercuric chloride*

$$CO(NH_2)_2{\cdot}HgCl_2;$$

with *zinc chloride* $CO(NH_2)_2{\cdot}ZnCl_2$; with *cadmium chloride* $CO(NH_2)_2,CdCl_2$; with *silver nitrate* $CO(NH_2)_2,AgNO_3$; with *palladium chloride* $PdCl_2{\cdot}2CO(NH_2)_2$; and with *magnesium bromide* $MgBr_2{\cdot}6CO(NH_2)_2$, m.p. 167°–170°, with decomposition, and $MgBr_2{\cdot}4CO(NH_2)_2$ decomposes at 165°–170° (Menschutkin, Petersberger polytechn. Inst., 1906, 6, 101). Among the double salts formed by urea are the *platinichlorides* $[CO(NH_2)_2{\cdot}HCl]_2{\cdot}PtCl_4,2H_2O$, hygroscopic yellow prisms (Heintz, Annalen, 1879, 198, 91) and $[CO(NH_2)_2]_4{\cdot}H_2PtCl_6$, m.p. 119°–120°, red prismatic crystals (Pickard and Kenyon, Chem. Soc. Trans. 1907, 91, 902); the *aurichlorides* $2CO(NH_2)_2{\cdot}HCl{\cdot}AuCl_3$ and $CO(NH_2)_2{\cdot}HCl{\cdot}AuCl_3,H_2O$; the *quinine hydrochloride* $C_{20}H_{24}N_2O_2{\cdot}HCl,CO(NH_2)_2{\cdot}HCl,5H_2O$, nd similar compounds containing quinidine nd cinchonidine (Drygin, Chem. Zentr. 1881, 45). The compounds with *mercuric nitrate* $CO(NH_2)_2\cdot Hg(NO_3)_2\cdot 3HgO$,

$$2CO(NH_2)_2\cdot Hg(NO_3)_2\cdot 2HgO$$

nd $2CO(NH_2)_2\cdot Hg(NO_3)_2\cdot HgO$ are obtained by recipitation between urea and mercuric nitrate nder different conditions of concentration. Jrea also combines with mercuric salts to form alts of the divalent radicle $CO(NHHg)_2$, mercurocarbamide'; the *hydroxide*

$$CO(NH\cdot HgOH)_2\ ;$$

he *chloride* $CO(NH\cdot HgCl)_2$, and

$$CO(NH\cdot HgCl)_2\cdot CO(NH_2)_2\cdot 2HCl\ ;$$

he *nitrate* $CO(NH\cdot HgNO_3)_2$, *sulphate*

$$CO(NHHg)_2SO_4,$$

nd the *acetate* $CO(NH\cdot HgOAc)$ (Ruspaggiari, lazz. chim. ital. 1897, 27, I, 1). Salts containg chromium complexes and urea have been lescribed by Sell (Proc. Roy. Soc. 1883, 33, 67; 1889, 45, 321).

Acyl derivatives of urea, v. UREIDES.

Chloro and *nitro derivatives. Chlorocarbamide*

$$NH_2\cdot CO\cdot NHCl$$

lecomposes at 71°, dissolves in five parts of rater at ordinary temperature, giving a neutral olution that loses nitrogen and forms biuret. t reacts slowly in aqueous solution on aliphatic etones, yielding the monochloroketone (Béhal nd Detoeuf, Compt. rend. 1911, 153, 681, 1229). *Dichlorocarbamide* $CO(NHCl)_2$, prepared by passng a rapid stream of chlorine into a well-cooled olution of urea in water, forms colourless lates that melt with decomposition at 82° when autiously heated and detonate when rapidly eated, forming nitrogen chloride; on decomosition with ammonia in strong aqueous solution p-*urazine* $CO{<}\substack{NH\cdot NH\\ NH\cdot NH}{>}CO$ is formed Chattaway, Proc. Roy. Soc. 1908, A. 81, 381; hem. Soc. Trans. 1909, 95, 236; compare Datta, *ibid.* 1912, 101, 166).

Nitrocarbamide $NO_2\cdot NH\cdot CO\cdot NH_2$, prepared y the action of concentrated sulphuric acid n urea nitrate; it forms sparingly soluble rystals that decompose on melting; it is a trong acid, liberating acetic acid from its salts. he potassium, sodium and mercury salts have een prepared. On reduction with zinc dust nd sodium hydroxide, it forms *nitrosocarbamide* $H_2\cdot CO\cdot NH\cdot NO$, and this develops a purple olour with ferrous sulphate (Thiele and Lachnann, Annalen, 1895, 288, 281). On further eduction it yields semicarbazide

$$NH_2\cdot CO\cdot NH\cdot NH_2.$$

arbaminoazoimide $NH_2\cdot CO\cdot N_3$ from sodium itrite and semicarbazide has m.p. 92°–93° Thiele and Stange, Annalen, 1894, 283, 1).

The *alkyl* and *aryl* derivatives of urea are repared by Wöhler's method from the corresonding mono- or di- substituted ammonium anate: by the action of ammonia on the ocyanic ester, and by the action of carbonyl loride on the amine. For a description of ese derivatives, see Michler, Ber. 1875, 8, 64; Schiff, Annalen. 1877, 189, 157; Michler d Escherich, Ber. 1879, 12, 1162; Hemmelayr, Monatsh. 1891, 12, 89; Chancel, Compt. nd. 1892, 115, 242; Schneegans, Arch. Pharm. 94, 231, 675; A. E. Dixon, Chem. Soc. Trans. 1895, 47, 559; Diels and Golimann, Ber. 1911, 44, 3158; Cannizzaro, Gazz. chim. ital. 1871, 1, 41; Letts, Chem. Soc. Trans. 1872, 25, 448; Paternó and Spica, Gazz. chim. ital. 1875, 5, 388; Michler, Ber. 1876, 9, 396, 710; Claus, *ibid.* 693; Weith, *ibid.* 821; Pagliani, Gazz. chim. ital. 1879, 9, 28; Cosack, Ber. 1879, 12, 1449; 1880, 13, 1088; Michler and Zimmermann, *ibid.* 1881, 14, 2177; Michler and Keller, *ibid.* 2181; Traube, *ibid.* 1882, 15, 2122; Kym, *ibid.* 1890, 23, 424; Kühn and Landau, *ibid.* 811; Manuelli and Conanducci, Gazz. chim. ital. 1899, 29, ii. 136. For a summary of the alkyl substituted ureas, see Abderhalden's Biochemisches Handlexikon, 1911, vol. i. part 2, pp. 772, 773.

Urea forms condensation derivatives with *formaldehyde* (Goldschmidt, Ber. 1896, 29, 2438; Chem. Zeit. 1897, 21, 460; Di Palma, Boll. Chim. Farm. 1912, 51, 78; Einhorn and Hamburgher, Ber. 1908, 41, 24); with *β-diketones* (Evans, J. pr. Chem. 1892, [ii.] 45, 489); with *maleic anhydride* (Dunlap and Phelps, Amer. Chem. J. 1897, 19, 492); with *acetone* (Weinschenk, Ber. 1901, 34, 2185); with *ethyl oxalacetate* (Müller, J. pr. Chem. 1897, [ii.] 55, 505); with *hydrazine* (Curtius and Heidenreich, Ber. 1894, 27, 55) and with *phenylhydrazine* (Edeleanu, Chem. Zentr. 1892, i. 628).

*iso***Ureas**, *ψ-carbamides.* The tautomeric form of urea $HN:C(OH)NH_2$ is not known in the free state, but certain of its ethers have been prepared by the action of hydrogen chloride on cyanamide and the corresponding alcohol at 60°–70°. *Methyl* iso*carbamide* $HN:C(OMe)NH_2$ has m.p. 44°–45°, b.p. 82°/9 mm.; the *hydrochloride* melts at 130°; *ethyl*iso*carbamide* $HN:C(OEt)NH_2$ has m.p. 42°, b.p. 95°–96°/15 mm.; asym. *phenylmethylethyl*iso*carbamide* $HN:C(OEt)NMePh$ has b.p. 137°/21 mm., the isomeric asym. *phenylethylmethyl*iso*carbamide* $HN:C(OMe)NEtPh$ has b.p. 126°/15 mm. (Stieglitz and McKee, Ber. 1900, 33, 807); *propyl*iso*carbamidehydrochloride* melts at 64° and decomposes at 121° (Stieglitz and Noble, *ibid.* 1905, 38, 2243); sym. m-*nitrobenzoylphenyl*iso*carbamide methyl ether*

$$NO_2\cdot C_6H_4\cdot CO\cdot N:C(OMe)NHPh$$

has m.p. 124° (Bruce, J. Amer. Chem. Soc. 1904, 26, 419).

Thiourea. Isomerism amongst the derivatives of the sulphur analogue of urea is much more general than is the case with the derivatives of urea, and the convention has been adopted of limiting the term *thiocarbamides* to derivatives of the true thiocarbamide

$$H_2N\cdot CS\cdot NH_2\ ;$$

derivatives of the isomeric form $HN:C(SH)NH_2$ being called *thioureas*[1] (Reynolds, Chem. Soc. Trans. 1891, 59, 395).

Thiourea is prepared by heating ammonium thiocyanate at 160°–170°, the reaction is a balanced one; equilibrium is reached in about

---

[1] To distinguish between the three isomeric forms of substituted derivatives of thiourea, Dixon (Chem. Soc. Trans. 1895, 67, 564) proposes to designate the NH and NH_2 attachments as *n* and *ν*, whilst if the sulphur attachment is occupied by the substituent the compound is designated a pseudothiourea. Thus, for example, the systematic names of $EtN:C(SH)NMe_2$, $NH:C(SMe)NH_2$ and $EtN:C(SMe)\cdot NHEt$ would be, respectively, *n*-ethyl-*ν*-dimethylthiourea, methyl-*ψ*-thiourea, and methyl-*ψ*-*nν*-diethylurea.

an hour, when the mixture contains about 25 p.c. of thiourea (Reynolds, Annalen, 1869, 150, 224; Reynolds and Werner, Chem. Soc. Trans. 1903, 83, 1; Findlay, *ibid.* 1904, 85, 403). Thiourea can also be obtained by the action of hydrogen sulphide on cyanamide

$$H_2N{\cdot}C\,\vdots\,N+H_2S=H_2N{\cdot}CS{\cdot}NH_2$$

(Baumann, Ber. 1875, 8, 26).

Thiourea crystallises in needles that melt at about 172° if rapidly heated; the true melting-point cannot be determined, owing to tautomeric change; it is probably above 177° (Findlay, *l.c.*).

Derivatives. The *nitrate* $CSN_2H_4{\cdot}HNO_3$, the *hydrochloride* $CSN_2H_4{\cdot}HCl$, and the *silver nitrate* derivative $CSN_2H_4{\cdot}AgNO_3$ are crystalline (Stevens, Chem. Soc. Proc. 1902, 17, 210; Kurnakow, Ber. 1891, 24, 3956). Dithiocarbamide dichloride $(CSN_2H_4)_2Cl_2$ can be crystallised from concentrated hydrochloric acid, and forms the *dinitrate* $(CSN_2H_4)_2(NO_3)_2$ by the action of dilute nitric acid; the *dibromide*

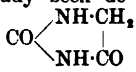
$$(CSN_2H_4)_2Br_2$$

and *di-iodide* $(CSN_2H_4)_2I_2$ are colourless and decompose on warming or by the action of solvents (Claus, Annalen, 1875, 179, 135; McGowan, Chem. Soc. Trans. 1886, 49, 190).

For the *alkyl* and *aryl* substituted derivatives of thiourea and thiocarbamide, see Arzruni, Ber. 1871, 4, 406; Miguel, Bull. Soc. chim. 1877, [ii.] 28, 104; de Clermont, Compt. rend. 1876, 82, 512; Blankenhorn, J. pr. Chem. 1877, [ii.] 16, 358; A. E. Dixon, Chem. Soc. Trans. 1891, 59, 562; 1892, 61, 536; 1893, 63, 318, 538; 1895, 67, 556; 1899, 75, 373; 1906, 89, 892; 1907, 91, 912; 1908, 93, 18. M. A. W.

UREASE *v.* FERMENTATION.

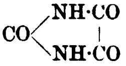
UREIDES or acyl derivatives of urea are formed by condensation between urea and the acid with the elimination of water; in the case of a monocarboxylic acid the product may be a *monoureide* $RCONH{\cdot}CO{\cdot}NH_2$ or a *diureide* $CO(NH{\cdot}COR)_2$, according as one or two molecules of the acid condense with one molecule of urea. Similar products may be obtained in the cases of the hydroxy acids and the di-carboxylic acids, but usually condensation occurs between one molecule of the acid and one of urea with the elimination of two molecules of a water and the formation of a *cyclic ureide.* The more important cyclic ureides have already been described; they include *glycolylurea*



$CO\left<\begin{array}{l}NH{\cdot}CH_2\\ \quad\ \ \vert\\ NH{\cdot}CO\end{array}\right.$

v. HYDANTOIN. *β-Lactylurea, hydracrylurea, hydrouracil* $CO\left<\begin{matrix}NH{\cdot}CH_2\\NH{\cdot}CO\end{matrix}\right>CH_2$ v. PYRIMIDINES.

Oxalylurea



$CO\left<\begin{array}{l}NH{\cdot}CO\\ \quad\ \ \vert\\ NH{\cdot}CO\end{array}\right.$

v. PARABANIC ACID. *Malonylurea* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH_2$ v. *Barbituric acid*, art. PYRIMIDINES. *Hydroxymalonylurea, tartronylurea* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH{\cdot}OH$ v. DIALURIC ACID. *Mesoxalylurea* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CO{\cdot}H_2O$ v. ALLOXAN. *Nitromalonylurea* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH{\cdot}NO_2$ v. DILITURIC ACID. iso*Nitrosomalonylurea* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>C{:}NOH$ v. *Violuric acid*, art. PYRIMIDINES. *Aminomalon- urea, aminobarbituric acid* $CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH{\cdot}NE$ v. *Uramil*, art. PYRIMIDINES.

Of the open chain mono- and di- ureides, th following have been described: *formylur* $NH_2{\cdot}CO{\cdot}NH{\cdot}CHO$, m.p. 168°–169° (Geuth Marsh and Scheitz, Zeitsch. Chem. 1868, 30 Gorski, Ber. 1896, 29, 2046), forms a *mercu* salt (Matignon, Bull. Soc. chim. 1880, [ii.] 3 207); *acetylurea* $H_2N{\cdot}CO{\cdot}NH{\cdot}COCH_3$, m.p. 21 (Behrend, Annalen, 1885, 229, 30; Ber. 18 28, Ref. 63), forms *mercury, silver* and *cupro* salts (Matignon, *l.c.*); ab-*diacetylurea*

$$CO(NH{\cdot}COCH_3)_2,$$

m.p. 152°–153° (Schmidt, J. pr. Chem. 1872, 5, 63); *chloracetylurea* $NH_2{\cdot}CO{\cdot}NH{\cdot}COCH_2$ decomposes at 160° (Tommasi, Bull. Soc. chi 1873 [ii.] 19); *trichloracetylurea*

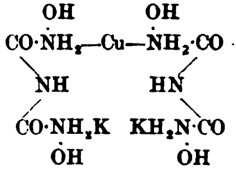
$$NH_2{\cdot}CO{\cdot}NH{\cdot}COCCl_3,$$

m.p. 150° with decomp. (Meldola and Tomma Chem. Soc. Trans. 1874, 404); *bromacetylur* $NH_2{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}CH_2Br$; *tribromacetylurea*

$$H_2N{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}CBr_3$$

m.p. 158° (Baeyer, Annalen, 1864, 130, 149 *cyanacetylurea* $H_2N{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}CH_2CN$, m. 200°–210°; iso*valerylurea* $NH_2{\cdot}CO{\cdot}NH{\cdot}C_5H_9$ m.p. 191°; *monobromoisovalerylcarbam* $CHMe_2{\cdot}CHBr{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}NH_2$ (*bromoural* m.p. 149°, is a narcotic (van der Eeckhou Arch. exp. Path. Pharm. 1907, 57, 338); *butyryl urea* $H_2N{\cdot}CO{\cdot}NH{\cdot}C_4H_7O$, m.p. 176°; *succiny urea* $C_4H_4O_2(NH{\cdot}CO{\cdot}NH_2)_2$; *benzoylur* $NH_2{\cdot}CO{\cdot}NHCOPh$, m.p. 200; ab-*dibenzoylur* $CO(NH{\cdot}COPh)_2$, m.p. 210°; aa-*dibenzoylur* $NH_2{\cdot}CO{\cdot}N(COPh)_2$, m.p. 197°.

Carbonyldiurea $CO(NH{\cdot}CO{\cdot}NH_2)_2$ decomposes on heating (Schmidt, J. pr. Chem. 187 [ii.] 5, 39); *carbonylurea, allophanic ac* $H_2N{\cdot}CO{\cdot}NH{\cdot}COOH$ does not exist in the fr state; the *methyl ester* has m.p. 208° (Ephrai Ber. 1893, 26, 2172), the *ethyl ester*, m.p. 19 (Liebig and Wöhler, Annalen, 20, 396; 59, 291 the *amide* $NH_2{\cdot}CO{\cdot}NH{\cdot}CONH_2,H_2O$ is *bur* m.p. 190°; it gives a purplish-violet col with copper sulphate and potassium hydrox due to the formation of the double salt



A similar reaction is given by proteids wh contain two amino groups in the molecu these groups being joined directly together through a single atom of nitrogen or carb The amino groups must be either two ·CONH groups or one $\cdot CONH_2$ group and one ·CSNH $C(NH)NH_2$, or $\cdot CH_2NH_2$ group. Substanc that are non-proteid in character but wh contain the necessary groups will also give t buiret reaction, for example, *oxamide* a *malonamide.*

Ureides of Sugars. The term *ureide* is applied to certain condensation product urea with aldehydes; these are of the ty $RCH{:}N{\cdot}CO{\cdot}NH_2$ and the most importan those derived from the aldoses. *Glucoseureide* $CH_2OH[CH\cdot OH]_4CH:N\cdot CO\cdot NH_2$, thick rhombic crystals, m.p. 207° (decomp.), $[\alpha]_D^{15}-23\cdot5^\circ$ in 10 p.c. aqueous solution; the *penta-acetyl derivative* $C_7H_9O_6N_2(CH_3CO)_5$ has m.p. 200°, and the *tetrabenzoyl* m.p. 117°. *Galactoseureide* is a white amorphous powder $[\alpha]_D+15^\circ$; *mannoseureide*, m.p. 188°, $[\alpha]_D^{20}-45\cdot8^\circ$; *lactoseureide* $(C_{12}H_{22}O_{10})N\cdot CO\cdot NH_2$ decomposes at 240°, $[\alpha]_D^{20}+2\cdot1^\circ$ (Schoorl, Rec. trav. chim. 1903, 22, 31; Mayer, Biochem. Zeitsch. 1909, 17, 145).

M. A. W.

URETHANE *v.* Synthetic drugs.

URETHANES are the esters of *carbamic acid* (*aminoformic acid*) $H_2N.COOH$; the free acid is not known. It is said to occur in blood serum (Drechsel, J. pr. Chem. 1875, [ii.] 12, 417; *cp.* Hofmeister, Archiv. Physiol. 1876, 12, 337), and in urine (Abel and Drechsel, Chem. Zentr. 1891, ii. 713; Hahn and Nencki. Arch. Sc. biol. Petersb. 1892, 1, 467; Abel and Muirhead, Arch. exp. Path. Pharm. 1893, 31, 15; 32, 467). The *ammonium* salt

$$NH_2\cdot COONH_4$$

is produced by the direct action of carbon dioxide on ammonia in cooled absolute alcohol. It is a white crystalline powder. The *sodium* $NaCH_2NO_2,H_2O$ and *potassium* KCH_2NO_2 salts are also crystalline; the *calcium* salt

$$Ca(CH_2NO_2)_2,H_2O$$

is insoluble in alcohol and crystallises from concentrated ammonia solution in four-sided prisms.

Carbamyl chloride, chloroformamide

$$Cl\cdot CO\cdot NH_2$$

prepared by passing hydrogen chloride over heated metallic cyanates, or carbonyl chloride over heated ammonium chloride, forms long, broad needles, m.p. 50°, b.p. 61°–62° (Gattermann and Schmidt, Ber. 1887, 20, 858).

Urethane, *ethyl carbamate* $NH_2\cdot COOEt$, prepared by the action of ammonia on ethyl carbonate or ethyl chlorocarbonate; by heating urea nitrate with alcohol; or by the action of alcohol on carbonyl chloride, crystallises in large pliable plates or prisms that break with a fibrous fracture, sublime readily, melt at 50° and boil at 184°.

Urethane has therapeutic properties, being employed as a hypnotic. Certain of its substituted derivatives have similar properties; for example, *phenylurethane* or *euphorine*

$$PhHN\cdot COOEt$$

and *methylpropylcarbinol urethane* or *hedonal*

$$H_2N\cdot CO\cdot OCHMe\cdot CH_2\cdot CH_2\cdot CH_3.$$

Nitrourethane $NO_2\cdot NH\cdot COOEt$ melts at 64°, is readily soluble in water and alcohol and forms metallic salts, the *potassium*, *mercury* and *silver* having been prepared (Thiele and Lachmann, Annalen, 1895, 288, 304); from spectrochemical considerations. Brühl assigns the formula

to nitrourethane (Zeitsch. physikal. Chem. 1898, 26, 47; 25, 577). *Nitrosourethane* $NO\cdot NH\cdot COOEt$ melts and decomposes at 51°–52° and does not develop a purple colour with ferrous sulphate and potassium hydroxide; the *silver*, *potassium* and *ammonium* derivatives are yellow (Thiele and Lachmann, *l.c.*). From index of refraction values, Brühl regards nitrosourethane as diazourethane

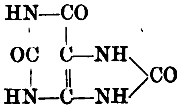
(Ber. 1902, 35, 1148), whilst Hantzsch formulates it as an *antidiazohydrate* $HO\cdot N:N\cdot COOEt$ (*ibid.* 1899, 32, 575). *Dibromourethane* $NBr_2\cdot COOEt$ has b.p. 100°–104°/10–11 mm. (Diels and Ochs, Ber. 1907, 40, 4571).

Urethane forms condensation products with aldehydes and keto acids. *Chloralurethane* $CCl_3\cdot CH(OH)NH\cdot COOEt$ has m.p. 103°; *bromalurethane* $CBr_3\cdot CH(OH)NH\cdot COOEt$ has m.p. 132° (Bischoff, Ber. 1874, 7, 628, 1078; Conrad and Hoëk, *ibid.* 1903, 36, 2206; Simon, Compt. rend. 1901, 133, 535; Simon and Chavanne, *ibid.* 1906, 143, 51).

Thiourethane, a mixture of the isomeric thiourethanes, is obtained by acting on an alcoholic solution of potassium thiocyanate with concentrated hydrochloric acid; these correspond with two of the isomeric forms of the hypothetical thiocarbamic acid, *ethyl xanthamide* $NH_2\cdot CS\cdot OEt$, has m.p. 38°, and *carbonylthioethylamine* $NH_2\cdot CS\cdot OMe$ (Blankenhorn, J. pr. Chem. 1877, [ii.] 16, 358).

M. A. W.

URIC ACID, 2 : 6 : 8-*trioxypurine*

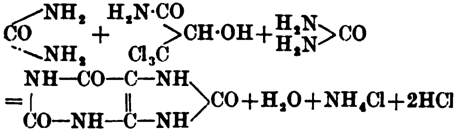


was discovered in human urine by Scheele in 1776 (Opuscula, 1776, 2, 73), independently by Bergmann in urinary calculi (*ibid.* 1776, 4, 232), and in 'chalk-stones' by Pearson in 1798 (Trans. Roy. Soc. 1798, 15).

Uric acid occurs in the urine of all animals, though only to a small extent in the case of herbivorous animals; the average daily excretion in normal man being 0·597 grm. (Hanzlik and Hawk, J. Biol. Chem. 1908, 5, 355). It occurs in the excrement of birds, reptiles, scaly amphibians, snails and insects; the wing scales of the group of butterflies known as the white *Pieridae* contain uric acid, those of the yellow *Pieridae* contain, as their pigment, a yellow derivative of uric acid, which can be obtained synthetically by heating uric acid with water in sealed tubes at a high temperature (Hopkins, Proc. Roy. Soc. 1894, 57, 5). Uric acid is a normal constituent of the organs and blood of birds, but only occurs in human blood under certain pathological conditions.

Preparation. Uric acid can be isolated from serpent's excrement, bird's excrement or guano by boiling the material with dilute alkali hydroxide or milk of lime, filtering the hot liquid and precipitating the uric acid by adding excess of hydrochloric acid to the filtrate. Uric acid can also be obtained from the yellow acid urates deposited from urine; this is boiled with sodium hydroxide until it ceases to evolve ammonia, the liquid is filtered and the acid sodium urate precipitated from the filtrate by means of carbon dioxide; this is redissolved in sodium hydroxide and the solution decomposed by acetic acid, or the hot solution of the alkali salt may be purified by boiling with a little potassium permanganate or dichromate and the filtrate decomposed by hydrochloric acid.

Synthesis. Uric acid was first synthesised by Horbaczewski by carefully fusing glycine with 10 to 15 times its weight of urea in small quantities at a time, until a considerable quantity of precipitate had formed in the molten mass; the uric acid was precipitated in the form of its sparingly soluble silver magnesium salt, which on treatment firstly with potassium sulphide and subsequently with hydrochloric acid, yielded pure uric acid (Monatsh. 1882, 3, 796; 1885, 6, 366). Further syntheses were effected by Horbaczewski (*ibid.* 1887, 8, 201) by fusing trichlorlactamide with 10 parts of carbamide

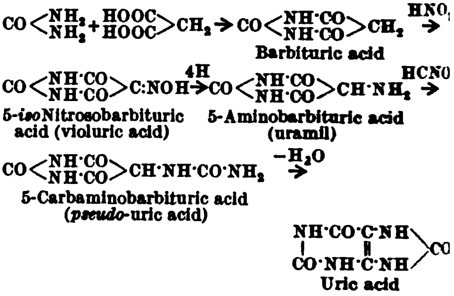


$$CO\left<\begin{matrix}NH_2\\NH_2\end{matrix}\right. + \begin{matrix}H_2N{\cdot}CO\\Cl_3C\end{matrix}\!\!>CH{\cdot}OH + \begin{matrix}H_2N\\H_2N\end{matrix}\!\!>CO$$

$$= \begin{matrix}NH-CO-C-NH\\ | \qquad\quad \| \\ CO-NH-C-NH\end{matrix}\!\!>CO + H_2O + NH_4Cl + 2HCl$$

and by fusing trichlorlactic acid or amino- acetic acid with carbamide (*ibid.* 1887, 8, 584).

In 1863, Baeyer (Annalen, 1863, 127, 3, 234) synthesised *pseudouric acid*, starting with malonic acid and carbamide; but it was not until 1895 that Fischer and Ach (Ber. 1895, 28, 2473) showed that uric acid could be readily obtained from pseudouric acid by fusion with oxalic acid or by boiling with hot dilute mineral acid (Fischer, *ibid.* 1897, 30, 559); a complete synthesis of uric acid from malonic acid and carbamide is therefore represented by the following equations:



$$CO\left<\begin{matrix}NH_2\\NH_2\end{matrix}\right. + \begin{matrix}HOOC\\HOOC\end{matrix}\!\!>CH_2 \rightarrow CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH_2 \xrightarrow{HNO_2}$$

Barbituric acid

$$CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>C{:}NOH \xrightarrow{4H} CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH{\cdot}NH_2 \xrightarrow{HCNO}$$

5-*iso*Nitrosobarbituric acid (violuric acid) 5-Aminobarbituric acid (uramil)

$$CO\left<\begin{matrix}NH{\cdot}CO\\NH{\cdot}CO\end{matrix}\right>CH{\cdot}NH{\cdot}CO{\cdot}NH_2 \xrightarrow{-H_2O}$$

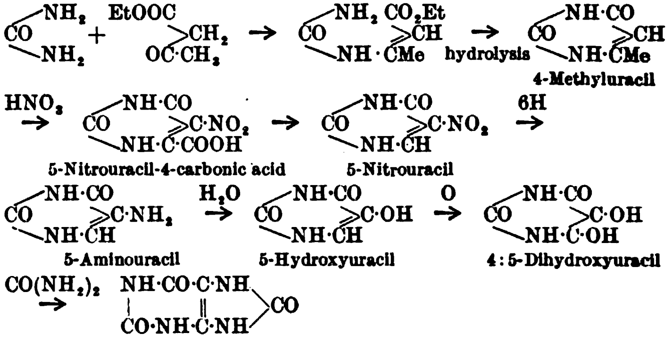
5-Carbaminobarbituric acid (*pseudo*-uric acid)

$$\begin{matrix}NH{\cdot}CO{\cdot}C{\cdot}NH\\ | \qquad\ \| \\ CO{\cdot}NH{\cdot}C{\cdot}NH\end{matrix}\!\!>CO$$

Uric acid

This is the most important synthetic method of preparing uric acid, and by replacing carbamide by its alkyl or aryl substituted derivatives, it is possible to prepare the corresponding alkyl or aryl substituted uric acids.

The synthesis of uric acid effected by Behrend and Roosen (Annalen, 1888, 251, 235), starting with ethyl acetoacetate and carbamide, is represented in the following series of equations:



4-Methyluracil

5-Nitrouracil-4-carbonic acid

5-Nitrouracil

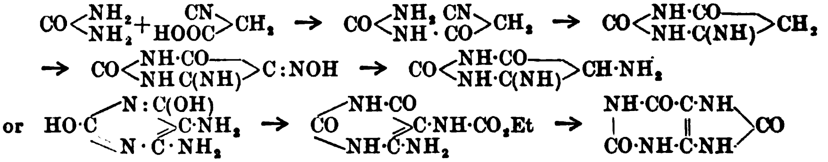
5-Aminouracil

5-Hydroxyuracil

4 : 5-Dihydroxyuracil

Uric acid

Traube's synthesis of uric acid, starting with cyanacetic acid and carbamide, is also important, and by substituting alkyl carbamides for carbamide, the method can be extended to the preparation of substituted uric acids. Cyanacetylcarbamide, prepared by the condensation of carbamide with cyanacetic acid, is converted by the action of alkali into 4-amino-2 : 6-dioxypyrimidine, from which 4 : 5-diamino-2 : 6-dioxypyrimidine is obtained by reducing its *iso*nitroso derivative; this diamine condenses with ethyl chloroformate to form a *urethane* derivative from the sodium derivative of which uric acid is produced by heating at 180°–190° (Ber. 1900, 33, 1375, 3035).



$$CO\left<\begin{matrix}NH_2\\NH_2\end{matrix}\right. + \begin{matrix}CN\\HOOC\end{matrix}\!\!>CH_2 \rightarrow CO\left<\begin{matrix}NH_2\ CN\\NH\cdot CO\end{matrix}\right>CH_2 \rightarrow CO\left<\begin{matrix}NH{\cdot}CO\text{——}\\NH{\cdot}C(NH)\end{matrix}\right>CH_2$$

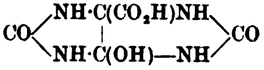
$$\rightarrow CO\left<\begin{matrix}NH{\cdot}CO\text{——}\\NH\,C(NH)\end{matrix}\right>C{:}NOH \rightarrow CO\left<\begin{matrix}NH{\cdot}CO\text{——}\\NH{\cdot}C(NH)\end{matrix}\right>CH{\cdot}NH_2$$

Properties. Pure uric acid forms a colourless microcrystalline powder consisting of rhombic transparent plates or prisms; as precipitated from urine or guano extracts, the crystals are yellowish red or brown. These exhibit, under the microscope, characteristic irregularities in form, due to the rounding of the obtuse angles of the rhombic prisms, and the interpenetration of the crystals, and present the form of dumb-bells, whetstones, rosettes of prismatic crystals, six-sided irregular plates or rectangular plates with partly jagged sides.

Uric acid is odourless and tasteless; it is sparingly soluble in water, one part dissolving in 39.480 parts at 18° (His and Paul, Zeitsch. physiol. Chem. 1900, 31, 41), or 15,505 parts at

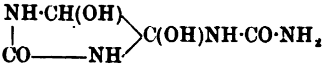
37^c (Gudzent, *ibid.* 1909, 60, 27). When shaken with water, uric acid decomposes so that the solubility tends to increase with the time; the increase is only noticeable at the end of 24 hours and then rises rapidly until at the end of 10 days the solubility is 11 times as great as at the end of a few hours, and in the same time the electrical conductivity has increased 55 times (Gudzent, *l.c.*). The molecular electrical conductivity of a saturated solution of uric acid is 32·24 at 18° (His and Paul, *l.c.*) or 33·92 at 37° (Gudzent, *l.c.*); the dissociation constant $k=0{\cdot}000151$ at 18° or 0·000233 at 37°. Uric acid is fairly readily soluble in lactic acid, acetic acid or warm concentrated sulphuric acid. It dissolves in glycerol, but is insoluble in alcohol or ether; it dissolves readily in aqueous solutions of alkali hydroxides, of lithium carbonate, and of certain organic bases such as ethylamine, propylamine, piperazine, but is only sparingly soluble in solutions of urotropine (hexamethylenetetramine), lycetol (piperazine tartrate) or ammonia (Stevens and May, J. Amer. Chem. Soc. 1911, 33, 434).

Uric acid is not volatile: on being strongly heated it breaks up into urea, hydrocyanic acid, cyanuric acid and ammonia (Wöhler, Pogg. Ann. 1839, 15, 529, 619). When oxidised by strong nitric acid or potassium chlorate and hydrochloric acid, or by chlorine or bromine water in the cold, uric acid is broken down into alloxan (mesoxalylcarbamide) (*q.v.*) and urea; warm dilute nitric acid produces parabanic acid (oxalylcarbamide) (*q.v.*). By the action of such oxidising agents as potassium permanganate, or ferricyanide, lead peroxide, mercuric oxide or ozone in neutral or alkaline media, uric acid yields carbon dioxide and allantoin (glyoxyldiureide) (*q.v.*). According to Behrend (Annalen, 1904, 333, 141) and Behrend and Schultz (*ibid.* 1909, 365, 21), the first product of oxidation of uric acid in alkaline media is *hydroxyglycolurilcarboxylic acid*



$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{NH{\cdot}C(CO_2H)NH}\\ \qquad\quad |\\ \mathrm{NH{\cdot}C(OH){-}NH}\end{array}\right\rangle\mathrm{CO}$$

This is next converted into the *compound*



$$\left.\begin{array}{l}\mathrm{NH{\cdot}CH(OH)}\\ |\\ \mathrm{CO{-\!-\!-}NH}\end{array}\right\rangle\mathrm{C(OH)NH{\cdot}CO{\cdot}NH_2}$$

which, on acidifying with acetic acid, yields carbon dioxide and allantoin. On heating with an excess of alkali hydroxide, hydroxy glycolurilcarboxylic acid takes up the elements of water, forming *uroxamic acid* (*dicarbaminomalonic acid*)

$$\mathrm{(COOH)_2C(NH{\cdot}CO{\cdot}NH_2)_2}$$

(*q.v.*). When oxidised by hydrogen peroxide in alkaline solution, uric acid yields *tetracarbonimide* $\mathrm{CO}\!\left\langle\begin{array}{l}\mathrm{NH{\cdot}CO{\cdot}NH}\\ \mathrm{NH{\cdot}CO{\cdot}NH}\end{array}\right\rangle\!\mathrm{CO}$ (Scholtz, Ber. 1901, 34, 4130), *carbonylcarbamide* $\mathrm{CO(NH{\cdot}CO{\cdot}NH_2)_2}$ and *carbamide* (Schittenhelm and Wiener, Zeitsch. physiol. Chem. 1909, 62, 100).

Uric acid is decomposed when fused with potassium hydroxide, yielding the potassium salts of prussic, cyanic, carbonic and oxalic acids. When heated under pressure at 160°–170° with concentrated hydrochloric or hydriodic acids, it yields carbon dioxide, ammonia and glycocoll; it is oxidised by a solution of copper oxide in ammonia (Schweizer's reagent) in the presence of potassium hydroxide to urea and oxalic acid, and a similar oxidation is effected by boiling with ferric chloride.

For the physiological properties of uric acid, its origin, and the rôle it plays in the animal economy, see Article URINE; also Biochemisches Handloxikon von Abderhalden, vol. iv. 1095–1106; and Oxidations and Reductions in the Animal Body, by H. D. Dakin, 92.

Detection. Uric acid is readily identified by the appearance of the crystals under the microscope. The most characteristic and delicate test for uric acid is the 'murexide test,' which is applied as follows: a few drops of strong nitric acid is added to the uric acid or urate and the solution evaporated to dryness on the water bath, preferably in a porcelain basin, a yellowish red residue of alloxantin is obtained which acquires the rich purple colour of ammonium purpurate (*murexide, q.v.*) on moistening with ammonia, the colour changing to blue on the addition of sodium hydroxide. The nitric acid employed in the test may be replaced by chlorine or bromine water, or by a few drops of concentrated hydrochloric acid and a small crystal of potassium chlorate. Other colour reactions of uric acid are described by (1) Denigès (J. Pharm. Chim. 1888, [v.] 18, 161), the uric acid is oxidised to alloxan by evaporating a solution in dilute nitric acid; on adding successively to the residue a few drops of concentrated sulphuric acid and of benzene containing thiophen, a bluish coloration is obtained; (2) Ganassini (Boll. chim. farm. 1908, 47, 715), the uric acid or urate is suspended in water and dissolved in 10 p.c. sodium hydroxide; subsequent saturation of the solution with potassium persulphate and the gradual addition of 10 p.c. zinc sulphate solution, until the precipitate formed no longer redissolves, causes the precipitate to assume a bluish-green colour. This test is not disturbed by the presence of proteins, other purines or pyrimidines, and may be applied for the detection of uric acid in urine or in blood. According to Vitali (*ibid.* 1911, 50, 799), sodium peroxide is the only oxidising agent that can replace the potassium persulphate in the above test, and no other metallic salt can be used instead of the zinc salt. (3) Folin and Denis (J. Biol. Chem. 1912, 12, 239), a blue coloration is developed when a solution containing 1 mg. of uric acid is mixed with 2 c.c. of a solution prepared by boiling for two hours a mixture of 100 grms. sodium tungstate, 80 c.c. of 85 p.c. phosphoric acid, and 750 grms. of water, cooling and diluting to a litre (compare Leturc, Ann. Chim. anal. 1907, 12, 194). Tests based upon the reducing properties of uric acid are the formation of a yellow, brown, or black stain of silver, when filter paper previously moistened with silver carbonate is treated with a drop of a solution of uric acid in sodium carbonate; and the reduction of Fehling solution on boiling an alkaline solution of uric acid with excess of the reagent. For the detection of uric acid in blood, Weber (Pharm. Zeit. 1912, 57, 252) recommends the following method: the blood is treated with sodium chloride and potassium phosphate to remove the proteins, the filtrate evaporated to a small bulk and saturated with ammonium chloride, the uric acid is thus precipitated as ammonium urate, which is collected and treated with a few drops of hydrochloric acid and the crystals of uric acid identified under the microscope or by the murexide test.

Estimation. The methods of estimating uric acid in urine are based upon the precipitation of the uric acid in the form of the sparingly soluble ammonium or the double silver magnesium salt, and the subsequent determination of the uric acid in the carefully washed precipitate. Hopkins' method (Proc. Roy. Soc. 1892, 52, 93; J. Path. and Bacteriology, 1893, 1, 451), 30 grms. of ammonium chloride are added to 150 c.c. of the filtered urine previously warmed to 40° to 45°, after about an hour the precipitate of ammonium urate is collected on a small filter, washed with a 10 p.c. solution of ammonium sulphate until free from chlorine, and transferred to a beaker by means of a jet of hot water, the solution cooled and diluted with water to 100 c.c., 20 c.c. of pure concentrated sulphuric acid are added, and N/20 potassium permanganate run into the acid liquid at 60° until it acquires a pink tint permanent for some seconds and not changed by stirring. Each c.c. of N/20 permanganate solution decolorised represents 0·00375 grm. of uric acid.

Wörner (Zeitsch. physiol. Chem. 1900, 29, 70) recommends decomposing the washed ammonium urate with 1–2 p.c. sodium hydroxide solution, heating the solution on the water-bath until it ceases to evolve ammonia and then determining the nitrogen in the residue by the Kjeldahl method; 1 c.c. N/10 sulphuric acid corresponds with 0·0042 grm. uric acid.

Folin and Shaffer's modification of Hopkins' method (Zeitsch. physiol. Chem. 1901, 32, 552) is as follows: A solution containing 500 grms. of ammonium sulphate, 5 grms. uranium acetate, and 10 p.c. acetic acid, 60 c.c. per litre is prepared, and 75 c.c. of this solution are mixed with 300 c.c. of the urine, kept for five minutes, passed through a double filter and two quantities of 125 c.c. each collected. Five c.c. of concentrated ammonia are added to each and after about 12 hours the precipitates of ammonium urate are collected and washed and the uric acid in each estimated by the permanganate method. The addition of uranium acetate is made in order to precipitate a small quantity of protein material which is otherwise thrown down on the addition of the ammonia, and which reduces permanganate.

Salkowski's method modified by Ludwig (Chem. Zentr. 1891, 390) consists in precipitating the uric acid in the urine (100 to 200 c.c.) with a mixture of ammoniacal silver solution and magnesia mixture; the precipitate containing all the uric and phosphoric acids is filtered and washed with very dilute ammonia. It is then decomposed by a warm dilute solution of potassium sulphide forming potassium urate which passes into solution, the filtrate is acidified with hydrochloric acid, evaporated to a small bulk, and the uric acid that separates on cooling is collected on a tared filter, washed with water, alcohol, ether, carbon disulphide, and again with ether, dried at 110° and weighed.

Folin and Shaffer (Zeitsch. physiol. Chem. 1901, 32, 552) recommend the following modification of the method in order to facilitate the removal of the silver from the silver magnesium urate: the double salt is decomposed by sulphuretted hydrogen in an acid solution containing 5 to 10 c.c. of 1 p.c. copper sulphate solution and the liquid boiled for a few minutes before filtering.

Derivatives. *Salts.* Uric acid behaves as a feeble dibasic acid and forms three series of salts, the *normal* urates of the type

$$Na_2C_5H_2O_3N_4$$

are readily soluble in water and are never found in the animal system; the *acid* or *diurates* $NaC_5H_3O_3N_4$ are sparingly soluble and occur pathologically in gouty concretions; and the *quadri-* or *hemi-urates*

$$NaC_5H_3O_3N_4,C_5H_4O_3N_4$$

are more readily soluble than the diurates and are the common form in which uric acid occurs physiologically.

Normal urates may be obtained by dissolving uric acid in the theoretical quantity of alkali. They are alkaline in reaction and are decomposed by carbon dioxide, forming the acid salt. The *potassium* salt $K_2C_5H_2O_3N_4$ is crystalline; it dissolves with partial decomposition into the acid salt in about 36 parts of cold water; the *sodium* salt $Na_2C_5H_2O_3N_4,H_2O$ is less soluble than the potassium salt; the *calcium*

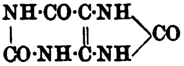
$$CaC_5H_2O_3N_4,$$

strontium $SrC_5H_2O_3N_4,2H_2O$, *barium*

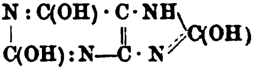
$$BaC_5H_2O_3N_4,H_2O,$$

and *lead* $PbC_5H_2O_3N_4$ salts are sparingly soluble. The *mercury* salt $C_5H_2O_3N_4Hg$ is a white amorphous precipitate; it does not give mercuric oxide with sodium hydroxide solution and is therefore probably a lactam salt (Auld, Chem. Soc. Trans. 1907, 1046).

Acid or *di-urates.* According to Gudzent (Zeitsch. physiol. Chem. 1909, 60, 38), uric acid forms two series of primary metallic salts (mono-sodium, potassium and ammonium urates), which differ as regards solubility. The salts of the *a*-series cannot be obtained pure, as at the moment of formation in water they tend to pass into the salts of the *b*-series. The probable cause of the change is an intramolecular rearrangement, so that the two series correspond with the two tautomeric forms of uric acid



Lactam



Lactim

The unstable *a*-salts are probably the *lactam* urates, and the stable *b*-salts the *lactim* urates. The *a*-salts have solubilities and specific conductivities that at 18° are some 33·4 p.c., or at 37° some 33·9 p.c. greater than the corresponding values for the more stable *b*-salts.

The *sodium* salt $NaC_5H_3O_3N_4,1\frac{1}{2}H_2O$ forms a crystalline powder soluble in 1200 parts of cold or 120 parts of boiling water, forming a neutral solution; the *potassium* salt

$$KC_5H_3O_3N_4$$

is amorphous and dissolves in 800 parts of cold or 70–80 parts of boiling water; *lithium* salt $LiC_5H_3O_3N_4$ forms crystalline grains and is soluble in 370 parts of cold or 39 parts of boiling water; the *ammonium* salt $NH_4C_5H_3O_3N_4$ is soluble in 1500 parts of cold water and quite insoluble in saturated solutions of ammonium chloride or sulphate; and the *magnesium* $(C_5H_2O_3N_4)_2 2Mg,6H_2O$, *calcium*

$$(C_5H_2O_3N_4)_2Ca,2H_2O,$$

strontium $(C_5H_2O_3N_4)_2Sr,2H_2O$, *barium*

$$(C_5H_2O_3N_4)_2Ba,3H_2O,$$

and *lead* $(C_5H_2O_3N_4)_2Pb$ salts are described.

The *quadri-urates* are difficult to obtain pure as they readily break down into diurates and uric acid; according to Rosenheim (Zeitsch. physiol. Chem. 1911, 71, 272) and Kohler (*ibid.* 70, 360) the quadriurates are only mixtures, in molecular proportions, of primary urates and uric acid; they are stated to exist normally in the urine and constitute the whole of the urinary excretion of birds and reptiles (*v.* URINE).

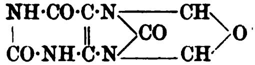
Adrenaline urate $C_9H_{13}O_3N{\cdot}C_5H_4O_3N_4$ forms small pointed plates (Pauly, Ber. 1904, 37, 1388). *Piperazine urate* $C_4H_{10}N_2,C_5H_4O_3N_4$ is soluble in 50 parts of water at 17°.

Uric acid forms the following condensation products with formaldehyde:—

Diformaldehyde-uric acid $C_5H_4N_4O_3,2CH_2O$ is a crystalline, sparingly soluble compound, monobasic towards N/3 sodium hydroxide and forms a *barium* and a *calcium* salt (Weber, Pott and Pollens, Ber. 1897, 30, 2514; Annalen, 1898, 299, 340). *Formaldehyde uric acid*

$$C_5H_4O_3N_4,CH_2O$$

crystallises in needles or prisms, decomposes at 37°, and forms crystalline alkali salts; and *anhydroformaldehyde-uric acid*



formed by dissolving diformaldehyde-uric acid in concentrated sulphuric acid and pouring the solution into ice water (Nicolaier, Chem. Zentr. 1907, i. 949). M. A. W.

ψ-URIC ACID *v.* PYRIMIDINES.

URIDINE *v.* PYRIMIDINES.

URINE. The kidneys are compound tubular glands, and possess the power of excreting from the blood certain waste products which in aqueous solution constitute the urine. Its most important constituents are the result of the breakdown of nitrogenous materials in the body, but these substances, urea, uric acid, &c., are not actually formed in the kidneys themselves. The liver is the most important organ for their actual formation; the kidney is merely the situation where they find an exit from the body.

The characters of the urine differ greatly in different parts of the animal kingdom, according to the character of the food ingested, and the different metabolic habits of animals. The most striking difference is seen when one compares the liquid urine of mammals (in which urea is the main substance in solution) and the semi-solid urine of birds and snakes, in which urates form the preponderant constituents. In the following account attention will be in the main directed to the urine which is most familiar, namely that of man and other mammals.

A man of average weight and height, taking a normal mixed diet, passes from 1400 to 1600 c.c. (about 50 oz.) daily, and this contains about 50 grms. (1¾ oz.) of solids. Its yellow colour varies considerably with the concentration of the urine, and is due to the presence of a number of pigments, of which *urochrome* (an amorphous nitrogenous substance of doubtful composition, originally so named by Thudichum) is the most abundant. Another named *urobilin*, a derivative of the bile pigment, is present in health in small quantities, but may be considerably increased in certain diseases.

The reaction of urine is acid; this is partly due to free acid, but mainly to acid salts, of which acid sodium phosphate is the most abundant. During digestion, however, there is a formation of free hydrochloric acid in the stomach, and a corresponding liberation of bases in the blood causes the urine to be less acid, or even alkaline. Alkaline urine is also seen in herbivorous animals and vegetarians; here the food contains excess of alkaline salts of acids such as tartaric, citric, malic, &c. These acids in the body are oxidised into carbonates which, passing into the urine, give it an alkaline reaction.

The specific gravity varies inversely as the quantity of urine passed; the quantity depends on the amount of water ingested, and also on the amount of water that leaves the body by other channels, such as the skin. It varies normally from 1·015 to 1·025. A sp.gr. below 1·010 should excite suspicion of hydruria; one over 1·030 of a febrile condition, or of diabetes, in which disease it may rise to 1·050. The sp.gr. has, however, been known to sink as low as 1·002 (after large potations, *urina potus*), or to rise as high as 1·035 (after great sweating) in perfectly healthy people.

The following table gives the average amounts of the urinary constituents passed by a man taking an ordinary diet containing about 100 grams. of protein in the 24 hours—

Total quantity of urine	1500	grms.
Water	1400	„
Solids	60	„
Urea	35	„
Creatinine	0·9	„
Uric acid	0·75	„
Hippuric acid	1·0	„
Ammonia	0·65	„
Sodium chloride	16·5	„
Phosphoric acid	3·5	„
Sulphuric acid	2·0	„
Chlorine	11·0	„
Potassium	2·5	„
Sodium	5·5	„
Calcium	0·26	„
Magnesium	0·21	„

The most abundant constituents are, therefore, water, urea, and sodium chloride. We will take the most important individual constituents one by one.

Urea or **carbamide** $CO(NH_2)_2$ is isomeric with ammonium cyanate, from which it was first prepared synthetically in 1828 by Wöhler. Wöhler's observation derives interest from the fact that this was one of the first organic substances prepared synthetically by chemists.

It crystallises in the dimetric system, and is readily soluble in water and in alcohol; it has a faint saltish taste, and is neutral to litmus. When treated with nitric acid, octahedra, or lozenge-shaped tablets are formed of urea nitrate $(CON_2H_4{\cdot}HNO_3)$; when treated with oxalic acid prismatic crystals of urea oxalate

$$[CO(NH_2)_2]_2{\cdot}C_2H_2O_4$$

are formed.

Under the influence of certain micro-organisms which grow readily in stale urine, it is converted into ammonium carbonate

$$[CON_2H_4+2H_2O=(NH_4)_2CO_3].$$

Hence the ammoniacal odour of putrid urine. In the soil the urinary ammonia is converted into nitrates by nitrifying organisms (*see* SOILS).

By means of nitrous acid, urea is broken up, as shown in the following equation

$$CON_2H_4+2HNO_2=CO_2+3H_2O+2N_2.$$

Sodium hypobromite decomposes urea as follows

$$CON_2H_4+3NaBrO=CO_2+N_2+2H_2O+3NaBr.$$

This reaction is important, for on it one of the readiest methods for estimating urea depends. If the hypobromite is mixed with excess of sodium hydroxide, the carbon dioxide is absorbed, and nitrogen is the only gas evolved; this is collected in a suitable measuring tube, and from its amount, the quantity of urea is easily calculated.

More accurate determinations may, however, be made by the methods of Mörner and Sjöquist, or of Folin (*v.* UREA). The former consists in treating the urine with a mixture of barium chloride, barium hydroxide, ether, and alcohol; all nitrogenous substances, except urea, are thus precipitated, and the nitrogen in the filtrate and washings is estimated by Kjeldahl's method. The latter method (Folin's) depends on the fact that urea is decomposed into ammonia and carbon dioxide by boiling with magnesium chloride in the presence of hydrochloric acid. The ammonia is estimated by distilling it into standard acid and subsequent titration. From the total ammonia so found, that preformed has to be deducted, and this amount is ascertained in another specimen of the same urine.

The quantity of urea is practically uninfluenced by muscular work, but depends mainly on the amount of protein ingested. The amino acid fragments formed by the digestion of protein are utilised in two ways. A small portion is used by the tissue cells to repair their waste. In time this will be catabolised and the waste products discharged as urea, ammonia, creatinine, &c. The amount of such *endogenous* metabolism is constant. The other and larger part of the cleavage products of the food protein are deamidised and converted into urea by the liver, the non-nitrogenous fatty residue being burnt, and so utilised as a source of heat and other forms of energy. This part of metabolism is termed *exogenous*. Urea excretion is usually at a maximum about 3 hours after a meal. The conversion of amino acids into urea is, in part at any rate, due to enzymic action; *e.g.* arginase is an enzyme which converts arginine (one of the more complex amino acids resulting from protein disintegration) quantitatively into urea and ornithine (di-amino-valeric acid). There is also no doubt that ammonia is an important intermediate between such amino acids as glycine (amino-acetic acid), leucine (amino-caproic acid), &c., and the final product urea. Ammonia so liberated unites with the carbon dioxide of the blood, and ammonium carbonate and carbamate are thus formed. The close relationship of these two salts to urea is apparent from their formulæ—

$$O=C<\begin{matrix}O{\cdot}NH_4\\O{\cdot}NH_4\end{matrix}$$

Ammonium carbonate.

$$O=C<\begin{matrix}NH_2\\O{\cdot}NH_4\end{matrix}$$

Ammonium carbamate.

$$O=C<\begin{matrix}NH_2\\NH_2\end{matrix}$$

Urea or carbamide.

A small quantity of ammonia always slips through into the urine, because a small quantity of the ammonia-containing blood passes through the kidney before reaching the organ (the liver), which is capable of converting it into urea. Acids are very toxic to the body, and the defence of the body against acids (administered as such, or produced in pathological metabolism, *e.g.* fatty acids in diabetes) is an increase of ammonia formation, or to put it more correctly, less of the ammonia formed is converted into urea.

Creatine and *creatinine*. Creatine is an abundant constituent of muscular tissue; *in vitro* by boiling it with baryta it takes up water and splits up into urea and methyl-glycine, as shown in the following equation—

$$C_4H_9N_3O_2+H_2O=CON_2H_4+CH(CH_3)NH_2{\cdot}COOH.$$

Creatine, however, is absent from normal urine, and only occurs in starvation and in other conditions, in which there is a rapid loss of muscular tissue. Its normal fate in the body is unknown, since creatine injected into the circulation leaves the body in the urine unchanged, and leads to no increase of urea.

It also is not converted into creatinine, which was formerly held to be its fate. Here, again, we have an instance of reactions, which occur *in vitro*, but not *in vivo*. Creatinine is a crystalline, strongly basic substance, which chemically is creatine *minus* a molecule of water. It is always present in the urine, and next to urea, is its most abundant nitrogenous constituent. Mellanby believes that certain products of protein catabolism, the nature of which is uncertain, are carried to the liver, and from these the liver forms creatinine; this is transported to the muscles, and there stored as creatine, excess being then eliminated in the urine. The small amount of creatinine excreted in liver disease favours the view that the liver is the great agent in its production, as it is in that of urea and uric acid. In health the amount of creatinine is very constant, and is not influenced by diet or muscular exercise.

Uric acid ($C_5H_4N_4O_3$) is excreted as urates in mammals in small quantities only, but in birds and serpents is the principal nitrogenous constituent of their urine. It can be readily prepared from the latter urine, in which it is mainly present as the acid ammonium urate, by dissolving it in sodium hydroxide and precipitating with hydrochloric acid. It crystallises in rectangular plates and prisms. It requires for its solution 1900 parts of hot, and 15,000 parts of cold, water. On oxidation it yields urea and oxalic acid, alloxan ($C_4H_2N_2O_4$) or allantoin ($C_4H_6N_4O_3$), being intermediate products, according to the oxidising agent employed. It can be best identified by the *murexide* reaction, which consists in evaporating to dryness with nitric acid; the yellowish-red residue gives, on the addition of ammonia, the violet ammonium purpurate.

Uric acid is dibasic, and forms two classes of salts, which may be exemplified by the acid sodium urate ($C_5H_3NaN_4O_3$) and the normal sodium urate ($C_5H_2Na_2N_4O_3$). The first-named of these salts is the chief constituent of the urate deposit which often occurs in concentrated urine.

If uric acid is represented by H_2U, the normal urates may be written M_2U, and the acid urates MHU. Bence-Jones, and later Sir W. Roberts, considered that the urates actually occurring in the urine are quadriurates

$$MHU{\cdot}H_2U.$$

There is no doubt that such compounds do not actually exist. It has been suggested that the mixture of urate and uric acid is of the nature of "solid solution." Uric acid is best estimated by Hopkins' method, which briefly consists in saturating the urine with an ammonium salt; ammonium urate thus precipitated is dissolved in alkali and titrated with standard potassium permanganate until a diffused pink-blush appears throughout the solution.

In birds uric acid originates from the combination of ammonia and lactic acid. In mammals it mainly arises from the purine bases of the food, or which are cleavage products of nucleic acid, the main constituent of the nuclei of the body cells. In this process several tissue enzymes come into play; first nuclease liberates adenine (amino-purine $C_5H_3N_4{\cdot}NH_2$) and guanine (amino-oxypurine $C_5H_3N_4O{\cdot}NH_2$) from nucleic acid; then 'deamidising' enzymes convert adenine into hypoxanthine (monoxypurine $C_5H_4N_4O$) and guanine into xanthine (dioxypurine $C_5H_4N_4O_2$); oxidases step in next and convert hypoxanthine into xanthine, and xanthine into uric acid (trioxypurine $C_5H_4N_4O_3$). The liver is the principal seat of these transformations, and in some animals some of the uric acid so formed is destroyed in the same organ, and appears as allantoin and urea. So far as tissue extracts can give a true picture of metabolism *in vivo* the human tissues are destitute of the uricolytic (uric acid destroying) enzyme.

Small quantities of purine bases are found in the urine in addition to uric acid.

Hippuric acid ($C_9H_9NO_3$) in the form of hippurates is present in small quantities in the urine of man, but is specially characteristic of herbivorous urine. This is due to the food of herbivora containing substances of the benzoic acid group. The condensation of benzoic acid with glycine to form hippuric acid appears to occur in the kidney itself, and may be represented by the following equation—

$$\underset{\text{Benzoic acid.}}{C_6H_5{\cdot}COOH} + \underset{\text{Glycine.}}{CH_2(NH_2)COOH}$$

$$= \underset{\text{Hippuric acid.}}{CH_2(NH{\cdot}CO{\cdot}C_6H_5)COOH} + H_2O.$$

Kynurenic and **urocanic acids** are present in small quantities in dog's urine. Kynurenic acid $C_{10}H_7NO_3$ is hydroxyquinoline-carboxylic acid ($HO{\cdot}C_9H_5N{\cdot}COOH$) and originates from one of the decomposition products of protein called tryptophan (indole-amino-propionic acid). Urocanic acid ($C_{12}H_{12}N_4O_4$) is a rarer constituent, and its origin in the body is not clear.

Inorganic constituents of urine. The principal salt is *sodium chloride*, and its amount varies with that in the food. The *sulphates* present are principally those of sodium and potassium. They are derived from the metabolism of protein, and their excretion, although it occurs earlier than that of urea, runs parallel with it. About one-tenth of the total sulphates are ethereal sulphates, such as potassium phenyl sulphate and potassium indoxyl sulphate (urinary indican); the organic radicles originate from protein putrefaction in the alimentary canal, and abnormally great putrefactive processes there lead to an increase in the excretion of such sulphates. Sulphur is also present in the form of less highly oxidised organic compounds, usually spoken of as 'neutral sulphur,' a term which includes thiocyanic acid and its salts, taurine, cystine, methyl mercaptan. A number of other substances also are present in minute quantities.

Carbonates are only present in alkaline urine. Alkaline and earthy *phosphates* are also present and small quantities of organic phosphates, for instance, glycero-phosphates. They arise partly from the food, but chiefly from the metabolism of organic phosphorised constituents of the body, such as nucleic acid, lecithin, and other phosphorised fats (phosphatides).

Abnormal constituents of urine. The most commonly occurring of these are albumin (in Bright's disease) and other proteins, dextrose, acetone, aceto-acetic acid, and β-hydroxybutyric acid in diabetes, lactose in nursing mothers, bile in jaundice, blood when hæmorrhage occurs in any part of the urinary tract, hæmoglobin, and certain derivatives of hæmoglobin in black water fever and other pathological states, and pus as the result of suppuration in any part of the urinary tract.

Urinary deposits. Normal urine is clear except for a faint cloud of mucus. Formed or anatomical elements such as blood corpuscles, pus corpuscles, bacteria, entozoa, &c., may be present in various pathological conditions, and are identified by microscopic examination. A special chemical interest attaches, however, to crystalline deposits, and without entering into any discussion of the medical reasons that lead to their appearance, these may be briefly enumerated as follows:—

A. In acid urine, may be found—

1. Uric acid, as whetstone, dumb-bell, or sheaf-like aggregations of crystals deeply tinged with urinary pigment, looking like cayenne pepper.

2. Urates. These are generally amorphous. The acid urate of sodium and ammonium may sometimes occur in star-shaped clusters of needles or spheroidal clumps with projecting spines. The deposit has the appearance of brick-dust, as it is coloured by one of the urinary pigments (uroerythrin). This deposit dissolves on warming the urine.

3. Calcium oxalate in the form of octahedral crystals insoluble in acid.

4. Cystine (diamino-dithio-lactic acid

$$C_6H_{12}N_2S_2O_4)$$

in colourless hexagons; a rare condition often hereditary.

5. Calcium phosphate $CaHPO_4,2H_2O$, rare.

6. Leucine (*amino-caproic acid*) and tyrosine βp-*hydroxyphenyl-a-aminopropionic acid*), rare.

B. In alkaline urine we may find—

1. Phosphates; calcium phosphate

$$Ca_3(PO_4)_2,$$

which is amorphous, triple phosphate

$$MgNH_4PO_4,6H_2O$$

in 'coffin lid' crystals or feathery stars, calcium hydrogen phosphate $CaHPO_4$ in rosettes, spherules, or dumb-bells; magnesium phosphate $Mg_3(PO_4)_2$ in long plates. All are soluble in acetic acid without effervescence.

2. Calcium carbonate $CaCO_3$, biscuit-shaped crystals, common in herbivorous urine, soluble in acetic acid with effervescence.

3. Ammonium urate $C_5H_2(NH_4)_2N_4O_3$ 'thorn apple' spherules.

4. Leucine and tyrosine, very rare.

Of these deposits, urates in acid urine, and phosphates in alkaline urine are the commonest; these are not necessarily pathological; thus urates may form in the urine when it cools, especially if that secretion is concentrated, *e.g.* after sweating profusely. Urine, when it becomes alkaline, always deposits phosphates, and the alkaline urine of herbivora is always thick for that reason.

Urinary calculi. Concretions called sand, gravel, and stones, according to their size, may form in the kidney, the ureter, or in the bladder. They result from the conglomeration of urinary deposits, the deposition occurring in concentric layers. The substances deposited in acid urine are most frequently uric acid, urates or calcium oxalate, or a mixture of these materials; in alkaline urine, phosphates. If the reaction of the urine changes during the formation of the calculus alternate layers of these two sets of materials will be found. The uric acid calculus is generally regarded as the commonest form of stone in the bladder, but in renal calculi, as B. Moore has shown, the most abundant constituent is calcium oxalate, frequently mixed with calcium phosphate, the second constituent in frequency and abundance. Calcium is practically the only base associated with oxalic acid, phosphoric acid, and in less amount with uric acid. All these acids form highly insoluble salts with calcium. Oxalic and uric acids are associated products in metabolism, and occur in cases of incomplete oxidation.

The physical properties of a calculus—colour, hardness, smoothness, or roughness, &c.—give little or no clue to its chemical nature. A chemical analysis is always necessary, and this gives valuable indications for after treatment; for instance, in renal calculi, consisting of calcium oxalate, the treatment should be designed to diminish alkalinity, to avoid calcium-rich foods, and to induce the taking of exercise to promote oxidation in the body.

There are, in addition to these common forms of stone, others of a rarer kind, and a list of the different varieties of calculus is as follows—

1. Those composed of uric acid or urates with little or no admixture with phosphates.
2. Mixed calculi, like the preceding, but containing often in alternate layers a large quantity of phosphate.
3. Calcium oxalate calculi, often containing small quantities of phosphates and urates.
4. Phosphatic calculi: a stone composed of pure calcium phosphate is rare; a nucleus of uric acid is generally present.
5. Calcium carbonate calculi are those generally found in the prostate.
6. Cystine calculi are mostly small, smooth, and have a yellow tinge, turning to green on exposure to air. These are rare.
7. Xanthine calculi are still rarer.
8. Fibrinous calculi composed of fibrin or inspissated albumin, have a glassy appearance on fracture; blood calculi have been described in cases of renal hæmaturia; 'urostealith' calculi have been described, and consist of fatty acid with more or less cholesterol. One case of 'indigo' calculus has been described.

No attempt has been made in the foregoing outline sketch of the chemical properties of the urine in health and disease to give any bibliographical references. The literature of urine is enormous, and those interested in it should consult standard works on physiology, physiological chemistry, pathology, and medicine. One of the most trustworthy handbooks on the urine only, and containing abundant references to literature, is Neubauer and Vogel's Analyse des Harns, edited by Huppert, Wiesbaden, C. W. Kreidel. W. D. H.

UROCITRAL, UROPHENIN, *v.* SYNTHETIC DRUGS.

UROPHERIN *v.* SALICYLIC ACID.

UROTROPIN. *Hexamethylenetetramine,* *v.* SYNTHETIC DRUGS.

UROXAMIC ACID, *dicarbaminomalonic acid* $(CO_2H)_2C(NH{\cdot}CO{\cdot}NH_2)_2$ is prepared by the gradual oxidation of uric acid in alkaline solution by the oxygen of the air (Städeler, Annalen, 1851, 78, 286; Strecker, *ibid.* 1870, 155, 177); by oxidising an alkaline solution of uric acid with 5 p.c. potassium permanganate solution (1 atom of oxygen to 1 mol. of uric acid) (Behrend, *ibid.* 1904, 333, 152; Behrend and Schultz, *ibid.* 1909, 365, 21).

Uroxamic acid crystallises in stout prisms or in tetrahedra; it is sparingly soluble in cold water and insoluble in alcohol; it is a strong dibasic acid and its normal alkali salts are neutral towards litmus and phenolphthalein. It readily loses CO_2 and yields allantoic acid when shaken for several days with cold methyl alcohol. When heated with water it breaks down into allanturic acid

$$CO\begin{cases}NH{\cdot}CH(OH)\\ \qquad\quad | \\ NH{\cdot}CO\end{cases}$$

mesoxalic acid and carbamide. The *aniline* and *hydroxylamine* salts are sparingly soluble; the latter melts at 155°; the normal *phenylhydrazine salt* $C_5H_8O_6N_4{\cdot}2C_6H_8N_2$ crystallises in colourless plates, m.p. 130°–132° (decomp.). when boiled with water it is decomposed, yielding the *phenylhydrazine salt* of *mesoxalic acid phenylhydrazone* $C_{15}H_{16}O_4N_4,\frac{1}{2}H_2O$, this forms yellow needles that melt at 154°–158°, solidify at 160° and then decompose at 183°. The normal *silver*, *sodium*, *potassium*, *barium*, *calcium* and *ammonium* salts of uroxamic acid are crystalline. M. A. W.

URUSHIOL *v.* LACQUER.

USNIC ACID $C_{18}H_{16}O_7$ (Stenhouse, Proc. Roy. Soc. 18, 222), $C_{18}H_{18}O_8$ (Paterno, Ber. 9, 345). An acid found in certain lichens (*v.* LICHENS).

UVAROVITE *v.* GARNET.

UVITONIC ACID *v.* BONE OIL.

V

VAL D'ARNO SUPERIORE RESIN *v.* RESINS.

VALENTINITE. Native antimonious oxide Sb_4O_6, *v.* ANTIMONY.

VALERIAN. The root of *Valeriana officinalis* (Linn.) yields on distillation with water an essential oil of a pale yellow or greenish colour, having a strong smell of valerian, an aromatic taste, and acid reaction; sp.gr. 0·90–0·93. Thickens at −15°, and begins to boil at about 200°. Consists of a mixture of valeric acid, a camphene, a stearoptene, and a resin (Pierlot, Ann. Chim. Phys. [iii.] 56, 291; Gerhardt, *ibid.* [iii.] 7, 275).

VALERIC or **PENTOIC ACIDS** C_4H_9COOH. Four isomerides are known.

1. *Valeric acid* $CH_3[CH_2]_3COOH$, is found in pyroligneous acid, and occurs free and as esters in the animal and vegetable kingdoms, chiefly in the roots of *Valeriana officinalis* (Linn.) and of *Archangelica officinalis* (Hoffm.), from which it may be isolated by boiling with water or sodium hydroxide. It may be obtained by boiling *n*-butyl cyanide with potash (Lieben and Rossi, Annalen, 159, 58); by oxidation of α-hydroxycaproic acid (Erlenmeyer, Ber. 1876, 1840); by reduction of lævulic acid (β-acetylpropionic acid) with phosphorus iodide or sodium amalgam (Kehrer and Tollens, Annalen, 206, 233; Fittig and Wolff, *ibid.* 208, 109); by heating propylmalonic acid (Juslin, Ber. 1885, 2504); or by the fermentation of calcium lactate (Fitz, *ibid.* 1880, 1309). A colourless oil having a disagreeable smell, b.p. 186°–186·4° (Fürth, Monatsh. 9, 310); sp.gr. 0·9415 at 20°/4° (Lieben and Rossi); 1 vol. of acid dissolves in 27 vols. of water at 16°.

Methyl valerate boils at 127·3°, and *ethyl valerate* at 144·6° (736·5 mm.).

2. iso*Valeric acid, β-methylbutyric acid*

$CH(CH_3)_2CH_2COOH$.

Discovered in 1817 by Chevreul in dolphin oil from *Delphinus globiceps* and *D. phocæna*, and termed by him *phocenic acid.* Found in other fish oils and in perspiration. In the roots of *Valeriana officinalis* (Linn.), *Archangelica officinalis* (Hoffm.), and in the berries of *Viburnum Opulus* (Linn.). Formed in the putrefaction of albuminoids; by the oxidation of glue, oleic acid, fats, and fusel oil (Lawkrow and Jazukowitsch. J. 1864, 337; Pierre and Pouchet, Ann. Chim. Phys. [iv.] 29, 229). Prepared by the action of alcoholic potash on *iso*propyl cyanide, and by long boiling of amyl alcohol with sodium methoxide (Guerbet, Compt. rend. 128, 512). Colourless oily liquid, smelling like valerian root and putrid cheese; b.p. 173·7° (Kahlbaum, Ber. 1883, 2480), sp.gr. 0·931 at 20°. Soluble in 23·6 parts of water at 20°. The valeric acid of pharmacy is prepared from valerian root or from amyl alcohol. The ammonium and zinc valerates are also used in medicine.

For quantitative estimation of *iso*valeric acid in the presence of acetic acid, *v.* Chapman, Annalen, 1899, 114.

Methyl iso*valerate* boils at 116·7°, and *Ethyl* iso*valerate* at 134·3°.

iso*Amyl* iso*valerate* $C_5H_{11}O(C_5H_9O)$; b.p. 194°; dissolved in spirits of wine is used in confectionery as *essence of apples.*

3. *α-Methylbutyric acid* $CH_3{\cdot}CH(C_2H_5)COOH$ is found in the oil of *Archangelica officinalis* (Hoffm.) (Ciamician and Silber, Ber. 1896, 1815), and may be obtained by heating methyl crotonic acid (tiglic acid) with hydriodic acid (Schmidt and Berendes, Annalen, 191, 117); by the action of sodium amalgam on bromomethyl ethyl acetic acid in a sulphuric acid solution (Pagenstecher, *ibid.* 195, 109); and by heating methyl ethyl malonic acid (Conrad and Bischoff, *ibid.* 204, 151). On oxidising optically active amyl alcohol, a mixture of *iso*valeric and α-methylbutyric acids is obtained which can be separated by converting them into their silver salts, silver *iso*valerate being six times less soluble in water than silver α-methylbutyrate (Erlenmeyer and Hell, Annalen, 160, 301; Conrad and Bischoff, *ibid.* 204, 157). A colourless somewhat mobile liquid; b.p. 173°–174°, sp.gr. 0·938 at 20°/20° (Schütz and Marckwald, Ber. 1896, 26).

4. *αα-Dimethylpropionic acid* $(CH_3)_3C{\cdot}COOH$. Obtained by heating trimethyl acetonitrile with strong hydrochloric acid (Butlerow, Annalen, 170, 151; 173, 355); or by the oxidation of pinacolin (Butlerow, *l.c.*; Friedel and Silva, Ber. 6, 146, and 816). Crystallises in the regular system; m.p. 34°–35°, b.p. 163° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 475), sp.gr. 0·905 at 50°; soluble in 45 parts of water at 20°.

VALERYDIN, VALIDOL, VALISAN, VALYL, *v.* SYNTHETIC DRUGS.

VALINE was the name given by Fischer (Ber. 1906, 29, 2320) to *α-amino*iso*valeric acid* $CHMe_2{\cdot}CH(NH_2)COOH$. It was isolated first by Gorup-Besanez (Annalen, 1856, 98, 1) from the pancreas of the ox, and occurs in the young seedlings of *Lupinus luteus* (L.), *Lupinus albus* (L.), *Lupinus angustifolius* (L.), *Vicia sativa* (L.), the etiolated seedlings containing more than the green plants (Schulze and Barbieri, J. pr. Chem. 1883, [i.] 27, 337; Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 308; Schulze, *ibid.* 1894, 20, 306; 1896, 22, 423; Schulze and Castoro, *ibid.* 1903, 38, 199; Wassilieff, Landw. Versuchsstat. 1901, 55, 45; Schulze, Zeitsch. physiol. Chem. 1893, 17, 193; Menozzi, Ber. 1888, 21, 619); it has been found also in Emmenthaler cheese (Winterstein, Zeitsch. physiol. Chem. 1904, 41, 500). Valine is one of the products of hydrolysis of a large number of proteins, such as horn, keratin, edestin, etc., and occurs together with leucine and proline in the fraction of esters, b.p. 60°–90°/10 mm.; it is formed during the process of autolysis of the pancreas and liver, and in peptic and tryptic digestion (Fischer and Dörpinghaus, *ibid.* 1902, 36, 462; Abderhalden and Voitinovici, *ibid.* 1907, 52, 348; Levene and van Slyke, J. Biol. Chem. 1909, 6, 419; Levene, Zeitsch. physiol. Chem. 1904, 41, 393; Lawrow, *ibid.* 1901, 33, 312). The valine occurring naturally is the dextrorotatory form; the racemic form was prepared first synthetically by Fittig and

Clark (Annalen, 1866, 139, 200) by the action of concentrated ammonia on α-bromo*iso*valeric acid at 100°; and later by Lipp (*ibid.* 1880, 205, 1) by hydrolysing the amino*iso*valeronitrile obtained by the condensation of *iso*butaldehyde with ammonia and hydrocyanic acid. It is prepared most conveniently, and the yield is 70 p.c. of the theoretical, by Slimmer's modification of Fittig and Clark's method (Ber. 1902, 35, 400); 500 grms. of α-bromo*iso*valeric acid with 1590 grms. of aqueous ammonia saturated at 15° and 500 grms. of powdered ammonium carbonate are heated in an autoclave at 100° for eight hours; the resulting brownish liquid is filtered and evaporated to one-third its bulk, when most of the amino acid crystallises out. The rest is obtained in the form of its hydrochloride by acidifying the mother liquor with hydrochloric acid, evaporating to dryness and extracting the residue with 80 p.c. alcohol.

Racemic valine can be resolved into its optically active isomerides by the fractional crystallisation of the brucine salt of the formyl derivative; the brucine salt of formyl-*l*-valine being less readily soluble in methyl alcohol than is the corresponding salt of formyl-*d*-valine: *d*-valine and *l*-valine are obtained by hydrolysing with hydrobromic acid the corresponding formyl derivatives (Fischer, Matsubara and Hilpert, Ber. 1906, 39, 2320).

***d,l*-Valine.** In addition to the synthetic methods already described for the preparation of *d,l*-valine, it can be obtained by racemising the active acids by heating them with baryta water at 180° (Fischer, Zeitsch. physiol. Chem. 1911, 33, 162).

d,l-Valine crystallises in colourless plates from alcohol, has a sweet taste, and melts in a closed tube at 298° (corr.) with decomposition; it is readily soluble in water, 1 part dissolving in 11·7 parts of water at 15°, is almost insoluble in cold alcohol or ether, sparingly so in boiling alcohol (Slimmer, *l.c.*); when oxidised by hydrogen peroxide it yields *iso*butaldehyde, *iso*butyric acid (part of which is further oxidised to acetone and carbon dioxide), ammonia and carbon dioxide; with lead peroxide or sodium hypochlorite as the oxidising agent, *iso*butaldehyde is the product (Dakin, J. Biol. Chem. 1908, 4, 63; Langheld, Ber. 1909, 42, 2360). When *dl*-valine undergoes putrefactive decomposition it yields *iso*valeric acid and a small quantity of butylamine; the residual aminovaleric acid is laevorotatory indicating an asymmetric attack by the bacteria (Neuberg and Karczag, Biochem. Zeitsch. 1908, 18, 435).

Salts and derivatives of d,l-*Valine.* The *copper salt* $(C_5H_{10}O_2N)_2Cu$, blue crystals soluble in 3644 parts of methyl alcohol at 20°, or in 9230 parts of 96 p.c. ethyl alcohol at 21°, and sparingly soluble in cold water (Ehrlich and Wendel, Biochem. Zeitsch. 1908, 8, 399); the *silver sal* $C_5H_{10}NO_2Ag$ is crystalline and insoluble in cold water; the *hydrochloride*

$$C_5H_{11}O_2N,HCl,$$

crystalline plates, readily soluble in water or in alcohol, insoluble in ether; the *nitrate*

$$C_5H_{11}O_2N,HNO_3$$

is a readily soluble crystalline mass. The *ethyl ester* $CHMe_2{\cdot}CH(NH_2)CO_2Et$ has b.p. 3·5°/8 mm. or 174° with decomposition under atmospheric pressure, sp.gr. 0·9617 at 15°/4°; it forms a sparingly soluble crystalline *picrate*, m.p. 139·5° (corr.), and a soluble *hydrogen* tartrate which on crystallisation suffers partial resolution into its optically active isomerides (Slimmer, *l.c.*). Of the *acyl* derivatives of *d,l*-valine, the *formyl* derivative

$$CHMe_2{\cdot}CH(COOH)NH{\cdot}CHO$$

obtained by heating *d,l*-valine with 1½ times its weight of formic acid crystallises in large rhombic plates from water, sinters at 137° and melts at 140°–145° (corr.), is readily soluble in hot water, alcohol or acetone (Fischer, Ber. 1906, 39, 2322); the *benzoyl* derivative

$$CHMe_2{\cdot}CH(CO_2H)NH{\cdot}CO{\cdot}C_6H_5$$

crystallises in plates, m.p. 132·5° (corr.), is readily soluble in alcohol or ether, sparingly so in water (Slimmer, *l.c.*); the *phenylisocyanate* derivative $CHMe_2{\cdot}CH(CO_2H)NH{\cdot}CO{\cdot}NHPh$ forms colourless plates, soluble in 130 parts of hot water, m.p. 163·5° (corr.) with decomposition, is readily soluble in hot alcohol, sparingly so in ether, and is converted into *phenylisopropylhydantoin*  $\mathrm{CO}\Big\langle\begin{array}{l}\mathrm{NH\cdot CHPr^{\beta}}\\ \qquad\quad |\\ \mathrm{NPh\cdot CO}\end{array}$ by boiling with hydrochloric acid; this compound crystallises in long needles from ether, m.p. 124°–125° (corr.), and is sparingly soluble in hot water, readily so in alcohol or ether (Slimmer, *l.c.*); the *carbamino* derivative

$$CHMe_2{\cdot}CH(CO_2H)NH{\cdot}CO{\cdot}NH_2,$$

crystallises in needles, m.p. 176°, is soluble in 213 parts of water at 20°, and forms crystalline *barium, mercury* and *silver* salts (Lippich, Ber. 1908, 41, 2962); the *picryl* derivative

$$CHMe_2{\cdot}CH(CO_2H)NH{\cdot}C_6H_2(NO_2)_3$$

forms bright yellow needles, sparingly soluble in cold water, and has m.p. 171° (Hirayama, Zeitsch. physiol. Chem. 1909, 59, 290). *d,l-Valinamide* $CHMe_2{\cdot}CH(NH_2)CONH_2$, obtained by the action of liquid ammonia on the ester prolonged over a period of three months, crystallises from benzene in colourless prisms, m.p. 78°–80° (corr.), and yields a *β-naphthalenesulphonic derivative* $C_{15}H_{18}O_3N_2S$, m.p. 256°–257° (corr.), a *carbethoxy derivative* $C_8H_{16}O_3N_2$, m.p. 143°–144° (corr.) (Königs and Mylo, Ber. 1908, 41, 4427); and a *hydrochloride*

$$CHMe_2{\cdot}CH(CO{\cdot}NH_2)NH_2{\cdot}HCl$$

crystallising in the monoclinic system, and forming a crystalline *platinochloride*

$$(C_5H_{13}ON_2)_2PtCl_6,H_2O$$

(Lipp, Annalen, 1880, 205, 1). d,l-*Valine anhydride* $C_{10}H_{18}O_2N_2$, obtained by heating *d,l*-valine, or by heating the ethyl ester under pressure at 180°–190°, forms long colourless needles, m.p. 303° (corr.) (Fischer and Schenkel, Annalen, 1907, 354, 1).

***d*-Valine** is most conveniently obtained from the two to three weeks old etiolated seedlings of *Lupinus luteus* and *Lupinus albus*, contamination with leucine, which is very difficult to separate from valine, can be obviated by removing the cotyledons from the young plants before they are dried (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 312). *d*-Valine is prepared from the synthetic compound by the fractional crystallisation of the brucine salts of the formyl derivative (Fischer, Matsubara and Hilpert, Ber. 1906, 29, 2320).

d-Valine crystallises in colourless, shining six-sided plates. It melts in a closed capillary tube at 315° (corr.); when heated in an open tube it sublimes and decomposes partially with formation of the anhydride. It dissolves in 11 parts of water at 16·5°. The taste is first slightly sweet, then bitter (Fischer, Matsubara and Hilpert, *l.c.*). The natural compound obtained from *Lupinus luteus* has $[\alpha]_D^{16}+28{\cdot}2°$ in 20 p.c. hydrochloric acid (0·5 grm. in 10 c.c.); from *Lupinus albus* $[\alpha]_D^{16}+27{\cdot}9$ in 20 p.c. hydrochloric acid (0·5012 grm. in 10 c.c.) (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 299). The synthetic compound prepared by hydrolysing the formyl derivative has $[\alpha]_D^{20}$ $+28{\cdot}75$ in 20 p.c. hydrochloric acid, or $[\alpha]_D^{20}$ $+6{\cdot}42$ in aqueous solution (Fischer, Matsubara and Hilpert, *l.c.*).

Salts and derivatives of d-*valine*. The *copper salt* $(C_5H_{10}O_2N)_2Cu$, blue crystalline plates, soluble in 52 parts of methyl alcohol at 18°. The *hydrochloride* $C_5H_{11}O_2N{\cdot}HCl$, small prismatic crystals readily soluble in water or alcohol, the *platinichloride* is also readily soluble (Schulze and Barbieri, J. pr. Chem. 1883, 27, 337); the *picrolonate* has m.p. 170°–180°, and $[\alpha]_D^{20}+23{\cdot}4$ (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127).

Formyl d-*valine*

$CHMe_2{\cdot}CH(CO_2H){\cdot}NH{\cdot}CHO$

obtained by the resolution of *dl*-formyl valine through the brucine salt, forms small prisms, sinters at 150° and melts at 156° (corr.), and has $[\alpha]_D^{20}+12{\cdot}8°$ to 13·27° in alcoholic solution; d-*valine phenylcarbimide*

$CHMe_2{\cdot}CH(CO_2H)NH{\cdot}CO{\cdot}NHPh$,

forms small microscopic prisms, m.p. 147° (corr.) with decomposition (Fischer, Matsubara and Hilpert, *l.c.*), m.p. 154° (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 303), and yields the d-*phenyl*iso*propylhydantoin*

$C_{12}H_{14}O_2N_2$

on treatment with concentrated hydrochloric acid. This forms colourless thin prisms, m.p. 131°–133° (corr.), and has $[\alpha]_D^{20}-97{\cdot}5°$ in alcoholic solution (Fischer, Matsubara and Hilpert, *l.c.*); m.p. 124° (Schulze and Winterstein, *l.c.*); *chloroacetyl*-d-*valine*

$CH_2Cl{\cdot}CO{\cdot}NH{\cdot}CHPr^{\beta}{\cdot}CO_2H$

has m.p. 113°–115° (corr.) $[\alpha]_D^{20}+15{\cdot}8$; *glycyl*-d-*valine* $NH_2{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}CHPr^{\beta}{\cdot}CO_2H$ has m.p. 254° (corr.), $[\alpha]_D^{20}-19{\cdot}7°$ in aqueous, $-10{\cdot}5°$ in hydrochloric acid or $-6{\cdot}9°$ in sodium hydroxide solution; it forms a crystalline *hydrochloride* and a *copper* salt. The *hydrochloride* of the *methyl ester* $C_8H_{16}O_3N_2{\cdot}HCl$ is converted by methyl alcoholic ammonia into *glycyl*-d-*valinanhydride* $CH_2<\substack{NH{\cdot}CO\\ CO{\cdot}NH}>CHPr^{\beta}$, m.p. 266° (corr.), $[\alpha]_D^{20}+20{\cdot}8°$ in glacial acetic, $+32{\cdot}7°$ in aqueous or $+41°$ in alcoholic solution; l-*valyl*-d-*valine* $C_{10}H_{20}O_3N_2,1\frac{1}{2}H_2O$ becomes anhydrous at 95°/12–15 mm. over phosphoric oxide; has m.p. 308° (corr.), and $[\alpha]_D^{20}-70{\cdot}6°$ to $-74°$; the *hydrochloride* of the *methyl ester* yields on treatment with methyl alcoholic ammonia the *trans-valine-anhydride* $CHPr^{\beta}<\substack{NH{\cdot}CO\\ CO{\cdot}NH}>CHPr^{\beta}$ prisms, m.p. 316°–318° (corr.), which is optically inactive (Fischer and Scheibler, Annalen, 1908, 363, 136).

l-**Valine** is obtained by the resolution of the racemic formyl derivative through the brucine salt (Fischer, Matsubara and Hilpert, *l.c.*); by the action of ammonia on *d*-α-bromo*iso*valeric acid (Fischer and Scheibler, Ber. 1908, 41, 2891); and by the selective action of yeast on *dl*-valine (Ehrlich, Biochem. Zeitsch. 1906, 1, 8; 1908, 8, 438).

l-Valine is soluble in 17·1 parts of water at 25°, possesses a markedly sweet taste, and has $[\alpha]_D^{20}-6{\cdot}06°$ in 6·24 p.c. aqueous solution; $-29{\cdot}04°$ in 20 p.c. hydrochloric acid solution (Fischer, Matsubara and Hilpert, *l.c.*). A specimen obtained from yeast had $[\alpha]_D^{20}-27{\cdot}62°$ in a 4·61 p.c. solution of 20 p.c. hydrochloric acid.

l-*Formylvaline* $CHMe_2{\cdot}CH(CO_2H){\cdot}NH{\cdot}CHO$ crystallises in small prisms, sinters at 150° and melts at 156° (corr.); it has $[\alpha]_D^{20}-12{\cdot}93°$ to 13·07° in alcoholic solution, or $+16{\cdot}9°$ in aqueous solution; l-*valine phenyl*iso*cyanate* $C_{12}H_{16}O_3N_2$ has m.p. 147° (corr.) decomp., and $[\alpha]_D^{20}-19{\cdot}02°$ in absolute alcoholic solution, and yields l-*phenyl*iso*propylhydantoin* $C_{12}H_{14}O_2N_2$ on treatment with hydrochloric acid. It has m.p. 131°–133° (corr.) and $[\alpha]_D^{20}+97{\cdot}22°$ in absolute alcoholic solution. M. A. W.

VALONIA (*Valonée*, Fr.; *Valonea, Ackerdoppen, Orientalische Knoppern*, Ger.). An important tanning material. Is the acorn cup of certain species of oak, usually *Quercus Aegilops* (Linn.), and probably *Q. macrolepsis, Q. graeca, Q. Ungeri*, and *Q. coccifera* (Linn.). The former is most prolific in the highlands of Morea, Roumelia, Greek Archipelago, Asia Minor, and Palestine, whereas the *Q. macrolepsis* forms great forests in Greece. These acorn cups have a diameter up to about 1½ ins., and in good condition possess a bright colour.

The fruit ripens in Asia Minor about July or August, and the trees are then shaken, and the material left on the ground to dry; this is subsequently collected into heaps, and allowed to ferment for some weeks, until the acorn contracts and falls from the cup. The acorn, which contains but little tannin, is employed for feeding purposes.

In Greece distinct qualities of valonia are known, the best (*chamada*) collected about April before the fruit is ripe, a second (*rhabdisto*) in September or October, and a third little used inferior variety (*charcala*).

Smyrna valonia may contain 40 p.c., Greek 19–30, and Candia valonia 41 p.c. of tannin matter, which consists of a mixture of a gallotannin and an ellagitannin. Valonia is, indeed, an excellent source for the preparation of ellagic acid, because it so readily yields a product easy to purify. Extract of valonia frequently undergoes fermentation with deposition of ellagic acid, and to avoid this the employment of antiseptics is to be recommended.

Valonia is especially suited for the manufacture of sole leather, and together with gambier and other materials for dressing leather, but is little employed for dyeing purposes (*cf.* Procter, Principles of Leather Manufacture, 259). A. G. P.

VANADINITE. A mineral consisting of lead chloro-vanadate $(PbCl)Pb_4(VO_4)_3$ crystallised in the hexagonal system and isomorphous with apatite and pyromorphite (*qq.v.*). The formula requires 19·4 p.c. V_2O_5, but this is often partly replaced by phosphoric and arsenic oxides; and the variety *endlichite* forms a passage to the species mimetite (lead chloro-arsenate). The mineral forms small hexagonal prisms usually terminated simply by the basal plane; at times the crystals are curved and barrel-shaped. Globular, warty, and cauliflower-like masses also occur. The colour is usually yellowish or brownish, but crystals from Arizona are bright scarlet. Sp.gr. 6·6–7·2. When touched with a drop of nitric acid a yellow coating of vanadic oxide is formed on the crystals; this affords an easy test for recognising the mineral.

Vanadinite is a mineral of secondary origin in the upper portions of lodes of lead ore, and it sometimes occurs in association with gold. It was formerly found in some quantity at Wanlockhead in Dumfriesshire and near Klagenfurt in Carinthia; and now abundantly in several of the mining districts of Arizona and New Mexico. Recently, it has been met with at Broken Hill in North-Western Rhodesia. Important localities in Arizona are the Red Cloud mine in Yuma Co., the Mammoth gold mine in Pinal Co., the Globe district in Gila Co., and in Pima Co. and Yavapai Co., &c. In New Mexico at the Sierra de los Caballos near Lake Valley in Sierra Co., Magdalena in Socorro Co., Georgetown in Grant Co., &c.

In New Mexico and Arizona the mineral is mined as a source of vanadium. The concentrate containing the vanadinite, together with descloizite, is treated in lead-lined vats with dilute sulphuric acid heated by steam, and the vanadium so obtained in solution as sulphate, the lead remaining in the insoluble residue. The solution is decanted and evaporated, and the vanadium salt ignited to give vanadic oxide. The bulk of this product appears to be used in the manufacture of vanadium-steel, and to a limited extent also as a pigment. Other minerals that have been worked for vanadium are carnotite, descloizite, patronite, and roscoelite (*qq.v.*). L. J. S.

VANADIUM. Sym. V. At.wt. 51·0. This element was discovered by Del Rio (Gilbert's Ann. 1801, 71, 7) in a lead ore, *vanadinite*, from Zimapan in Mexico; the discovery was confirmed by Sefström (Pogg. Ann. 1830, 21, 48), and by Wöhler and Berzelius (*ibid.* 1831, 22, 1; *cf.* Collet-Descotils, Ann. Chim. Phys. 1805, [i.] 53, 260). Upon the work of Berzelius was based the view that vanadium was allied to chromium and molybdenum and, like them, yielded an acidic trioxide, and this idea was current till Roscoe, in 1867, showed that the substance believed to be the metal in earlier investigations had been either an oxide or a nitride, and that the compounds of vanadium in general showed that the elements belonged to the phosphorus group.

Occurrence. Minerals containing a large proportion of vanadium are rare, but the metal is very widely distributed in small quantities. Vanadium occurs as vanadic acid in *vanadinite* with the native copper of Lake Superior, and in *alaite* (Nenadkevitsch, Bull. Acad. Sci. St. Petersbourg, 1909, 185); as lead vanadate, with lead chloride, in *vanadinite*; as lead pyrovanadate as *descloizite*; as hydrated vanadate of lead and copper in *mottramite* and *psittacinite*; as vanadate of copper in *turanite* (Nenadkevitsch, *l.c.*); as lead vanadate containing zinc and manganese in *dechenite*, *aroxene*, and *eusynchite*; as vanadate of lead and arsenic in *endlichite*; as bismuth vanadate in *pucherite*; as the basic oxide V_2O_3 in the vanadium muscovite *roscoelite* (Hillebrand, Turner and Clarke, Amer. J. Sci. 1899. [iv.] 7, 451); as vanadate of copper, barium, and calcium in *volborthite*; and as vanadium sulphide V_2S_5 with sulphur, in *patronite* (Hillebrand, *ibid.* 1907, [iv.] 24, 141; Hewett, Eng. & Min. J. 1906, 82, 385; Trans. Amer. Inst. Min. Eng. 1910, 40).

Vanadium is present in magnetites and in most other iron ores (Pope, Chem. Soc. Abstr. 1900, ii. 409), and becomes concentrated in the residues from their treatment, especially by the Thomas-Gilchrist process. It is said to be diffused, with titanium, through all primitive granite rocks (Dieulafait; Hillebrand, Amer. J. Sci. 1898, 6, 209; 7, 294), and has been found by Deville in *bauxite*, *rutile*, and many other minerals, and by Bechi and others in the ashes of plants and in argillaceous limestones, schists, and sands. Jorissen has found vanadium in the coal of Liége (Bull. Accad. Roy. Belg. 1905. 178). Scacchi has observed its presence in incrustations on the Vesuvian lava of 1631, and Donath has found as much as 0·16 p.c. of vanadic acid in a sample of commercial caustic soda (Dingl. poly. J. 240, 318). It occurs in the sun and has been found in stony meteorites (Hasselberg, Vetensk. Akad. Svenska. 1899, 56, 131).

Extraction.—Ammonium metavanadate was formerly prepared on a commercial scale by the Magnesium Metal Co. at Patricroft near Manchester.

The mineral employed was *mottramite* $(PbCu)_3(VO_4)_2.2PbCu(HO)_2$, which occurs in the copper-bearing Keuper beds at Alderley Edge and Mottram St. Andrew's, in Cheshire, as a film on the grains of standstone. The sand is digested in concentrated hydrochloric acid, and the acid liquid is withdrawn. The solution, with the washings of the residue, is concentrated and evaporated with an excess of ammonium chloride, forming ammonium metavanadate, which, being insoluble in a concentrated solution of ammonium chloride, is precipitated. After being freed from copper and iron by repeated crystallisation, it is gently roasted in a porcelain vessel, with production of vanadium pentoxide. This is suspended in water and subjected to a current of ammonia gas, with formation of ammonium metavanadate, the solution being separated from the silica, phosphates, &c., which are not affected by ammonia, crystallised until free from phosphates, and gently ignited to produce pure vanadium pentoxide (*v.* Roscoe, Phil. Trans. 1867, 158, 1

The greater part of the vanadium of commerce is now extracted from the vanadinite of Spain, Chile, and the Argentine. The mineral is fused with potassium nitrate, alone or mixed with sodium carbonate, the mass is lixiviated, and the solution acidified, or, better, evaporated with ammonium chloride in order to precipitate alumina and silica. From the clear solution barium chloride and ammonia precipitate the barium salts of vanadic, chromic, and molybdic acids, &c., and on treating the product with sulphuric acid, followed by ammonia and water, the vanadium goes into solution as ammonium metavanadate, which is finally precipitated by the addition of ammonium chloride. Vanadic acid may also be separated from mixtures of sodium vanadate and silicate by the addition of more vanadic acid. This precipitates the silica and leaves only fairly pure sodium vanadate in solution (Herrenschmidt, Compt. rend. 1904, 139, 862).

According to Witz and Osmond (Bull. Soc. chim. 1882, [ii.] 38, 49; Compt. rend. 95, 42), the slags produced while working the Thomas-Gilchrist process at the Creusot ironworks contain nearly 1·5 p.c. of vanadium, the quantity of that metal thus concentrated amounting to 60,000 kilos (nearly 59 tons) annually. They recommend the following process for the separation: 1 kilo of the roughly broken slag is treated with a quantity of hydrochloric acid insufficient to attack the whole (about 1 litre of acid of 21°–22°Bé.) without stirring, 3 litres of water being added, and the whole remaining at rest for 2 days. The solution, having a sp.gr. of about 27°Bé. at 36°, is decanted and diluted to 15°Bé., and the silica is removed. The solution contains the vanadium in the hypovanadic condition, and may be used at once for the production of aniline black. If it is desired to produce hypovanadic phosphate, the solution is nearly neutralised and about 250 c.c. of saturated ammonium acetate solution is added. The bluish-grey precipitate produced, containing phosphates of iron, aluminium, and vanadium, is re-dissolved and again treated with ammonium acetate, the precipitate containing about 20 p.c. of vanadium.

If the slag contains less than 1·5 p.c. of vanadium, the hydrochloric acid solution is neutralised by the addition of a further quantity of finely-powdered slag. The solution becomes colourless, and a greyish granular precipitate separates, containing the whole of the vanadium and smaller proportions of the other less soluble phosphates. The precipitate is re-dissolved and re-precipitated as before. For the preparation of ammonium metavanadate, the phosphatic precipitate is roasted at incipient redness, and the ochreous-yellow mass of impure pentoxide is dissolved with the aid of ammonia, boiled until colourless and filtered, the ammonium metavanadate being precipitated by the addition of excess of ammonium chloride. From 4 kilos. of slag containing 1·5 p.c. of vanadium, about 250 grms. of ammonium metavanadate may be produced. It is a colourless transparent salt, or white powder, difficultly soluble in water, insoluble in a concentrated solution of ammonium chloride and in ether. It was formerly used, in conjunction with sodium chlorate, as an oxygen-carrier in the formation of the finest aniline black, only an extremely small quantity of the salt being required for a large amount of aniline.

Später attempted (1896) to employ the ash of an anthracite from Yauli (Peru) containing 28 p.c. of vanadium, but was unsuccessful.

From minerals in which it occurs with uranium, vanadium may be extracted by fusing with potassium hydrogen sulphate, lixiviating the mass and concentrating the solution thus obtained. The solution is reduced with zinc and the vanadium precipitated with ammonia and ammonium carbonate (Gin, Elektrochem. Zeit. 1906, 13, 119).

Haynes states (Mines and Minerals, 1909, 30, 139) that vanadium is extracted from *carnotite*, in West Colorado, by dissolving out the uranium and vanadium with hot sodium carbonate solution, precipitating the uranium with caustic soda, and throwing down the vanadium from the mother liquor as calcium vanadate.

Fleck and Haldane recommend that the crushed ore be treated with 15–20 p.c. sulphuric acid, the acid liquid neutralised by the addition of fresh ore, and the clear solution fractionally precipitated with limestone, whereby a complex mixture, rich in vanadium, is obtained, from which the element may be extracted by any ordinary method (U. S. Pat. 880752).

Preparation of metallic vanadium. Roscoe has given two methods for the preparation of the metal: (*a*) the reduction of vanadium nitride in hydrogen, which never gives a pure product; and (*b*) the reduction of anhydrous, oxygen-free vanadium dichloride in dry hydrogen. For a long time the latter method was the only one known by which the pure metal could be obtained (*v.* Roscoe and Schorlemmer, Treatise on Chemistry), but it can also be prepared by the reduction of vanadium pentoxide with 'mischmetall,' a mixture of alkaline earth metals extracted from the residues from the manufacture of thoria (Weiss and Aichel, Annalen, 1904, 337, 380). The mixture of mischmetall and pentoxide is placed in a magnesia crucible and fired; the heat of reaction is sufficient to melt the reduced metal, which is afterwards found as a compact mass in the crucible (Muthmann, Weiss and Riedelbauch, *ibid.* 1907, 355, 58).

It was formerly supposed that Goldschmidt's aluminium reduction method would not give pure vanadium from the pentoxide (Koppel and Kaufmann, Zeitsch. anorg. Chem. 1905, 45, 352), but under certain conditions Vogel and Tammann have, by this method, obtained a regulus containing 99 p.c. vanadium, with a little silicon and aluminium (*ibid.* 1909, 64, 225).

Reduction of the oxide with metallic calcium, according to Muthmann's method, gives a product containing only 91–93 p.c. of vanadium. A purer regulus is obtained by reducing with a mixture of calcium and aluminium (Prandtl and Bleyer, *ibid.* 1909, 64, 217).

Vanadium produced by the reduction of the pentoxide in the electric furnace contains 10–25 p.c. of carbon and consists chiefly of vanadium carbide. A product containing less carbon can be obtained by conducting the operation in an atmosphere of hydrogen (Moissan, Compt. rend. 116, 1225; 122, 1297; Zeitsch. anorg. Chem. 14, 174).

The pure metal can also be obtained by the electrolysis of a solution of sodium vanadate in hydrochloric acid, using carbon electrodes and a current density of 0·018–0·020 amp. per sq. cm., and maintaining the temperature about 80° (Cowper-Coles, Eng. and Min. J. 67, 744; von Bolton, Zeitsch. Elektrochem. 1905, 11, 45).

Properties.—Pure vanadium is a silver-white metal, similar in appearance to cast iron, and crystallises in hexagonal rhombohedra, like the other elements of its group. Its hardness is 7·5 on Mohr's scale, and it is as brittle as glass. It has sp.gr. 6·025 at 15°/15° (sp.gr. 5·5 at 15°/15°, Roscoe), and its specific heat is 0·124 (Matignon and Monnet, Compt. rend. 134, 542; Muthmann, Weiss and Riedelbauch, *l.c.*), which, assuming the atomic heat to be 6·4, confirms the atomic weight of 51.

The melting-point is very high, but the data given by various investigators are not in agreement. Werner von Bolton, using the photometric method of Lummer, found it to be 1680°. Vogel and Tammann give it as 1750°, ±30° (Zeitsch. anorg. Chem. 1908, 58, 73).

It is stable in moist or dry air at ordinary temperatures, and a polished surface retains its lustre for weeks. It is unacted upon by bromine water, aqueous alkali solutions, hydrochloric acid, or cold sulphuric acid. It is dissolved by hydrofluoric acid or hot sulphuric acid forming green solutions, and is attacked by nitric acid or *aqua-regia.* Molten potash or saltpetre rapidly dissolve the metal with formation of an alkali vanadate. Metallic vanadium reduces solutions of mercuric chloride and bromide, cupric chloride and bromide, and ferric chloride to the lower haloid salts, and it precipitates the metal from solutions of auric chloride, silver nitrate, platinic chloride, iridium tetrachloride, &c.

Alloys of vanadium can be prepared in the electric furnace by the reduction of the pentoxide in presence of a second metal or its oxide (Moissan, Compt. rend. 1896, 122, 1297). The chief industrial use of vanadium is in the preparation of special steels, which are largely used for motor-car work; it is introduced into the molten steel as *ferro-vanadium*, an alloy prepared by electric-furnace methods. The addition of 0·1–0·25 p.c. of vanadium to chromium, manganese, or other open-hearth or crucible steels greatly increases the elastic limit and the ultimate tensile stress without reducing the ductility (J. Kent Smith, J. Soc. Chem. Ind. 1906, 291; *cf.* Auchy, J. Ind. and Eng. Chem. 1909, 1, 455).

Colloidal solutions of vanadium have been prepared by Svedberg (Ber. 1906, 39, 1712).

OXIDES OF VANADIUM.

There are five oxides of vanadium, analogous to the oxides of nitrogen—

Vanadium suboxide, V_2O;
„ monoxide, hypovanadious oxide, V_2O_2;
„ sesquioxide or trioxide, V_2O_3;
„ dioxide, hypovanadic oxide, $V_2O_4(VO_2)$;
„ pentoxide, vanadic anhydride, V_2O_5

The first three of these act as basic oxides, forming salts with acids; the last two behave both as weak basic oxides and acid-forming oxides.

Vanadium suboxide V_2O is obtained as a brown powder by the exposure of finely divided metallic vanadium to the air. No salts of this oxide have been prepared.

Vanadium monoxide V_2O_2 or VO (*vanadyl*) is obtained as a lustrous grey solid by reducing the higher oxides with metallic potassium, or by passing the vapour of vanadyl trichloride with hydrogen over red-hot carbon. It has sp.gr. 3·64, is brittle and conducts electricity. At a red heat it burns in air to form the trioxide, and it combines directly with chlorine to form the oxytrichloride. This oxide was supposed by Berzelius to be the metal.

Vanadium monoxide dissolves in acids to form the corresponding salts, which have a violet colour and act as powerful reducing agents. The solution in hydrochloric acid has been suggested as a reagent for the removal of arsenic from hydrochloric acid gas in the process of manufacture, the arsenic being reduced to the free state and remaining suspended in the liquid (D. R. P. 164355).

Vanadium trioxide V_2O_3, obtained by reducing the pentoxide with hydrogen or carbon at a red heat, is a black powder of sp.gr. 4·7. In air it oxidises, slowly at the ordinary temperature, quickly when heated, forming the dioxide V_2O_4. It is insoluble in most acids.

Vanadium dioxide V_2O_4 or VO_2 is prepared by the oxidation of the trioxide or by the partial reduction of the pentoxide. It is a steel-coloured powder composed of dark indigo-coloured crystals. It dissolves in acids to form solutions of vanadyl salts of a bright blue colour, and in alkalis to form *vanadites* (*v.i.*). A *hydrate*, $V_2O_4,7H_2O$, or $V_2O_2(OH)_4,5H_2O$, is obtained as a greyish-white precipitate by adding sodium carbonate to a solution of a vanadyl salt. At 100° it loses 4 molecules of water, forming $V_2O_4,3H_2O$.

Hypovanadic acid (*vanadious acid*) $H_4V_2O_6$ has been prepared by boiling a solution of the dioxide VO_2, in aqueous sulphurous acid. It is a pink crystalline powder (Gain, Compt. rend. 1906, 143, 823; *see* also *ibid.* 1154), and can exist in a green isomeric form (Gain, *ibid.* 1907, 146, 403; Ann. Chim. Phys. 1908, [viii.] 14, 224).

The salts in which VO_2 is the acidic oxide are derived from the partial anhydrides $H_2V_2O_5$ and $H_2V_4O_9$.

Potassium and *sodium vanadites*

$K_2V_4O_9,4H_2O$ and $Na_2V_4O_9,4H_2O$

are prepared by adding excess of caustic alkali to a solution of vanadyl sulphate or chloride (*v.* Koppel and Goldmann, Zeitsch. anorg. Chem. 1903, 36, 281). They form reddish-brown crystalline scales and dissolve in water to dark-brown solutions.

Vanadium pentoxide V_2O_5 is the final product of most commercial processes for the extraction of vanadium from its ores. The pure oxide is best prepared by decomposing vanadyl trichloride with water and fusing the product, or by the decomposition of ammonium metavanadate by heat (Matignon, Chem. Zeit. 1905, 29, 986; *see* also Beard, Ann. Chim. anal. 1905, 10, 41).

Vanadium pentoxide forms large rhombic prisms, of a fine ruby-red colour by transmitted light, of sp.gr. 3·35, soluble in about 1000 parts of water with formation of a yellowish, tasteless solution which reddens litmus. At 658° (Carnelley) it fuses, forming a red liquid, which recrystallises in needles, with incandescence, on cooling.

When prepared by igniting ammonium metavanadate, treating the residue with nitric acid and drying at a gentle heat, it is a yellow, hygroscopic powder which forms hydrates with 1, 2, and 8 molecules of water, and is soluble in water to the extent of 8 parts in 1000. When the oxide is heated at 440°, or fused, two different sparingly soluble modifications are formed (Ditte, Compt. rend. 1885, 101, 698).

Vanadium pentoxide is reduced to V_2O_4 by the action of SO_2, or by evaporation with hydrochloric acid; to V_2O_3 by hydriodic acid, by magnesium and hydrochloric acid, or by hydrogen in the dry way; to V_2O_2 by zinc and hydrochloric acid (Glasmann, Ber. 1905, 38, 600; Chapman, Analyst, 1907, 32, 250).

The pentoxide was formerly used in the preparation of aniline black, and it acts as a carrier of oxygen in many reactions, *e.g.* the electrolytic oxidation of organic compounds in acid solution (Meister, Lucius and Brüning, D. R. P. 172654), and the oxidation of sugar to oxalic acid or of stannous to stannic chloride (Ludwig, Moeser and Lindenbaum, J. pr. Chem. 1907, [ii.] 75, 146; D. R. P. 183022).

The Vanadic Acids and their Salts.

Orthovanadic acid H_3VO_4 has not been prepared.

Metavanadic acid HVO_3 may be obtained by boiling copper metavanadate with aqueous sulphurous acid. A mixture of brown and yellow crystals is first produced, the former being redissolved on continued boiling with excess of sulphurous acid. The remaining yellow crystals consist of metavanadic acid. The acid may also be prepared by addition of a solution of ammonium metavanadate to one of copper sulphate containing excess of ammonium chloride, until a permanent precipitate is produced, and heating for a few hours at 75°. The whole of the vanadium is slowly precipitated, the colour being finer when precipitation is slow (Gerland, Ber. 1876, 9, 874). Metavanadic acid forms brilliant golden or orange-coloured scales, which are used as a pigment in place of gold bronze under the name 'vanadium bronze.'

Pyrovanadic acid $H_4V_2O_7$, prepared by the action of nitric acid on an acid vanadate, is a brown precipitate which when air-dried has the above composition (von Hauer, *v.i.*).

Hexavanadic acid $H_4V_6O_{17}$, formed when a solution of pervanadic acid is allowed to stand, is known only in solution (Düllberg, Zeitsch. physikal. Chem. 1903, 45, 170).

The following sodium vanadates are known, and may be taken as typical of the vanadates in general—

Sodium metavanadate, $NaVO_3$;
„ orthovanadate, Na_3VO_4;
„ pyrovanadate, $Na_4V_2O_7$;
„ tetravanadate, $Na_3HV_4O_{12}$;
„ hexavanadate, $Na_2H_2V_6O_{17}$

(*v.* also von Hauer, J. pr. Chem. 1856, [i.] 69, 385; 1859, 76, 156 and 929; 1860, 80, 324; Carnelley, Chem. Soc. Trans. 1873, 323). In solution the metavanadates are most stable, and the orthovanadates least stable, the pyrovanadates being intermediate. This is the reverse of the order of stability of the phosphates. At high temperatures orthovanadates are the most stable salts, being produced, *e.g.*, by fusing alkali carbonates with vanadium pentoxide. The *alkali pyrovanadates*, prepared by fusing the pentoxide with excess of alkali carbonate and crystallising from water, are soluble, whilst the pyrovanadates of heavy metals are mostly insoluble.

The *alkali metavanadates* are obtained by boiling a solution of alkali carbonate with the pentoxide, and are colourless salts which give yellowish-red anhydro-salts on treatment with acid. The metavanadates of heavier metals are usually yellow. Pure silver metavanadate is precipitated on addition of silver nitrate to a neutral solution of an alkali vanadate (Browning and Palmer, Amer. J. Sci. 1910, 30, 220).

A test which distinguishes between ortho- and meta- vanadates depends on the colour of the copper salts of the acids which are blue-green and light yellow respectively.

A series of double stannates and vanadates of sodium has been described by Prandtl and Rosenthal (Ber. 1907, 40, 2125).

Ammonium metavanadate NH_4VO_3 is the most important salt of vanadic acid. It may be prepared by dissolving vanadium pentoxide in excess of aqueous ammonia and then, by evaporation or by adding alcohol or excess of ammonium chloride, it is thrown out of solution as a white crystalline powder.

A 'vanadium ink' is produced by the addition of gallic acid to a mixture of neutral ammonium metavanadate and gum water. This ink is not destroyed by acids, alkalis, or chlorine, but does not appear to be permanent. Soerensen (J. Soc. Chem. Ind. 1, 185) recommends the use of a solution of 1 lb. neutral ammonium metavanadate in 10 gals. of water for producing a permanent black dye on leather which has been tanned with nut galls.

Pervanadic acid HVO_4, prepared by adding finely powdered vanadium pentoxide to a solution of hydrogen peroxide acidified with sulphuric acid, forms yellow crystals soluble in water, giving a deep-red solution (Werther, J. pr. Chem. 1861, 83, 195; Pissarjewsky, Zeitsch. physikal. Chem. 1903, 43, 173). The *potassium salt* KVO_4 forms a yellow microcrystalline precipitate (*see* also Melikoff and Pissarjewsky, Zeitsch. anorg. Chem. 1899, 19, 405; Pissarjewsky, *ibid.* 1903, 32, 341; Melikoff and Kasanezky, *ibid.* 1901, 28, 242; Melikoff and Jelhchaninoff, Ber. 1909, 42, 2291).

Vanadiselenious acid $3V_2O_5{\cdot}4SeO_2,4H_2O$ and its salts have been described by Prandtl (Ber. 1905, 38, 1305).

SALTS OF VANADIUM.

Vanadium trifluoride $VF_3,3H_2O$ crystallises in dark-green octahedra from a solution of the trioxide in hydrofluoric acid. Addition of potassium fluoride precipitates the *double potassium salt* $2KF{\cdot}VF_3,H_2O$ as a bright green crystalline powder.

Vanadium oxydifluoride VOF_2, from the dioxide and hydrofluoric acid, forms blue prismatic crystals (hydrated).

The pentoxide also dissolves in hydrofluoric acid, but no other fluoride has been isolated. Numerous double fluorides have been described (*see* Petersen, J. pr. Chem. 1889, [ii.] 40, 193, 271; Piccini and Giorgis, Gazz. chim. ital. 1888, 18, 186; Baker, *ibid.* 1878, 388; Costăchescu, Ann. Sci. Univ. Jassy, 1910, 6, 117).

Vanadium tetrachloride VCl_4 is formed by the action of excess of chlorine on the metal or the mononitride. It is prepared by passing the vapour of vanadyl trichloride with chlorine over red-hot sugar charcoal, or by the action of chlorine on the impure metal obtained by Goldschmidt's method (Koppel, Goldmann and Kaufmann, Zeitsch. anorg. Chem. 1905, 45, 345). and is separated from admixed oxychloride by fractional distillation.

It is a deep brown-red, viscous liquid which fumes in air. It boils at 154°, and when heated or exposed to light loses chlorine, forming the trichloride (*v.i.*). It has sp.gr. 1·8584 at 0°, and V.D. 6·69 at 205°. Water decomposes it with formation of a blue solution of vanadyl chloride.

The *pentachloride* does not appear to exist.

Vanadium trichloride VCl_3 is obtained by the decomposition of the tetrachloride, by passing the vapour of the tetrachloride with hydrogen through a red-hot tube, or by heating the trisulphide in chlorine (Halberstadt, Ber. 1882, 15, 1619). It is most easily prepared by passing first the vapour of carbon disulphide and then dry chlorine over heated vanadium pentoxide.

The trichloride thus obtained forms beautiful purple tabular crystals, resembling chromium trichloride. Heated in air, it decomposes yielding the pentoxide. When ignited in hydrogen it does not volatilise, but is reduced to the dichloride. It has sp.gr. 3·0, and is extremely hygroscopic.

The hydrated salt $VCl_3,6H_2O$ is obtained by evaporating *in vacuô* a solution of the trioxide in hydrochloric acid (Locke and Edwards, Amer. Chem. J. 1898, 20, 594), or by reducing electrolytically a solution of the pentoxide in hydrochloric acid and saturating the resulting solution with hydrogen chloride (Piccini and Brizzi, Zeitsch. anorg. Chem. 1899, 19, 394). It is a green crystalline powder, and when heated begins to decompose before all the water has been driven off.

Vanadium dichloride VCl_2 is prepared by reducing the trichloride, by heating to redness a mixture of the tetrachloride and hydrogen, or by heating the silicide VSi_2 in chlorine (Moissan and Holt, Compt. rend. 1902, 135, 78).

It forms deliquescent, apple-green hexagonal plates having a micaceous lustre; it dissolves in water to form a solution which bleaches strongly, and is a more powerful reducing agent even than chromous chloride (Piccini and Marino, Zeitsch. anorg. Chem. 1902, 32, 68).

When the solid is heated in hydrogen the pure metal is obtained (Roscoe).

Vanadyl trichloride $VOCl_3$ (*vanadium oxytrichloride*) is prepared (1) by the action of chlorine on the trioxide, some pentoxide being formed according to the equation

$$3V_2O_3+6Cl_2=4VOCl_3+V_2O_5;$$

(2) by heating a mixture of the pentoxide and carbon in a current of chlorine; (3) by passing dry hydrogen chloride over a mixture of vanadium and phosphorus pentoxides at 60° (Ephraim, Zeitsch. anorg. Chem. 1903, 35, 66).

The product is usually dark-coloured from the presence of the tetrachloride, and is best purified by distillation over metallic sodium in an atmosphere of carbon dioxide.

A solution in acetic acid may be obtained by the action of dry hydrogen chloride on a solution of the pentoxide in glacial acetic acid (Koppel and Kaufmann, *ibid.* 1905, 45, 352).

Pure vanadyl trichloride is a lemon-yellow mobile liquid; b.p. 127·°2, sp.gr. 1·86534 at 0°/4° (Thorpe). In contact with moist air it evolves dense red fumes. Water decomposes it with formation of vanadic and hydrochloric acids, and with a large quantity of water it yields a yellow solution (*see* Agafonoff, J. Russ. Phys. Chem. Soc. 1903, 35, 649). Heated in a current of ammonia it yields the mononitride. At 70° it combines with ether yielding the compound $VCl_3(OC_2H_5)_3$, crystallising in red needles (Bedson, Chem. Soc. Trans. 1876, i. 309), and it forms a compound with pyridine.

Vanadium may be quantitatively volatilised as the trichloride by heating its compounds in a current of carbon tetrachloride vapour (Jannasch and Harwood, J. pr. Chem. 1909, [ii.] 80, 127).

Vanadyl dichloride $VOCl_2$, crystallising in deliquescent green tablets, is formed when the oxytrichloride is heated with zinc at 400°, or with hydrogen at a red heat. The latter method of reduction yields *vanadyl monochloride* $VOCl$, a flocculent brown powder, insoluble in water, and *divanadyl monochloride* V_2O_2Cl, a yellow crystalline powder. Double compounds of $VOCl_2$, with the hydrochlorides of pyridine and quinoline, have been described (Koppel, Goldmann and Kaufmann, Zeitsch. anorg. Chem. 1905, 45, 345).

Divanadyl tetrachloride $V_2O_2Cl_4,5H_2O$ is obtained as a brown, amorphous deliquescent mass by the evaporation of a solution of the pentoxide in hot concentrated hydrochloric acid. It dissolves in water to a blue solution which is turned brown by hydrochloric acid or alcohol, possibly owing to the formation of different hydrates (Crow, Chem. Soc. Trans. 1876, ii. 453).

Another oxychloride $V_2O_3Cl_2,4H_2O$ is obtained by similar methods as a dark-green deliquescent solid (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium tribromide VBr_3 is prepared by the action of dry bromine on the metal or on the mononitride, or a mixture of the trioxide and carbon at a red heat. It is a deliquescent solid which is very unstable and loses bromine even at the ordinary temperature.

The hydrated bromide $VBr_3,6H_2O$ is prepared in a similar manner to the corresponding chloride (*q.v.*).

Vanadyl tribromide $VOBr_3$, prepared by passing bromine vapour over the heated trioxide, is a dark-red liquid, sp.gr. 2·967 at 0°, b.p. 130° under 100 mm. Heated to 180° it suddenly decomposes into free bromine and *vanadyl dibromide* $VOBr_2$, a brownish-yellow powder.

Vanadium triiodide (hydrated) $VI_3,6H_2O$ is prepared in the same manner as the corresponding bromide and iodide.

Divanadyl tetriodide $V_2O_2I_4,8H_2O$ is obtained as a dark-coloured deliquescent solid by the action of hydriodic acid on vanadium pentoxide (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium monosulphide VS, obtained by heating the sesquisulphide in hydrogen, is a brown powder soluble in nitric acid.

Vanadium sesquisulphide (*vanadium trisulphide*) V_2S_3 is prepared by heating the trioxide in a current of hydrogen sulphide or the pentoxide in the vapour of carbon disulphide. It is a greenish-black powder (*see* Kay, Chem. Soc. Trans. 1880, 728).

Vanadium pentasulphide V_2S_5 is obtained as a black powder by heating the trisulphide with sulphur. This sulphide is acidic and gives rise to a series of *thiovanadates*, which are best prepared by passing hydrogen sulphide into cooled solutions of the corresponding vanadates.

Vanadyl sulphite $6VO_2{\cdot}4SO_2,9H_2O$ is obtained as a dark blue crystalline powder by reducing barium vanadate with sulphur dioxide. Gain has described a sulphite $4VO_2{\cdot}3SO_2,10H_2O$, crystallising in silky blue needles (Compt. rend. 1906, 143, 823; *see* also *ibid.* 1907, 144, 1157).

Vanadious sulphate $VSO_4,7H_2O$ is best prepared by acting with sulphur dioxide on a suspension of vanadium pentoxide in sulphuric acid and then reducing the solution electrolytically. On evaporation *in vacuô* the salt is obtained in reddish-violet monoclinic crystals which appear to be isomorphous with ferrous sulphate. The solution of the salt is a powerful reducing agent and bleaches strongly.

Vanadious sulphate forms a series of double salts with the alkali sulphates (*see* Piccini, Zeitsch. anorg. Chem. 1899, 19, 204; Piccini and Marino, *ibid.* 1902, 32, 55; Marino, *ibid.* 1906, 50, 49; Rutter, *ibid.* 1907, 52, 368; and Zeitsch. Elektrochem. 1906, 12, 230).

Vanadium sesquisulphate $V_2(SO_4)_3$, prepared by reducing a solution of vanadium pentoxide in sulphuric acid with magnesium, or by the electrolytic reduction of vanadyl sulphate, forms a green solution from which green crystals of the acid salt $V_2(SO_4)_3,H_2SO_4,12H_2O$ separate out. By dissolving this salt in water, adding sulphuric acid and heating at 180° in a current of carbon dioxide, the sesquisulphate separates out as a yellow crystalline powder, insoluble in water (Stähler and Wirthwein, Ber. 1905, 38, 3978).

Several *vanadium alums* have been prepared.

Vanadyl sulphate $V_2O_2(SO_4)_2$ is prepared (*a*) in the insoluble form by dissolving the dioxide VO_2 in sulphuric acid and heating the solution at 260° (Gerland, Ber. 1877, 10, 2109; Koppel and Behrendt, Zeitsch. anorg. Chem. 1903, 35, 154); (*b*) in the soluble form by heating the insoluble form with water at 130°, or by dissolving the dioxide in sulphuric acid, evaporating, and treating the residue with alcohol. Both forms are blue, and by crystallisation of the soluble form under different conditions hydrates with 13, 10, 7, 4, 3, and 2 molecules of water are obtained.

Strongly acid solutions deposit the acid sulphate $(V_2O_2)H_2(SO_4)_3$, crystallising with 5 molecules of water. When heated it gradually loses water, yielding various lower hydrates, and, finally, at 190°, the *anhydrous salt*

$$2VO_2{\cdot}3SO_3,$$

which forms microscopic green tetragonal crystals, sparingly soluble in water (Koppel and Behrendt, *l.c.*; Gain, Compt. rend. 1906, 143, 1154).

Divanadyl trisulphate $(VO)_2(SO_4)_3$ is obtained in ruby-red octahedra by boiling the pentoxide with excess of sulphuric acid (*see* Ditte, *ibid.* 1886, 102, 757). Other basic salts, *e.g.* $(VO_2)O(SO_4)_2$ and $VO(OH)SO_4$ have been described (*see* Gerland, Ber. 1878, 11, 98).

Vanadium mononitride VN may be obtained by the direct union of its elements or by heating ammonium metavanadate or the pentoxide to whiteness in a current of ammonia. It is a brown powder, oxidised to the blue oxide when heated in air.

Vanadium dinitride VN_2 is a black powder obtained by the action of ammonia on vanadyl trichloride.

Many phosphovanadic and arsenovanadic acids are known, giving rise to numerous derivatives (*see* Ditte, Compt. rend. 1886, 102, 757; Gibbs, Amer. Chem. J. 1886, 7, 118, 209; Friedheim, Ber. 1890, 23, 1530, 2600; Gain, Compt. rend. 1907, 144, 1271; Mawrow, Zeitsch. anorg. Chem. 1907, 55, 147). Blum has described a series of phosphovanadic molybdates (J. Amer. Chem. Soc. 1908, 30, 1858).

Vanadium carbide VC, obtained by heating the pentoxide with carbon in the electric furnace, forms hard crystals of sp.gr. 5·36.

Vanadium silicides. Two silicides are known: V_2Si, sp.gr. 5·48; and VSi_2, sp.gr. 4·42. Both are obtained in the electric furnace from the oxide and silicon. They are hard, crystalline substances, having a metallic lustre (Moissan and Holt, Compt. rend. 1902, 135, 78, 493).

A vanadium aluminium silicide $V_6Al_2Si_{12}$ has been described by Manchot and Fischer (Annalen, 1907, 357, 129).

Detection and estimation of vanadium. Vanadium may be detected *qualitatively* by the behaviour of its compounds on oxidation and reduction, yellow or red solutions of vanadates yielding blue solutions of vanadyl salts on reduction with zinc and acid. Addition of ammonium chloride to a solution of a vanadate precipitates white ammonium metavanadate. The most delicate test known for vanadium consists in adding hydrogen peroxide and ether to a solution of a vanadate acidified with sulphuric acid; a yellow or red colour is produced in the *aqueous* layer (G. Werther, J. pr. Chem. 1863, [i.] 88, 195; Campagne, Chem. Zentr. 1904, [ii.] 1167). Vanadium may also be detected spectroscopically (*see* Purvis, Trans. Camb. Phil. Soc. 1906, 20, 193; Pollok, Sci. Proc. Roy. Dubl. Soc. 1909, 11, 331).

Vanadium is usually estimated volumetrically by oxidation methods after other reducible metals have been eliminated. *See* art. ANALYSIS.

VANADIUM INK *v.* VANADIUM.

VANADIUM MICA *v.* ROSCOELITE.

VANILLA is the dried fermented pod of certain orchids, indigenous to Mexico, but also found in Java, Réunion, the Seychelles, Brazil, Peru, on the banks of the Orinico, Parahyba and other rivers of South America.

The chief cultivated variety is *V. planifolia* (Andr.), which is grown on a considerable scale in Mexico, Réunion, Mauritius, the Seychelles, and in Java. The long fleshy stem of the plant clings by its aerial rootlets to trees, and bears a greenish-white flower. The fruit is a pulpy pod, about 6–12 ins. long and half an inch thick. In Mexico the plant is cultivated by planting cuttings at the feet of trees left in a clearing of the forest; these root in a few weeks and bear in the third year. In Réunion and in the Seychelles the plants are trained on trellis-work supported by trees, and are fertilised by hand. Care has to be taken to gather the pods at the proper time of maturity, as if over-ripe they split in drying, and if under-ripe they are deficient in flavour.

The fruit is usually gathered in the late autumn when full grown, but just before it ripens.

The curing of the fruits consists essentially of a slow process of drying in warm air, using either artificial or solar heat, but the details vary in different countries; thus in Mexico the gathered pods are allowed to lie in heaps until they begin to shrivel, after which they are heated, either by exposure to the sun or in ovens, when they gradually acquire a dark-brown colour. In Réunion the pods are immersed in boiling water for a few seconds, and then exposed to the sun for a few weeks in woollen cloths until they acquire the proper brown colour. As they become dry, they discharge a viscid liquid from the upper end, and are pressed from time to time to promote its flow. They are usually packed for the market in small bundles of fifty or one hundred in each.

It has also been suggested to use calcium chloride in the drying of the beans (J. Soc. Chem. Ind. 1898, 180).

For literature on the culture and curing of the vanilla beans, *v. ibid.* 1893, 707; *ibid.* 1896, 670; *ibid.* 1900, 847; *ibid.* 1901, 1048; *ibid.* 1906, 1117; *ibid.* 1909, 1002; Fr. Pat. 367285, 1906.

Those who habitually handle vanilla beans are often subjected to a cutaneous affection in the form of an eruption on the hands, face, or neck, which causes intense irritation; this is probably due to the oily juice which exudes from the beans. To avoid the affection, good ventilation of the factories and thorough washing of the hands are recommended (Claverie, J. Soc. Chem. Ind. 1908, 1082).

Commercial vanilla beans are almost black, 15–20 cm. long and 6–9 mm. thick. They are of a flattened cylindrical shape, tapering towards each end wrinkled and flexible. The best varieties, chiefly the Mexican, are the largest; they are very dark, glossy, and frost or *giore* (*i.e.* become covered with white crystals) very quickly. The inferior varieties are shorter, lighter in colour, and do not frost much.

Vanillons are the cured fruits of uncultivated vanilla plants; they are usually of poor quality. The unripe beans are said to contain coniferin and two enzymes, one of which converts coniferin into coniferyl alcohol and glucose, and the other oxidises the former to vanillin (Lecomte, Compt. rend. 1901, 133, 745).

Best Mexican vanilla beans contain 1·69–1·86 p.c. vanillin, Bourbon 1·91–2·90, Java 2·75, German East African 2·16, Ceylon 1·48, Tahiti 1·55–2·02, but the flavour of vanilla does not depend merely on the quantity of vanillin it contains (Busse, Zeitsch Nahr Genussm. 1899, 2, 519).

In addition to vanillin, the beans also contain vanillic acid $C_6H_3(OH)(OCH_3)CO_2H$, resins, fat, sugar, and 4–5 p.c. ash (Winton and Silverman, J. Soc. Chem. Ind. 1902, 1300; U.S. Pat. 931805; *ibid.* 1909, 1062; Gautier and Kling. Ann. Falsif. 1910, 3, 200). Anisyl alcohol and anisaldehyde have also been detected (Walbaum, Chem. Zentr. 1909, ii. 2181).

When the green vanilla pods are exposed to ultra violet rays, they emit a smell of vanillin, the process being accelerated by a rise in temperature and by previous immersion in dilute manganous chloride (Pougnet, Compt. rend. 1911, 152, 1184).

Tincture or essence of vanilla is formed by extracting the ground or cut up vanilla (10 parts) with a mixture of alcohol and water, and mixing the extract with 20 parts of refined sugar, the whole being made up to 100 parts.

The chief adulterant in vanilla extracts is coumarin, either artificial or from tonka beans: good imitation extracts may be obtained from 3 parts of vanilla, and 1 part of tonka beans, but most commercial imitations contain no vanilla, and are made up of artificial vanilla and coumarin and extract of tonka beans, the whole being coloured with caramel (Winton and Silverman, *l.c.*). In the preparation of inferior extracts weak alcohol and alkali are employed; these can be distinguished from good extracts by shaking a few c.c. with 3 volumes of water, when, if no alkali has been employed, a flocculent red precipitate will be formed. With hydrochloric acid a good extract should give only a slight turbidity (Hess, J. Amer. Chem. Soc. 1899, 21, 719).

Vanilla in the form of its tincture, is employed for flavouring chocolate and confectionery. It is also largely used in the manufacture of liqueurs and perfumes.

VANILLIN (Methoxyprotocatechuic aldehyde $C_6H_3(OH)(CHO)(OCH_3)[1:3:4]$) is contained in vanilla beans (*v.* VANILLA); in *Habenaria nigra* (R. Br.) (Lippmann, Ber. 1894, 27, 3409); in dahlia tubers (*ibid.* 1906, 39, 4147); in the woody parts of plants (*ibid.* 1904, 37, 4521); in the fruit and roots of *Avena sativa* [L.] (Rawton, Compt. rend. 1897, 125, 797). It also occurs in many other plants, in resins, balsams, and other substances (Campani and Grimaldi, Bull. Soc. chim. 1890, [iii.] 3, 458; Weld, Tollens and Lindsey, Ber. 1890, 23, 2990; Thomas, Arch. Pharm. 1899, 237, 271; Knitl, *ibid.* 256; Itallie, *ibid.* 1901, 239, 506). Vanillin may be obtained from vanilla pods by disintegrating the latter with sand and extracting with ether or a mixture of ether and alcohol (Tiemann and Haarmann, Ber. 1876, 9, 1287).

Vanillin may be obtained artificially by oxidising coniferin or coniferyl alcohol with chromic acid; by oxidising eugenol or, better, *iso*eugenol with air (Fr. Pat. 316526, 1902; Eng. Pat. 4909, 1902; J. Soc. Chem. Ind. 1902, 722; *ibid.* 1903, 439); with ozone or ozonised air (Trillat, Compt. rend. 1901, 133, 822; Bull. Soc. chim. 1903, 29, 45; Fr. Pats. 326775, 421784, 1909; U.S. Pat. 829300, 1906; J. Soc. Chem. Ind. 1903, 819); with peroxides (Eng. Pats. 11952, 1894; 14928, 1896; J. Soc. Chem. Ind. 1895, 506; *ibid.* 1897, 633); or electrolytically (Eng. Pats. 1624, 1895; *ibid.* 1896, 49, 292).

A 95 p.c. yield and a much purer product is said to be obtained by oxidising eugenol, *iso*eugenol, coniferin, or coniferyl alcohol, simultaneously with air and ultra violet rays at 50°–60° (D. R. P. 224071; J. Soc. Chem. Ind. 1910, 1036).

Vanillin may also be prepared by dissolving 14·2 kilos. protocatechuic aldehyde in concentrated sodium carbonate solution, and mixing it with 12·6 kilos. of dimethyl sulphate. The whole is heated on the water-bath, acidified, and extracted with ether. The latter is evaporated, and the vanillin extracted from the residue with chloroform (J. Soc. Chem. Ind. 1902, 274; *see* also *ibid.* 1897, 633; *ibid.* 1894, 1218; *ibid.* 1895, 1061).

Pure vanillin may be synthesised by the following method, the yield being 70–80 p.c. of the theoretical: 1 grm. molecule of a methyl or ethyl ester of mesoxalic acid or of any *aβ*-diketonic acid (or of the free acid), is added to a solution of 250 grms. of zinc chloride in 500 grms. of glacial acetic acid. The whole is kept at the ordinary temperature for 15 hours, after which it is heated at 50° for some hours, and then diluted with water and shaken with ether. The ethereal extract is washed with dilute aqueous sodium carbonate, distilled with steam to remove guaiacol (if present), and oxidised with copper chloride or acetate, vanilloylcarboxylic acid being formed. The latter, when heated with an equal weight of dimethyl-*p*-toluidine at 170°, yields vanillin, which is extracted from the acidified mixture by means of ether (Guyot and Gry, Compt. rend. 1909, 149, 928). Vanillin may also be synthesised by treating guaiacol with hydrocyanic acid, hydrochloric acid, and zinc chloride in the presence of infusorial earth (D. R. P. 189037; Chem. Zentr. 1908, i. 75).

Vanillin has also been prepared by other methods.

Literature.—Tiemann, Ber. 1891, 24, 2877; Augier and Boissien, Bull. Soc. chim. 1895, 13, 519; Bouveault, *ibid.* 1898, [iii.] 19, 75; Verley, *ibid.* 1901, [iii.] 25, 48; J. Soc. Chem. Ind. 1896, 556, 740; *ibid.* 1902, 68; *ibid.* 1908, 644; Stolz, Ber. 1904, 37, 4149; Frdl. 1877–87, i. 583–590; 1890–94, iii. 894–900; 1894–97, iv. 1273–1291; 1897–1900, v. 101, 110; 1902–04, vii. 755; 1905–07, viii. 1280, 1281; 1907–10, ix. 162, 1130, 1166.

Vanillin forms white needles having a strong characteristic taste and smell, m.p. 80°–81°, b.p. 285° (without decomposition in a stream of carbon dioxide) or 170°/15 mm. It is soluble in 90–100 parts of water at 14°, and in 20 parts at 75°–80°; it is readily soluble in ether, alcohol, and chloroform. The aqueous solution is acid, and gives a blue-violet colour with ferric chloride. When treated with ferrous sulphate and bromine water, vanillin is coloured bluish-green, then yellow (Pharm. J. 1897, 58, 167). Vanillin in hydrochloric acid gives characteristic colour reactions with phenols, ketones, and other substances; thus with acetone and its homologues a rose colour is formed, which becomes green on warming (Rosenthaler, Zeitsch. anal. Chem. 1905, 44, 292). A nitric acid solution of vanillin on standing yields a small quantity of hydrogen cyanide (Jorissen, J. Soc. Chem. Ind. 1910, 1036).

When oxidised with ferric chloride, nitric acid, or with fungus extract, or with gum arabic solution, vanillin forms *dehydrodivanillin*

$$[C_6H_2(CHO)(OCH_3)(OH)]_2,$$

white needles, m.p. 303°–304° (Tiemann, Ber. 1885, 18, 3493; *v.* Lerat, Bull. Soc. chim. 1904, [iii.] 31, 270; Bourquelot and Marchadier, *ibid.* 1248; Bentley, *ibid.* 1900, [iii.] 24, 942).

Vanillin may be estimated by converting it into its hydrazone by treatment with a hydrazide (Hanuš, Zeitsch. Nahr. Genussm. 1900, 3, 531, 657; *ibid.* 1905, 10, 585); or by converting it into its bisulphite derivative, decomposing the latter with sulphuric acid, removing the sulphur dioxide with a stream of carbon dioxide, then extracting the vanillin with ether; the ether is evaporated and the residue weighed (Busse, *ibid.* 1899, 2, 519). For other methods, *see* J. Soc. Chem. Ind. 1893, 718; *ibid.* 1903, 514.

Vanillin is frequently adulterated with coumarin, acetanilide, and with acetyl *iso*eugenol (Hess and Prescott, J. Amer. Chem. Soc. 1899, 21, 256; *see* also J. Soc. Chem. Ind. 1898, 1076; *ibid.* 1899, 604).

According to Winton and Lott (*ibid.* 1910, 1268) genuine vanillin may be distinguished from imitations by determining the lead number which, for the former, should lie between 0·29 and 0·34.

DERIVATIVES OF VANILLIN.

Vanillin forms salts with *zinc*, *lead*, *sodium*, and *magnesium* of the type $(C_8H_7O_3)M'$ (Tiemann and Haarmann, Ber. 1874, 7, 614).

Bromovanillin $C_6H_2Br(MeO)(CHO)(OH)$, m.p. 160°–161°, odourless, yellow leaflets (Tiemann and Haarmann, *l.c.*); the corresponding *iodo* compound has m.p. 174° (Bentley, Amer. Chem. J. 1900, 24, 172).

2-Nitrovanillin has m.p. 137°, **5-nitrovanillin** m.p. 176° (Bentley, *l.c.*; Pschorr and Sumuleanu Ber. 1899, 32, 3405).

Vanillin forms an *aldoxime*, m.p. 121°–122° (Decker and Klauser, *ibid.* 1904, 37, 520); a *phenylhydrazone*, m.p. 105° (Tiemann and Kees, *ibid.* 1885, 18, 1662); an *azine*, m.p. 174°–176° (Knöpfer, Monatsh. 1909, 30, 29); an *acetyl* derivative, m.p. 77° (Pschorr and Sumuleanu, *l.c.*); a *benzoyl* derivative, m.p. 75° (Wörner, Ber. 1896, 29, 143); also a *di*- and *trithio* derivative, in which the oxygen of the aldehyde group is replaced by sulphur, m.p. 129°–130°, 235°–237°, respectively (Manchot and Zahn, Annalen, 1905, 345, 320; Wörner, *l.c.*). *Vanillinacetic acid* $CHO{\cdot}C_6H_3(OMe)O{\cdot}CH_2{\cdot}CO_2H$ has m.p. 188° (Gassmann and Krafft, Ber. 1895, 28, 1871).

Vanillin-*p*-phenetidine (*eupyrin*)

$$OH{\cdot}C_6H_3(OCH_3)CH : N{\cdot}C_6H_4{\cdot}OC_2H_5$$

is formed by the interaction of vanillin and *p*-phenetidine at 140°; m.p. 97°. It is said to have hypnotic and antineuralgic properties (D. R. P. 91171, 96342; Frdl. 1894–97, iv. 1183, 1185).

Benzaldivanillin forms microscopic needles, m.p. 221·5°–222·5° (Rogoff, Ber. 1901, 34, 3881; *ibid.* 1902, 35, 1961).

Methyl ether of vanillin (veratraldehyde) $(CH_3O)_2C_6H_3{\cdot}CHO$ may be obtained by the methylation of vanillin, and by other methods. It is best to dissolve 1 mol. of vanillin in less than the equivalent quantity of 10 p.c. methysulphate on the water-bath, 1 mol. of potash in solution is then added in drops. When the reaction is over the solution is made slightly alkaline when it separates into two layers. The upper layer is extracted with ether, and on distilling off the latter, the pure aldehyde is obtained (Decker and Koch, Ber. 1907, 40, 4794). It has m.p. 47° (Juliusberg, *ibid.* 119), and possesses hypnotic properties. The corresponding *ethyl* derivative $CH_3O·C_6H_3(OC_2H_5)CHO$ has m.p. 64°–65° (Tiemann, Ber. 1875, 8, 1120). Homologues of vanillin have also been prepared (Eng. Pat. 10112, 1895; J. Soc. Chem. Ind. 1895, 595).

o-**Vanillin** (*m*-methoxysalicylic aldehyde) (CHO : OH : OMe=1 : 2 : 3) is, in the pure state, a solid which crystallises from water in pale yellow needles, m.p. 45·5°, b.p. 265°–266°. It dyes wool and silk from an acid bath a golden or lighter yellow, but the shades are not fast to soap (Noelting, Bull. Soc. Ind. Mulhouse, 1909, 79, 401; J. Pharm. chim. 1908, 28, 173).

It gives a phenyl hydrazone, m.p. 130°–131°, and a large number of other derivatives.

The root of a species of *Chlorocodon* of Uganda, where it is termed *Murando*, contains an odorous constituent $C_7H_5O_2·OMe$, m.p. 41°–42°, b.p. 257°–258°, which forms thin, colourless plate, is isomeric with vanillin, and yields an *oxime*, m.p. 138°, and a phenyl hydrazone, m.p. 137°–138° (Goulding and Pelly, Chem. Soc. Proc. 1908, 62).

VAPOUR DENSITY *v.* Specific gravity.

VAREC. *Kelp v.* Iodine.

VARIOLARIN *v.* Lichens.

VARISCITE. One of the many minerals consisting of hydrated aluminium phosphate, here with the formula $AlPO_4,2H_2O$. It forms concretionary and compact nodular masses, sometimes with a minutely crystallised (orthorhombic) surface. The colour is bright apple-green (due to chromium); sp.gr. 2·5–2·6; H. 4–5. It was first found in 1837 in Saxon Voigtland (the ancient Variscia), and within recent years has been mined in considerable quantities (3½ tons in 1909, and 2½ tons in 1910) at several places in Utah and Nevada. It is used as a gem-stone, taking the place of green turquoise (D. B. Sterrett, Min. Res. U.S., Annual Reports for 1910 and earlier). L. J. S.

VARNISH (*Syn. Vernis*, Fr.; *Lac. Firniss*, Ger.). A varnish may be described as a homogeneous fluid, which, when applied by any suitable means in a thin layer over the surface of any object, dries either by the evaporation of the volatile solvent, or by the combined evaporation of the volatile solvent, and the oxidation of the oil and resins to a more or less impervious elastic film unaffected by wear and tear, and by weather. Varnishes, in the drying of which heat is applied in a closed compartment so as to expel the solvent and then fuse the residual layer so that it is uniform like glass, are termed 'Japans.' A process has been patented for obtaining the necessary heat by generating it in the metal itself by the passage through it of an electric current. The simplest form of varnish is the spirit varnish, which is merely a solution of a more or less elastic solid in a volatile solvent. Spirit varnishes dry the most rapidly, but are liable to be brittle, and eventually to crack and peel off. Oil varnishes are, to a large extent, free from this defect, the drying oil which they contain binding and softening the resin, and although they take longer to dry, they are generally more lustrous and durable. When varnish is used as a vehicle or medium for the application of a pigment to an object, an enamel is produced. Such enamels dry with a gloss, and save labour by combining painting and varnishing in one operation. The solvents employed in making the various varnishes are chiefly methylated spirit, turpentine, naphtha, and petroleum spirit. Linseed oil is the oil in most general use, but tung oil (Chinese or Japanese wood oil) is now being employed, although its properties prevent its replacing linseed oil altogether. Walnut and poppy oils are also used, but only for certain special purposes. The solids, *i.e.* resins, &c., mostly employed in oil varnish making are: 1. Amber; 2. Copal, including Kauri and Manilla; 3. Rosin; 4. Asphaltum, including the various pitches. Pure resins are solid bodies, generally more or less coloured, amorphous or crystalline, which melt, as a rule, at a comparatively low temperature. They are insoluble in water, but partially or wholly soluble in a number of fluids such as alcohol, ether, chloroform, toluene, light petroleum, acetone, spirits of turpentine, &c.

Scale of hardness of varnish resins (Andés).

Oil Varnish Resins.

(A.) Amber.

(B.) Copal:—

Hard	Medium	Soft
1. Zanzibar	4. Sierra Leone fossil	17. Manilla
2. Mozambique	5. Angola red	18. Borneo
3 Madagascar	6. Benguela	19. Singapore
	7. Bastard Angola	20. S. American
	8. Copal pebble	21. Brazil
	9. Akra	22. Cochin China
	10 Benin	
	11. Loango	
	12. Gaboon	
	13. Congo	
	14. Sierra Leone ordinary	
	15. Angola white	
	16. Kauri	

Other (chiefly spirit) varnish resins.

1. Dammar
2. Shellac
3. Mastic
4. Sandarac
5. Rosin
6. Elemi
7. Oleo-resin turpentine
8. Burgundy pitch
9. Asphaltum.

The solubility of a resin may be said to be in inverse proportion to its hardness. The hard resins and semi-hard resins are but very slightly soluble in their original condition, working in the cold, but they are easily dissolved by spirits of turpentine, linseed oil, and other solvents by previously heating them in such a manner as to cause them to lose by destructive fractional distillation 10–25 p.c. or more of their weight of a resinous oil according to the resin dealt with. The partial destructive distillation of the harder resins is necessary before they dissolve in oil or other solvents. A great deal more oil must be distilled from hard resins before they become soluble than from soft resins.

The first process in preparing an oil varnish is the selection of the 'gum'; the pieces are sorted out by hand and graded according to their colour and general soundness, and as the gum gives the hardening properties to the varnish and is the most expensive constituent, great care is exercised in its selection. The selected gum is melted or 'run,' as it is called, and then caused to unite with the oil. To this end the gum is heated in a copper vessel over a rapid fire until it is perfectly liquid; a hood is placed over the pot and connected to large flues in which the varnish 'fumes' are condensed. The oil, specially chosen for varnish making, and clarified, is heated and cautiously added to the melted gum, the whole being kept well stirred, and the heating continued until the mixture is perfectly clear. If a drying oil has not been employed, the driers—lead and manganese compounds—are now carefully sprinkled in and the mixture further boiled with continual stirring until the drier has all dissolved. The pot is then removed from the fire, and when sufficiently cooled, turpentine is added gradually, stirring all the while until the whole is thoroughly mixed. A good deal of inflammable vapour is given off during these operations, and it is therefore necessary that the varnish house be so constructed as to carry away the vapours from contact with fire.

After thinning with turpentine, the varnish is strained into a tank, and allowed to stand until clear enough for use. The time required for this varies, and as all varnishes improve by age, the longer they are tanked the better. Old varnishes produce surfaces of much greater lustre than new ones, which are usually poor and dull. The good qualities of a varnish largely depend upon the efficient mixing of the gum and oil; if these are thoroughly incorporated, the varnish will be free from spots and blemishes on its surface, while if well boiled, a varnish is said to flow more freely and to dry more rapidly. Excessive boiling, however, causes the varnish to stouten and thus to require more turpentine to bring to working consistency, and the resulting fluid being poorer in its non-volatile constituents, yields a thinner and less lustrous coat. No strict rule on this point can be given, as some oils and gums stouten more rapidly than others, and the final result has to be manipulated according to circumstances.

The drying of oil varnishes varies considerably according to their composition, and the objects to which they have to be applied; thus a gold size may dry in a few minutes, while body or coach varnishes require 12–24 hours, and even then should be allowed 2 or 3 days to harden.

Of recent years many attempts have been made to prepare oil varnishes without previous fusion of the gum.

According to Coffignier, only one has led to successful results, viz. that in which naphthalene under pressure is employed. By this process, which was patented by Terisse, gums and resins such as copals are dissolved in naphthalene without melting the resin by heating under pressure to 250°–290°; linseed oil or other drying oil is added to the solution and the naphthalene distilled off. For example, 1 kilo. of Zanzibar resin is heated with 3 kilos. of naphthalene under a pressure of 4½ atmospheres at 290° for 2 hours; 250 grms. of linseed oil are added, and the mixture again heated under pressure at 290° for 45 mins., when it is filtered if necessary. 750 grms. of linseed oil heated to 220° are next added, and the mixture is distilled, exhaustion to a partial vacuum being resorted to as the temperature approaches 280°, at which point distillation will be finished. The varnish is completed by diluting the product with 2½ kilos. of thickened linseed oil and adding the requisite amounts of spirit of turpentine and drier.

Coffignier has compared the properties of a copal from Madagascar with those of the same rendered soluble by fusion and by heating with naphthalene under pressure. The advantages of this latter method—he states—are: (1) there is no loss of weight; (2) the resulting product is pale in colour; (3) its hardness is almost unimpaired. The effects of each process in the properties of the copal are shown in the following table—

	Original Copal	Fusion Process	Naphthalene Process
Sp.gr. at 16°C. .	1·058	1·062	1·061
Melting-point .	above 300°	205°	165°
Acid value . .	93·0	68·2	68·0

Amyl acetate .	24·6	51·2	„

The manufacture of spirit varnishes is much less complicated than that of the oil preparations, the former being simply solutions of one or more resins in various solvents. On evaporation of the solvent a coating of varnish is obtained, consisting practically of the unchanged resins. The resins employed for this purpose are shellac, sandarac, soluble manilla, copal, dammar, benzoin, accroides, elemi, colophony, &c. The solution of the resins is effected either cold or hot as circumstances require, heat presenting the advantages of rapid solution and clearing, while the palest varnishes are obtained by the cold process.

To facilitate solution the gum should be kept continually agitated, thus preventing the particles of gum from forming a mass. It will be readily seen that the larger the surface of the gum exposed to the solvent the quicker will be the solution. For this purpose a revolving churn is used and the rotation keeps the particles in motion and prevents them from caking together. When the gum is all dissolved the varnishes are set aside to settle, and are ready for use almost immediately. They dry very rapidly, and are, generally speaking, harder and more brittle than oil varnishes, and as their drying is merely dependent on the evaporation of the solvent, the addition of 'driers' is not required.

Owing to the high price of shellac it is not surprising that inventors have directed their attentions to making artificial shellac, and a number of patents have been taken out, of which a few will now be mentioned.

1. *Fabr. de Prod. de Chim. organ de Laire*, 1905. Transparent synthetic resins which can be used in place of copal, amber, shellac, &c., are prepared by condensing commercial phenol or its homologues with formaldehyde or its homologues, and heating the condensation product in air, under pressure or *in vacuô*. For example, 10 parts of phenol are treated with 5–10 parts (7½ gave best results, L. M. N.) of a 40 p.c. solution of formaldehyde, and about 10 parts of 15 p.c. hydrochloric acid. The product is washed free from acid and excess of phenol, and the resulting plastic mass is heated for about half an hour at 140°.

2. *Birchoff*, 1906. An alcoholic extract of copal resin is mixed with olein, and the alcohol is distilled off from the product.

In an additional patent the use of other fatty acids, animal or vegetable oils, fats or waxes or mineral oils, soluble in alcohol, is put forward instead of olein.

3. *Englehardt and Beyersmann*, 1907. The process consists in heating resins at ordinary or increased pressure with a small quantity of aldehydes, simple or polymerised. For example, 6 kilos. of colophony, 3 kilos of gum sandarac, and 1 kilo of gum elemi, are melted, and 50 grms. of paraformaldehyde are added. The mass is heated until it becomes clear. The product is soluble in all the usual solvents.

4. *Farbenfabriken vorm. F. Bayer & Co.*, 1907. *o*-Cresol is heated for several hours at 100° with formaldehyde or substances capable of producing it, in the presence of acids and the cooled mass washed with water and purified by treatment with steam. The resulting product is a hard resin varying in colour from yellow to light brown, and melting at about 110°–128°. Used as a substitute for shellac, it gives varnishes which dry well on wood or metal. The hardness of the product depends upon the proportion of formaldehyde used.

5. *Meyer*, 1908. 400 parts of a resin or mixture of resins soluble in alcohol are treated with a solution of 60 parts of anhydrous sodium carbonate in 1000 parts of water, the mixture is boiled, then allowed to cool, filtered, and the filtrate added to a hot liquid prepared by dissolving 8 parts of stearin in 8 parts of a 33 p.c. solution of potassium hydroxide, and adding 80 parts of water. The mixture is neutralised with a mineral acid at a low temperature, the whole is stirred for some time, then heated to about 70°, filtered, and the precipitate washed and dried.

6. *Blumer*, 1908. The resinous products soluble in alkali, obtained by the condensation of phenols and formaldehyde, are treated in acid or alkaline solution with oxidising agents such as persulphates or perborates. The resulting products are odourless and differ from the original condensation products in that they are not affected by exposure to light and air. In their behaviour towards solvents the products resemble shellac.

7. *Loeschigk*, 1909. The 'foots' obtained in refining cotton-seed oil and similar products are oxidised in alkaline solution (*e.g.* by hydrogen peroxide) and then treated with acid, when the fatty matter separates from the remainder and may be recovered by means of a solvent: the residue is an amorphous resinous mass resembling shellac.

Natural varnishes or **lacquers.** Japanese lacquer (Urushi) is the milky juice that exudes from the trunk of the lacquer tree *Rhus vernicifera* (DC.). It seems that Chinese lacquer is obtained from the same tree, which is indigenous to, and growing wild in, central China at altitudes of 7000–7500 ft., and from which country it was transplanted to Japan in the remote ages. (*Cf.* LACQUER, vol. iii. 219.)

Burmese lacquer is obtained from a closely allied tree, *Melanorrhœa Usitata*.

On exposure to sunlight, or when warmed, the juice loses its moisture and becomes a brown, oily liquid to which oils, pigments, &c., are added to form the finished lacquer. Its chief constituent is urushiol. Miyama gives the following analysis for the Japanese lacquer: moisture 17·81–27·62, urushiol 64·14–77·63, gum 2·62–7·57, and nitrogenous matter 1·78–2·47. The lacquer collected during the summer is the best, and in the dried state contains 94·5 p.c. of urushiol. Chinese and Indian lacquer contain more moisture, more gum (23·5 and 37·78 p.c. in the Chinese and Japanese samples respectively), less urushiol (36·88 p.c. in inferior Chinese, and 26·39 p.c. in medium Indian). P. Sing, however, states that the principal constituent of Burmese lacquer, which he calls urushic acid, is identical with and equal in amount to the principal constituent of Japanese lacquer. The greater the proportion of urushiol, the better the quality of the lacquer, while the more gum there is the poorer the quality. The lacquer is obtained by tapping the trees, when a greyish-white juice exudes, which is collected in shells or other receptacles. These are covered with oil paper to protect the varnish from oxidation. Subsequently it is strained and exposed to the sun or heated slowly over a fire. The varnish then becomes brown and separates into two layers on standing. The upper or more fluid layer is used as a finishing coating over the ground layers. The nitrogenous matter contains an oxidising enzyme essential to the drying of the lacquer at low temperature. The drying process is retarded by raising the temperature above 50°, and it is suspended at 70°–80°, but at temperatures above 100° drying takes place without enzyme action in 4–5 hours, at 150° within 30 mins., and at 180° within 10 mins. In practice the best results are obtained by thinning the lacquer with turpentine oil or other solvent. As the layer turns brown at a high temperature, lacquers of light colour should be dried at 120°–150°, and even in the case of dark lacquers, the temperatures ought not to exceed 180°. The lacquered ware is prepared by applying several coats of an inferior quality of varnish mixed with pottery dust or dry powdered clay and rice paste. After each coat the ware is dried in a moist chamber and is then rubbed smooth with sandstone. The decorations are then applied in coloured lacquers. Since the lacquer blackens most pigments, only a limited number of coloured preparations is available. Of white pigments barium sulphate and bismuth oxychloride are used; red lacquers are prepared with vermilion and red oxide of iron; blue with prussian blue; yellow with cadmium sulphide, lead chromate and orpiment; green with chromium oxide; and black with lamp black or (to obtain a more brilliant layer) with iron powder or some compound of iron. A golden coating is obtained by lacquering the article with a mixture of 10 parts of finished lacquer, 1–3 parts of gamboge, and 5 parts of solvent and drying for about 2 hours in an oven at 120°.

Tung oil varnishes. Tung oil in combination with pigs' blood, constitutes what is known as Ningpo varnish, in colour a rich reddish-brown, and extensively used as a coating for woodwork in the Far East. It is stated to be very poisonous when moist to those who touch or even smell it. When dry, however, it is susceptible of a high polish, is very durable, and ornamental. *V.* TUNG OIL, p. 562.

In order to prepare tung oil for use in varnish making, it is necessary to heat it for some time at a high temperature, as the raw oil dries with an opaque film wanting in strength and elasticity. Great care must be exercised in heating the oil, as the whole charge may be wasted owing to sudden polymerisation which causes the mass to be changed into a more or less hard jelly which cannot be afterwards liquefied. The principal use for tung oil in varnish making is in combination with 'fused rosin' (calcium resinate), with which some very good varnishes for internal work can be produced.

According to a German patent (Sept. 8, 1908) tung oil may be converted into a product which gives a smooth, hard, lac-like coating. The oil is heated above its temperature of polymerisation, while keeping it in constant motion to prevent its solidifying. The product, which is of the same colour as the original oil, may be thickened in the same way as linseed oil, and when diluted with turpentine oil is said to yield varnishes possessing properties similar to those of the best copal varnishes.

Asphaltum. The chief asphaltums used for varnish making are manjak, gilsonite, Trinidad, Syrian, Egyptian, American, and West Indian. They are employed for preparing black japans, insulating varnishes, coach varnishes, &c.

In giving recipes for the preparation of varnishes, it is only intended to indicate the lines on which the varnish maker works, as each manufacturer has his own methods, which he guards jealously, and regards as secret processes.

Best body varnish for coachmakers. Fuse 8 lbs. of fine African gum copal, add 2 gals. of clarified oil previously heated, boil very slowly for 4 or 5 hours until quite stringy; thin with 3½ gals. turpentine, strain and tank. This gives a good elastic varnish; if required harder, substitute animé for part of the copal.

Best pale carriage varnish.

8 lbs. African copal
2½ gals. clarified oil
} boiled until stringy.

¼ lb. dried copperas
¼ lb. litharge
5½ gals. turpentine
} strained, &c.

8 lbs. animé
2½ gals. clarified oil
¼ lb. dried lead acetate
¼ lb. litharge
5½ gals. turpentine
} mix this to above while hot.

Pale oak varnish. Fuse 20 lbs. copal, and mix with 2 gals. hot drying oil, boil until it strings well, and thin with 5 gals. turpentine.

Leather varnish. Shellac 100 parts, sandarac 25, Venice turpentine 25, pale rosin 25, castor oil 20, nigrosin (spirit soluble) 15, spirit 790. The resins and colouring matters are placed in a shaking cask, and shaken with the spirit until dissolved, the varnish being then strained and bottled.

Varnish for tinfoil. 200 parts by weight of shellac are dissolved in about 700 parts of spirit, and filtered, the scum on the filter being allowed to drain, and a glass plate being used to cover the filter to prevent waste of the spirit by evaporation. This shellac varnish is incorporated, by stirring, with 100 parts of best white elemi resin and 25 parts of warm Venice turpenine. After filtration, the elemi resin left on the filter is pressed and returned to the filtrate. The resulting varnish can be stained, in the same way as the brilliant lacquers.

Coloured varnish for straw hats. A stock varnish is prepared from sandarac 35, elemi resin 54, pine resin 45, castor oil 11, and methylated spirit 850 parts. The crushed resins are suffused with the spirit in a suitable vessel, and left to dissolve, being shaken at intervals, the castor oil being added last of all. From this stock varnish, different coloured varnishes can be prepared by the addition of about 1 p.c. of aniline dye—aniline yellow, Bismarck brown, and ivory-black being the most suitable.

Inside oak varnish. Melt together 40 lbs. rosinate of lime, and 20 lbs. thickened oil, thin with 8 gals. turpentine, and add a little terebine.

Miller's india-rubber varnish. Caoutchouc 5 lbs., carbon disulphide 2½ lbs., spirit of turpentine 5 lbs. The rubber is cut into very small pieces and digested with the carbon disulphide in a glass retort in a sand-bath until complete solution is effected. Linseed oil is then heated, and while still hot, added to the above solution which, after cooling, is thinned down with the spirit of turpentine.

Dammar oil varnish. Dammar varnishes are soft, very flexible and transparent, but dry rather slowly. They are employed for inside work or upon metals, or on tissue paper, which they render transparent.

The proportion of the different ingredients varies as follows—

Dammar . . .	100 parts
Boiled linseed oil .	50–120 „
Spirit of turpentine .	200–500 „

The dammar is pulverised and dissolved hot in spirit of turpentine, and boiled linseed oil is run into the solution.

Wall paper varnish. 8 gals. linseed oil are heated to 340°F. until it ceases to froth; there are then added 32 lbs. rosin, 16 lbs. paraffin wax, 4 lbs. beeswax, and 1 pint copal varnish.

Asphaltum varnish for locks. Asphaltum 100 lbs., boiled linseed oil 5–16 lbs., spirit of turpentine 50–60 lbs. Melt the asphaltum and stir in the linseed oil and turpentine.

Asphaltum varnish for cycles. Fuse 50 lbs. Angola copal, add to it 41 lbs. boiled linseed oil. Pour the mixture into 200 lbs. of fused American asphaltum and boil until the mass draws out into threads. Then add 100 lbs. of a liquid drier and 336 lbs. spirit of turpentine.

Asphaltum varnish for wooden vessels. 200 parts asphaltum are dissolved in 900–1000 turpentine at moderate heat, and followed by 100 of elemi, 100 of yellow wax, and 100 of Venice turpentine; the whole being gently boiled for a ¼–½ an hour and strained when cold.

Varnish for rubber shoes. Hard rosin 5, shoemakers' pitch 15, Syrian asphaltum 15, coal tar 5, benzene 50, benzine 10 parts. The rosin, pitch, tar, and asphaltum are placed in a rolling cask, the benzene is poured over them, and the cask is rolled until all is dissolved, whereupon the varnish is thinned down with the benzine. Owing to the difficulty of straining the product, care should be exercised in selecting material free from impurities, otherwise the product will have to be left for some time to settle.

Varnishes for the production of drawing crayons—

(1) Sandarac 10 parts, alcohol (95 p.c.) 90 parts;

(2) Gum dammar 10 parts, alcohol 90 parts;

(3) White gum lac 5 parts, Venice turpentine 5 parts, alcohol 90 parts;

(4) Caoutchouc 2 parts, sandarac 8 parts, spirit of turpentine 45 parts, benzene 45 parts;

(5) Gutta-percha 2 parts, white gum lac 8 parts, benzene 40 parts, oil of turpentine 45 parts;

(6) Gutta-percha 3 parts, copal 7 parts, raw linseed oil 10 parts, spirit of turpentine 80 parts;

(7) Caoutchouc 1 part, dammar 35 parts, chloroform 6 parts, benzine 250 parts. A little sodium silicate is added to neutralise the acidity of the resin;

(8) An ammoniacal solution of casein, containing 10 p.c. of calcium tannate.

Best brunswick black. In an iron pot over a slow fire boil 45 lbs. asphaltum for at least 6 hours, and during the same time heat in another pot 6 gals. of oil which has been previously boiled. During the heating of the oil, introduce 6 lbs. of litharge gradually and boil it until it feels stringy between the fingers, then pour it into the pot containing the boiling asphaltum. Let the mixture boil until upon trial it will roll into hard pills, then let it cool, and mix it with 25 gals. turpentine or until it is of a proper consistency.

Photographic varnish. 1 part collodion is dissolved in 1 part of alcohol and 1½ parts of ether. The collodion must be perfectly dry before being dissolved.

Celluloid varnishes. Celluloid 5 parts, amyl acetate 16 parts, acetone 16 parts, ether 16 parts; celluloid 10 parts, amyl acetate 30 parts, acetone 30 parts, ether 30 parts, camphor 4 parts.

Dammar varnish. Dammar 20 parts, spirit turpentine 21–23 parts. This varnish is not quite transparent, but the addition of about 7½ p.c. by volume of absolute alcohol will remedy this defect.

Bookbinders' varnish. Shellac 10 parts, mastic or sandarac 9 parts, alcohol 50 parts.

Leather varnish. Shellac 10 parts, mastic, sandarac, or Venice turpentine 10 parts, alcohol 50 parts.

Floor varnish. Sandarac 50 lbs., orange shellac 80 lbs., methylated spirit 45 gals.

Paper varnish. Sandarac 50 lbs., Venice turpentine 30 lbs., methylated spirits 18 gals.

Rosin varnish for toys, &c. Rosin 20 parts, alcohol 95 p.c., 12·7–14·5 parts. To this may be added Venice turpentine 3–6 parts.

Varnish for stiffening felt hats. Water 200 parts, borax 15 parts, shellac 50 parts. The water is raised to boiling, the borax added, and then the shellac.

White label varnishes. White manilla copal 20 lbs., white rosin 10 lbs., methylated spirit 20 lbs.

Coffin varnish. Pale yellow rosin 18 lbs., manilla copal 12 lbs., methylated spirit 25 lbs. The varnish can be coloured brown or black with aniline dye.

Spirit copal varnish for leather. Methylated spirit 70 gals., Manilla copal 300 lbs., Venice turpentine 100 lbs., nigrosin 6 lbs. The nigrosin is dissolved in 3 gals. of spirit, the turpentine being dissolved in 8–10 gals. of the same solvent. The copal is dissolved in the remainder of the spirit, and the three solutions mixed.

Varnish for book leather. Grain lac 25 parts, sandarac 10 parts, white shellac 5 parts.

Dissolve in methylated spirit 82 parts. Add Venice turpentine 5 parts, filter and stir in 2 p.c. of castor oil.

Russian leather varnish. Sandarac 20 lbs., mastic 10 lbs., Venice turpentine 2 lbs., elemi 1 lb., castor oil 1 lb., birch tar oil 2 lbs., fuchsin or ponceau (for red) 1 lb., nigrosin (for black) 8 lbs., methylated spirit 20 gals.

For further information, *see* The Manufacture of Varnishes, vols. ii. and iii., by McIntosh, to which the writer is indebted for some of the above recipes.
L. M. N.

VARVICITE. *Hydrated manganese ore* $MnO_2 \cdot Mn_2O_3,H_2O$ (Rammelsberg), or

$$MnO \cdot 3Mn_2O_3,H_2O$$

(Phillips) (*v.* MANGANESE).

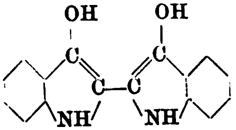
VASOTONIN. Trade name given to a combination of yohimbine and urethane which produces a fall of blood pressure, and appears to have considerable therapeutic value (Chem. Soc. Abstr. 1910, ii. 725).

VAT DYES. The term 'vat dye' is applied to those dyestuffs which, like indigo, are insoluble in water, dilute acids, and alkalis, but which, on being treated with suitable reducing agents, yield leuco compounds which are soluble in the hydroxides of the alkalis or of the alkaline earths, and in dyeing are taken up as such by textile fibres. By subsequent exposure to the air the leuco compound is oxidised on and in the fibre, with the re-formation of the original colouring matter. The characteristic fastness of the colours thus produced is, in a large measure, due to the insolubility of the dyestuff.

Indigo (*q.v.*), which was formerly the only known vat dye, is by far the most important of this series of colouring matters, and has been used in dyeing from time immemorial. A blue, dyed with it on cotton, is still referred to as a 'vatted blue,' whilst in the woollen industry, the term 'woaded blue' means a blue which is dyed either wholly or in part with indigo.

In preparing or 'setting' the indigo vat, various methods are employed in practice :

bring about the reduction of the indigotin. This is effected either by purely chemical or by bacteriological means, but in either case the product of the reaction is the same, viz. indigo white, $C_{16}H_{12}N_2O_2$, or graphically,



which dissolves in caustic soda with the formation of either the mono- or di-sodium salt ($C_{16}H_{11}N_2O_2Na$ or $C_{16}H_{10}N_2O_2Na_2$), according to the amount of caustic soda present in the bath. In aqueous solution, the mono-sodium salt has been shown to be an electrolyte, though it is not so strongly ionised as sodium chloride (Knecht and Batey, J. Soc. Dyers, 1910, 171).

The so-called chemical vats are distinguished, according to the reducing agent employed, as the copperas, the zinc, and the hydrosulphite vats. They are used in cotton dyeing, but the hydrosulphite vat also finds a limited application in wool dyeing. In the setting of any indigo vat, it is essential that the indigo should be in a finely divided state. The 20 p.c. artificial indigo paste contains the colouring matter in a sufficiently finely divided condition for the purpose, but the natural product must be ground, before use, to an impalpable powder.

The *copperas vat* depends upon the reducing action of ferrous hydroxide, and is made up of indigo, copperas and slaked lime. The lime reacting with the copperas forms ferrous hydroxide:

$$FeSO_4+Ca(OH)_2=Fe(OH)_2+CaSO_4$$

which in turn reduces the indigotin to indigo white:

$$2Fe(OH)_2+C_{16}H_{10}N_2O_2+2H_2O$$
$$=2Fe(OH)_3+C_{16}H_{12}N_2O_2$$

which then dissolves in the excess of lime present to form the soluble calcium salt. In the copperas vat, there is always a large amount of sediment, and to prevent this coming into contact with the goods during dyeing, deeper vessels are required than with the other chemical vats. At the present time, the copperas vat is not largely used in this country, the main reason being that its use involves a considerable loss in indigo.

In the *zinc vat*, zinc powder is the reducing agent. For satisfactory working, this should contain not less than 80 p.c. of metallic zinc. The vat is set with indigo, zinc powder and lime (or caustic soda). The reduction may be regarded as taking place as follows:

$$C_{16}H_{10}N_2O_2+Zn+2NaOH$$
$$=C_{16}H_{10}N_2O_2Na_2+Zn(OH)_2$$

although, according to Binz (Chem. Ind. 11, 1902), it is probable that combination of the indigotin with the alkali takes place first, with the formation of a compound $C_{16}H_{10}N_2O_2\cdot 2NaOH$, which then reacts with the zinc, forming the same products as shown in the above equation.

This vat is the one which is most largely used in cotton dyeing.

The *hydrosulphite vat* depends upon the reduction of the indigotin by sodium hydrosulphite, which is usually prepared by stirring zinc dust into commercial sodium bisulphite, in the proportion of a pound of the former to a gallon of the solution; and after allowing to stand for some time, adding to the solution an excess of milk of lime. The so-called 'stock vat' or concentrated vat is made by dissolving the indigo in this muddy liquid. (A product of this kind, containing about 3 p.c. of indigotin, was formerly sold under the name of 'reduced indigo.') This stock vat serves either for making up or for replenishing the dye vat proper. The reduction by means of sodium hydrosulphite may be regarded as taking place according to the following equation:

$$C_{16}H_{10}N_2O_2+Na_2S_2O_4+4NaOH$$
$$=C_{16}H_{10}N_2O_2Na_2+2Na_2SO_3+2H_2O$$

By employing artificial indigo paste, caustic soda, and the solid commercial sodium hydrosulphite, which is now placed on the market in an almost pure condition and at a reasonable price, it is possible to obtain a vat practically free from sediment.

The dyeing of cotton in the indigo vat is in itself a comparatively simple operation, although the management of the vat requires careful supervision and considerable practical experience. In hank dyeing, the wetted-out hanks are immersed in the vat and turned by hand under the surface of the liquid until thoroughly impregnated with the vat liquor, after which they are withdrawn and wrung, the liquor being returned to the vat. The hanks are then exposed freely to the air, in order to allow of the oxidation of the indigo white to indigotin. By repeating this operation several times, the shade becomes successively darker, and its depth will therefore depend upon the number of 'dips' in one and the same or in different vats. Although it is possible to obtain a dark shade by a single dip in a strong vat, this is not practised, because it would result in a large proportion of the indigo being loosely fixed and much of it would be lost in washing off; besides, the resulting blue would 'rub off' very badly. If lime has been used to render the vat alkaline, the goods are soured, after dyeing, in dilute sulphuric acid. In the dyeing of cotton warps and of piece goods, the material is guided through the vat by means of submerged rollers, so that it passes many times up and down between the time of entering and leaving; excess of liquor is expressed at the point of exit by means of a pair of squeezing rollers. In case it is desired to give the pieces two or more 'dips' in the same vat, they are stitched together, end to end, so as to form a continuous band, and, after leaving the vat, are passed up and down over a series of loosely running wooden rollers (which are usually placed immediately above the vat in order to economise space) for a sufficient length of time to allow of the oxidation of the indigo white before they re-enter the vat.

The reason why indigo white should be taken up from its aqueous solution by the cotton fibre is imperfectly understood. It has been suggested that it is a case of mutual precipitation between colloids, but as it has been definitely shown (see above) that indigo white lacks some of the most essential properties of a colloid, this theory cannot hold good. In any case, the affinity of indigo white for cotton is but slight as, when once taken up, it can be completely removed by continued washing with cold, air-free water, whereas a boiling solution of dilute caustic soda removes it from the fibre almost instantaneously. The affinity of indigo white for cotton appears to be similar in character to that of tannic acid for this fibre (Knecht and Nair, *ibid.* 1912, 28).

If the cotton to be dyed in indigo or other vat dyes has been previously mercerised, darker shades are obtained than on untreated cotton. The same applies with regard to indigo and certain indigoid dyestuffs if the cotton has been previously dyed manganese bronze or has been steeped for some time in strong nitric acid (see MERCERISING). In the latter case, the increase in depth is due in a greater measure to partial nitration of this fibre than to the mercerising effect of the acid.

Indigo dyed on cotton is sometimes associated with other colours. Thus, if a light shade of indigo is 'topped' or subsequently dyed chrome yellow, pleasing and very fast shades of green result. The old-fashioned 'fast black' was obtained by a combination of a heavy shade of indigo and catechu brown. The dyeing of a black of this description was practised by the Incas of Peru previous to the Spanish invasion.

Indigo dyed on cotton is usually regarded as fast to washing and to light. Strictly speaking, however, these qualities are only relative, for by repeated washing in soap or continued exposure to light, the colour (especially in light shades) gradually fades. But in fading it always retains the characteristic colour of indigo and does not change, as is the case with most other blues, to an unsightly grey or drab. It is noteworthy that the fastness of indigo to light may be considerably enhanced by treating the dyed fabric for a few minutes in a boiling dilute solution of copper sulphate.

In Egypt, Persia, India, China, Japan, and other Eastern countries, where dyeing is still almost entirely a household industry, fermentation vats are generally used for cotton dyeing. Such vats are occasionally used in this country for the dyeing of goods for certain markets. The fermentation vat imparts a certain peculiar smell to the goods dyed in it, and unless they possess this smell, the natives in some markets will not accept them as indigo-dyed.

The dyeing of *wool* with indigo differs from the dyeing of cotton in that whereas cotton is invariably dyed cold, the temperature of the vat for wool dyeing must be maintained at from 50° to 55°. Another point of difference is that in the case of wool, the time of immersion in the vat has to be much longer than in the case of cotton.

For wool dyeing, especially where fermentation vats are used, natural indigo is generally preferred to the artificial product.

Only one of the vats generally used in cotton dyeing can be used with advantage in wool dyeing, viz. the hydrosulphite vat. This is set with indigo, sodium hydrosulphite and ammonia. Although the cost of working this vat is greater, as far as materials are concerned, than that of the fermentation vats, this is more than compensated by its greater output. It is, however, only suitable for light to medium shades of blue.

The fermentation vats, of which a considerable variety are in use in different countries and sometimes in one and the same country, might appear at first sight to depend for their action upon different principles. But it is probable that in all cases the action depends upon a bacterial decomposition (butyric acid fermentation) of the carbohydrates, in which hydrogen is generated. Various substances containing carbohydrates, such as bran, flour, sugar, treacle or dates, are used along with lime, potash, or soda for the purpose. The setting and management of fermentation vats require considerable skill and experience, and in all large works these matters are under the sole control of the 'blue dyer,' upon whose intelligence and efficiency the prosperity of the works largely depends.

The fermentation vat mostly used in this country is the so-called *woad vat*, which is set in a vessel having a capacity of from 1600 to 3000 gals. with indigo, woad, bran, madder and lime, the temperature being maintained at 60°. The fermentation will have set in, as a rule, in from three to five days, and the vat will then be ready for use. Once set, a woad vat simply requires replenishing, from time to time, with the necessary additions of indigo, lime, and bran, and may remain in use continuously for many years. It should be explained that in this vat, the woad, which in former times (before the introduction of indigo from India) was the only indigo-bearing dyestuff used in this country and on the Continent, now acts solely by virtue of the bacteria which it contains, for in commercial woad there is, at the present day, no indigotin, the whole of the colouring matter having been destroyed by bacterial action.

Dyed on wool, indigo resists the action of light better than when dyed on cotton.

The disulphonic acid of indigotin, which is obtained by heating the dyestuff to about 100° with excess of concentrated sulphuric acid, is known commercially as indigo extract or, in the form of its sodium salt, as indigo carmine. It dyes wool 'at the boil' from a bath containing sulphuric acid and Glauber salt a much brighter shade of blue than that obtained in the vat, but the colour is neither fast to light nor to soap, and goods so dyed cannot be classed as being dyed with indigo.

Silk is seldom dyed in the indigo vat, although fast and pleasing shades can be obtained in this way.

Indigo in printing. In textile printing, notably in calico printing, indigo may be regarded as the most important individual dyestuff in use at the present time. This is partly due to the favour which it finds with the public as being pleasing to the eye and relatively fast, and partly to the variety of styles to which it lends itself in this branch of textile colouring. Effects are obtained with indigo in printing in three entirely different ways, viz. by direct printing, by the discharge process, and by the resist process.

In direct printing, the indigo is not printed on to the fabric in the reduced condition (a process which would obviously suggest itself at once to any one acquainted with its properties and its application in dyeing) owing to practical difficulties which this mode of application entails. The process in actual use is the so-called glucose process, in which glucose and caustic soda serve as the reducing agent. The pieces are first prepared by padding in a solution of glucose and are then dried. The finely ground indigo is made up with strong caustic soda thickened with maize starch and British gum. This is printed on to the prepared calico and the goods are run through a rapid ager containing air-free moist steam, the time required for this treatment being about half a minute. During the steaming, the indigo is reduced to indigo white which dissolves in the caustic soda and penetrates into the fibres. By subsequent exposure to air, the indigo white slowly oxidises back to indigo blue. The operations of preparing in glucose and drying may be dispensed with by adding to the printing colour a suitable reducing agent such as the formaldehyde compound of sodium sulphoxylate (hydrosulphite N.F.). This has no action on indigo in the cold, but reduces it on steaming for two to three minutes. The goods are then exposed to the air as in the glucose process.

In the discharge process, which lends itself to a greater variety of effects, the whole piece is first dyed to the required depth of blue in the vat and the colour is then removed locally either by destroying it by means of oxidising agents or by reducing it to the leuco compound and removing this by means of boiling dilute alkali. The former process, which is the one chiefly employed, consists in printing sodium chromate, suitably thickened, on to the blue fabric. After printing, the goods are run through a warm solution of sulphuric and oxalic acids, when in consequence of the liberation of chromic acid, the indigo is oxidised to isatin and this is removed in the subsequent washing, a white pattern on a blue ground resulting. For coloured discharges, the chromate is mixed with albumen and a suitable pigment, such as vermilion or chrome yellow, and the goods are run, after being printed, through the mixture of acids at a temperature high enough to coagulate the albumen. The fixation of the pigment and the destruction of the indigo thus take place simultaneously. The process is capable of many modifications. Thus, in order to obtain a bright scarlet on a blue ground, the indigo dyed fabric is padded first with an alkaline solution of β-naphthol, dried and printed with a colour containing diazotised *p*-nitraniline and sodium dichromate. The *p*-nitraniline red thus formed resists the action of the chromic acid formed when the pieces are run through acid and a bright red on a blue ground results.

Indigo may also be discharged by printing on sodium nitrate and running the goods through warm sulphuric acid of 100°Tw. (Freiberger's process).

In the reduction discharge process, the pieces are printed with the formaldehyde compound of sodium sulphoxylate with or without the addition of a catalyst such as anthraquinone. They are then steamed in the rapid ager to reduce the indigo and immediately run through a boiling bath of caustic soda, soda ash, or sodium silicate. The indigo white is thus completely removed and there is no tendering of the discharged places, as is invariably the case when the chromate discharge is used. In place of sulphoxylates, titanous thiocyanate may be used for this class of discharge.

In the resist process, the fabric is first printed with a mechanical or chemical 'resist,' and is then dyed in the vat. Wherever the resist has been printed no colour is fixed, and a white pattern on a blue ground results. In the East, and also to some extent in European print works, wax is used as the resist. After dyeing it is removed by soap and alkali. When the goods are handled (as in dyeing) after the wax has been printed on, the latter cracks in places so that in the dyeing some of the indigo liquor penetrates through the fissures, with the result that fine blue veins are afterwards seen in the pattern. This defect is characteristic of all true Battick work, which the modern printers are at pains to imitate. The resist mostly used at the present time is a very thick colour containing copper sulphate, lead nitrate, and China clay, usually thickened with flour and British gum and with or without the addition of such mechanical resists as tallow or rosin. As with the wax resist, the dyeing is best conducted in the zinc vat.

By increasing the amount of lead nitrate in this resist so as to exceed its equivalent in copper sulphate, and running the goods after dyeing through sodium dichromate, lead chromate is formed in the resisted parts and a yellow pattern on a blue ground results.

Vat Dyes other than Indigo.

Although it has long been known that indirubin (an isomeride of indigotin which occurs in almost all natural indigos) can be dyed in the same manner as indigo, it has never found any technical application, partly on account of the shade it yields being undesirable and partly for other reasons. Indophenol, which was discovered in 1882 by Koechlin and Witt, is also a vat dye, and although it was a commercial article in the 90's it was never much used, mainly because it produced loose colours, and it is now entirely obsolete.

The enormous development in the vat colour industry that has taken place during the last few years may be traced, on the one hand, to the discovery of indanthrene blue by Bohn in 1901, and on the other hand to the synthesis of thioindigo red by Friedländer in 1905. At the present time there are well over one hundred individual dyestuffs which may be strictly classed as vat dyes, without taking into account the large number of sulphide colours (*q.v.*) which, in a sense, might also be classed as vat dyes. It would obviously be out of place to embody the whole of our present knowledge of the vat dyes in this work, as that would require an amount of space which would not be commensurate with the general interest attaching to the subject. In the following, it will therefore be understood that the examples given are only typical of the various classes. For further information on the subject of vat dyes, see Engi, Chem. Zeit. 1908, 1178; Bohn, Ber. 1910, 987; Staeble, Chem. Zeit. 1910, 731 *et seq.*; Friedländer, *ibid.* 1911, 640; Masera, Färber-Zeit. 1911, 336; Grandmougin and Battegay, Els. Text. Bl. 1910, Malloch, J. Soc. Dyers, 1910, 26; Ermen, *ibid.* 1910, 56 and 236; E. de Barry Barnett, *ibid.* 1913, 183; Knecht, Rawson and Loewenthal, A Manual of Dyeing; Knecht and

Fothergill, The Principles and Practice of Textile Printing.

These vat dyes, other than indigo, may be classed under two headings, viz. as (*a*) indigoid dyestuffs, and (*b*) anthraquinonoid dyestuffs. The former come into the market under various trade names such as indigos of various brands, thioindigos (Kalle & Co.), helindone colours[1] (Meister Lucius & Brüning), ciba colours (Soc. of Chem. Ind., Basel), while the latter are generally classed as indanthrene colours (Badische Co.), algole colours (F. Bayer & Co.) or cibanon colours (Soc. of Chem. Ind., Basel). *V.* INDIGOID DYESTUFFS, Vol. III.

The bromo derivatives of indigotin are brought into the market under different designations, such as indigo pure R.B.N., ciba blue, indigo K2B, and generally yield, in dyeing and in printing, either redder or greener shades of blue than indigo itself, according to the amount of bromine which they contain. Thus, indigo 2R is 5 bromindigo, ciba blue 2B is 5 : 7 : 5′ : 7′-tetrabromindigo, and indigo KG consists mainly of 4 : 5 : 7 : 4′ : 5′ : 7′-hexabromindigo. The 6 : 6′-dibromindigo synthesised by Friedländer, and shown by him to be identical with the Tyrian purple of the ancients, is not a commercial article.

Of homologues of indigo, the 7 : 7′-dimethyl indigo (Indigo G) and naphthindigo (Ciba Green G) are so far the only commercial representatives.

Thioindigo red B or thionaphthene indigo

$$\mathrm{C_6H_4}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C}=\mathrm{C}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C_6H_4}$$

was discovered in 1905 by Friedländer and is obtained by fusing *o*-carboxyphenylthioglycollic acid with caustic potash. The discovery of this product marks the beginning of a new era in the history of organic colouring matters, for it opened up a new field and has already resulted in the introduction of a large number of new and valuable vat dyes. Like artificial indigo and most other commercial vat dyes, thioindigo red B comes into the market in the form of a 20 p.c. paste. The pure colouring matter is readily obtained from the dried paste by crystallisation from benzene or toluene and is obtained in well-defined dark red crystals. Its solution in benzene is red and shows a characteristic intense yellow fluorescence. In concentrated sulphuric acid it dissolves with a bluish-green colour; but on pouring the solution into water, the original dyestuff separates. By warming with fuming sulphuric acid, it is sulphonated and the soluble sulphonic acid thus obtained dyes wool from an acid bath a bluish shade of red. Unlike indigo, thioindigo red is not affected by oxidising agents, remaining unaffected by chromic acid, alkaline ferrocyanide and bleaching powder; whilst, on the other hand, it is more readily reduced than indigo. It has been shown that the reduction of thioindigo red to its leuco compound is analogous to that of indigo, two molecules of hydrogen or their equivalent being required for one molecular weight of the dyestuff (Knecht, J. Soc. Dyers, 1906, 156). Like indigo white, the leuco compound dissolves readily in caustic alkalis, forming a yellow vat from which it is taken up by the cotton fibre, the red reappearing on exposure to the air.

Of derivatives of thioindigo red, the following may be mentioned:

Thioindigo red B.G (dichlorthionaphthene indigo) $\mathrm{C_6H_3Cl}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C}=\mathrm{C}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C_6H_3Cl}$; thioindigo red 3 B (dichlordimethylthionaphthene indigo)

$$\genfrac{}{}{0pt}{}{\mathrm{CH_3}}{\mathrm{Cl}}>\mathrm{C_6H_2}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C}=\mathrm{C}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C_6H_2}<\genfrac{}{}{0pt}{}{\mathrm{CH_3}}{\mathrm{Cl}};$$

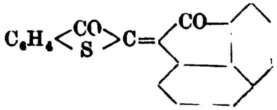
thioindigo violet 2B (dichlordimethyldimethoxythionaphthene indigo); *thioindigo orange R* (6 : 6′-diethoxythionaphthene indigo); and *thioindigo gray* (7 : 7′-diaminothioindigo)

Thioindigo scarlet R

$$\mathrm{C_6H_4}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{S}}>\mathrm{C}=\mathrm{C}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{NH}}>\mathrm{C_6H_4}$$

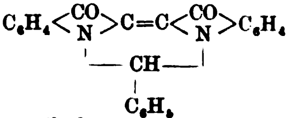
obtained by the action of hydroxythionaphthene on isatin may be regarded as a hemi-thioindigo. When acted upon by bromine in sulphuric acid solution it yields a dibromo derivative which is placed on the market under the name of thioindigo violet K. The tribromo-6-amino derivative represents thioindigo brown G.

Ciba scarlet G (also known as thioindigo scarlet 2G) is a non-nitrogenous product, obtained by the condensation of hydroxythionaphthene with acenaphthene quinone and has the constitution



By the bromination of this dyestuff, *Ciba red R* results.

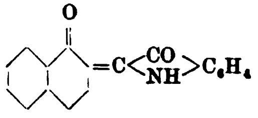
Of other indigoid dyestuffs, mention may be made of *Ciba yellow*, which is obtained by boiling indigo with benzoyl chloride and copper powder and to which the constitution



$$\mathrm{C_6H_4}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{N}}>\mathrm{C}=\mathrm{C}<\genfrac{}{}{0pt}{}{\mathrm{CO}}{\mathrm{N}}>\mathrm{C_6H_4}\quad(\mathrm{N},\mathrm{N}{-}\mathrm{CH}{-}\mathrm{C_6H_5})$$

has been ascribed.

Alizarin indigo 3R, obtained by the condensation of *a*-naphthol with *a*-isatinchloride, is supposed to possess the following *ortho*-quinonoid structure



and is, in a sense, also indigoid in character. The corresponding derivative of *a*-hydroxyanthranol is known as *helindone blue 3GN*.

The indigoid dyestuffs all behave very much like indigo towards reducing agents, *i.e.* they yield leuco compounds (corresponding to indigo white) which dissolve readily in caustic alkalis, and in this condition show affinity for the textile fibres. The affinity of the different dyestuffs for the cotton fibre varies, however, in each case, so that their successful application

---

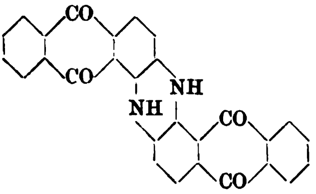
[1] Some helindone colours (especially browns and yellows) are anthraquinonoid in character.

especially in the production of mixed shades, requires a considerable amount of practical experience. The reducing agent employed for these colouring matters (in fact for all vat dyes other than indigo) is invariably sodium hydrosulphite, for although it is not the most economical, it is the most effective and convenient reagent for the purpose and yields vats which are free from sediment. In principle, the dyeing of cotton with these dyestuffs is the same as the dyeing of indigo in the hydrosulphite vat. The range of shades obtainable contains almost every colour of the spectrum, and some of these vie in brilliancy with the basic colours. Most of the colours are characterised by great fastness, and are in this respect superior to indigo. Hitherto no indigoid black has been produced.

Although originally applied to dyeing and printing on cotton and other vegetable fibres, methods have been devised by which these colouring matters can be successfully applied in wool dyeing, by substituting ammonia for the caustic soda in the vat or neutralising the effect on the fibre of the caustic soda by the addition of some soluble oil (see H. Kämmerer, J. Soc. Dyers, 1913, 68).

In calico printing, the indigoid dyestuffs can be applied by methods similar to those employed for indigo, with the exception of the chromic acid discharge, which cannot be used owing to these dyestuffs being either not affected at all by chromic acid, on the one hand, or yielding imperfect discharges on the other. They can, however, be discharged by means of the formaldehyde compound of sodium hydrosulphite. For further information on the use of these colours in calico printing, see N. Evans, J. Soc. Dyers, 1913, 144.

Anthraquinonoid dyes. The first of these dyestuffs brought into the market was *indanthrene blue*, a product formed by the action of molten caustic potash on β-aminoanthraquinone, and possessing the constitution



It is a dark blue compound insoluble in water, dilute acids, alkalis and most ordinary organic solvents. It can, however, be obtained in well-defined crystals from its solution in quinoline or by sublimation. Powerful oxidising agents convert it into the azine (containing 2 atoms of hydrogen less), but this is readily reconverted into the dyestuff by the action of reducing agents. Acted upon by hydrosulphite in presence of an excess of caustic soda, indanthrene blue yields a blue vat from which cotton and other vegetable fibres can be dyed in exceedingly fast shades of blue. The composition of the leuco compound of indanthrene blue is not known with certainty, but it is evident from the behaviour of anthraquinone, alizarin and the non-nitrogenous anthraquinonoid dyes that reduction takes place in the —CO— group, resulting in the formation of compounds analogous to hydroxyanthranol

$$C_6H_4{<}\genfrac{}{}{0pt}{}{CH(OH)}{CO}{>}C_6H_4$$

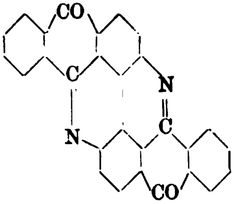
or dihydroxyanthranol

$$C_6H_4{<}\genfrac{}{}{0pt}{}{CH(OH)}{CH(OH)}{>}C_6H_4$$

according to the extent of the reduction. To what extent the four —CO— groups of indanthrene blue suffer reduction in the formation of a 'vat' is not known at the present time, and this applies also to the other anthraquinonoid dyes.

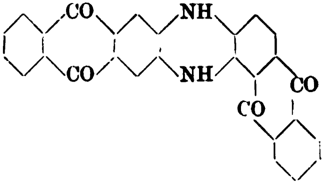
Halogen derivatives (Cl and Br) of indanthrene blue are also commercial articles and yield in dyeing greener shades of blue which are faster to bleaching powder than ordinary indanthrene blue (*v.* INDANTHRENE).

Flavanthrene or *indanthrene yellow* is formed as a by-product in the manufacture of indanthrene blue, but is obtained in much better yield, according to D. R. P. 138119, by the oxidation of β-aminoanthraquinone with antimony pentachloride in boiling nitrobenzene, or by the action of manganese peroxide in nitric acid solution (D. R. P. 141355). Flavanthrene has been shown to possess the constitution



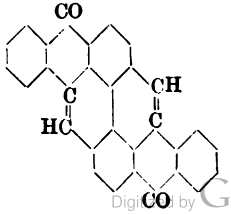
and comes into the market in the form of a yellow paste. With caustic soda and hydrosulphite (or other reducing agents) it yields a deep cobalt-blue vat from which cotton takes up the leuco compound and is dyed, after exposure to the air, a fast yellow. The halogen derivatives of flavanthrene dye redder shades than flavanthrene itself.

By the condensation of alizarin with 2:3-diaminoanthraquinone, a compound having the following constitution



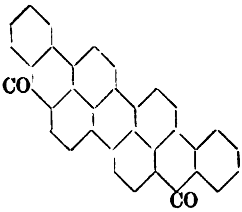
is obtained, halogen derivatives of which come into the market under the names *algol blue* and *algol green*.

That nitrog and ensulphur are not essential constituents of vat dyes is shown by the fact that *pyranthrone* or *indanthrene golden orange G*



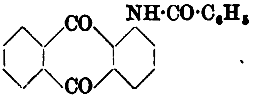
obtained by the condensation of two molecules of 2 : 2′-dimethyl-1:1′-dianthraquinonyl behaves in exactly the same manner towards reducing agents and in dyeing as the other vat dyes of this series. By the introduction of halogens into this dyestuff the shade is altered towards red. Thus, the brominated product represents *indanthrene scarlet G.*

By the alkaline condensation of two benzanthrone (or benzanthronequinoline) molecules, vat dyes are obtained, the simplest representative of which (*violanthrene* or *indanthrene violet*) is represented by the constitution

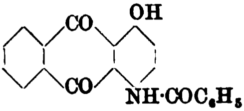


which, when nitrated, yields *indanthrene green* (D. R. PP. 172609, 185221).

Some of the dyestuffs of this series are derivatives of aminoanthraquinones and are represented by comparatively simple constitutional formulæ. Thus, *algol yellow N.G* is α-benzoylaminoanthraquinone



whilst *algol pink R* is the benzoyl derivative of a hydroxyaminoanthraquinone



It is noteworthy that the arylaminoanthraquinones do not act as vat dyes for cotton, although some of them are, in the form of their sulphonic acids, valuable wool dyes. In this connection it may be mentioned that whereas alizarin is quantitatively reduced by titanous chloride in presence of Rochelle salt to dehydroalizarin, alizarin orange cannot be reduced further than to β-aminoalizarin.

The anthraquinonoid dyes are employed in cotton dyeing much in the same way as the indigoid dyes. Generally speaking, they require, however, a much larger amount of caustic soda in the vat and are not dyed cold, but at a temperature of 50°–60°. In dyeing light shades, the dyebath is generally exhausted under these conditions. After dyeing, the goods are soaped hot, a process which in most cases considerably enhances the brilliancy of the colour. With some of the colours, the fastness to bleaching powder is increased by steaming under pressure after dyeing. Although no black anthraquinonoid dyestuff is known, a black of extraordinary fastness can be obtained on cotton by dyeing it first indanthrene green and then subjecting the dyed material to the action of bleaching powder. The colours obtained with the dyes of the anthraquinoid series are generally somewhat faster to light than those obtained with the indigoid dyes. They are not applicable to wool dyeing owing to the necessity of keeping the vat strongly alkaline with caustic soda with the inherent risk of damaging or destroying the fibre.

In calico printing, the anthraquinonoid dyes are largely used for some of the best classes of work. The usual method of using the indanthrene colours is to print a colour containing the vat dye, stannous chloride, ferrous sulphate and thickening, and after drying to pass rapidly through a hot strong solution of caustic soda. The fixation may also be effected in one operation by using a printing colour containing the vat dye, hydrosulphite-formaldehyde and soda ash, after which the goods are steamed for 5–7 mins. in air-free steam. The glucose process, as described for indigo, is also applicable to vat dyes in general.

By the introduction of the vat dyes the public demand for fast colours, especially in dyed and printed cotton and linen fabrics, has been met, and it is now possible to obtain by means of them almost any shade fast to washing, light, perspiration, rubbing, and even bleaching powder. It should, however, not be taken for granted that a vat dye is of necessity a fast colour. Those on the market have, however, generally been carefully tested and selected by the makers and usually possess this attribute. Many of the vat dyes are so fast that they can be put through the full bleaching process for cotton pieces without suffering any material diminution of intensity and brilliancy, and advantage is taken of this in the production of white fabrics with coloured stripes or figures. Whereas it was formerly necessary, in order to obtain these effects, to bleach both warp and weft before weaving, the bleaching is now effected in the piece and considerable economy is thus effected. With the exception of indigo, the vat dyes are still too expensive to admit of their being employed for any but the best class of work. This is due in part to the high cost of manufacture, but more especially to the fact that most of them are tinctorially weak, as compared with, for instance, the basic and direct cotton colours. Even indigo itself shows this drawback, but most of the other vat dyes show it to a much greater extent.

For the identification of the vat dyes in dyed and printed fabrics, see A. G. Green and G. H. Frank (J. Soc. Dyers, 1910, 83), also G. E. Holden (*ibid.* 1909, 47). Indigo can readily be distinguished from the other vat blues by dissolving the fabric in warm 80 p.c. sulphuric acid. The solution is poured into water and filtered through a small asbestos filter. After washing and drying, the residue on the filter is heated to about 100° with concentrated sulphuric acid and again poured into water and filtered. Under these conditions, the indigo is sulphonated and passes into the filtrate with a bright blue colour, whereas the other vat blues remain unaffected.

VAUQUELINITE. Native lead and copper chromate.

VEGETABLE BUTTER *v.* BASSIA OILS; also OILS, FIXED, AND FATS.

VEGETABLE ETHIOPS. A form of charcoal obtained by the incineration of *Fuci.*

VEGETABLE FATS *v.* Oils, fixed, and fats.

VEGETABLE IVORY. The fruit of *Phytelephas macrocarpa* (Ruiz. and Pav.) found in Columbia, South America.

VEGETABLE PARCHMENT *v. Parchment paper*, art. Cellulose.

VEGETABLE SPERMACETI. *Insect wax, v.* Waxes.

VEGETO-ALKALOIDS. The vegetable alkaloids are nitrogenous carbon compounds possessing basic properties. They occur in plants, usually as the salts of organic acids. The greater number of them contain carbon, hydrogen, nitrogen, and oxygen, but in a few cases oxygen is absent, *e.g.* nicotine, coniine. Chemically the vegetable alkaloids belong almost entirely to six groups: (1) derivatives of piperidine, *e.g.* nicotine, coniine; (2) derivatives of a condensed pyrrolidine—piperidine nucleus, *e.g.* hyoscyamine, cocaine; (3) derivatives of quinoline, *e.g.* quinine, strychnine; (4) derivatives of *iso*quinoline, *e.g.* papaverine, corydaline, morphine, thebaine; (5) derivatives of cyclic nuclei containing 2 nitrogen atoms, *e.g.* caffeine, theobromine, pilocarpine; (6) derivatives of aliphatic amines, *e.g.* choline.

The discovery of these bodies is due to the German pharmacist, Sertürner, who, about the year 1807, isolated from opium a basic, salt-forming substance, to which he gave the name 'morphium.' The principal physiological action of opium was found to be exerted by this substance, which is now called morphine. The isolation, from other medicinal plants, of similar compounds capable of producing the physiological effect of the plants themselves quickly followed the discovery of morphine, and in the next few years strychnine and brucine were isolated from *Strychnos Nux-vomica* seeds, and quinine and cinchonine from cinchona bark by Pelletier and Caventou. The first volatile alkaloid, coniine, was obtained from hemlock in 1827 by Giesecke, and in the following year nicotine was described by Posselt and Riemann. At the present day a very large number of vegetable alkaloids are known, and the list is being extended every year.

Distribution and mode of formation. Plants yielding alkaloids are widely distributed throughout the vegetable kingdom, but it is remarkable that of the two great sub-divisions of flowering plants, viz. monocotyledons and dicotyledons, the former yield very few alkaloids, the great majority being derived from dicotyledonous plants. In the latter sub-division certain orders are poor in alkaloids, *e.g. Labiatæ*, and *Graminaceæ*, whilst the *Ranunculaceæ*, *Solanaceæ*, and *Papaveraceæ* are typically rich in alkaloids. The gymnosperms, ferns, and fungi furnish few alkaloids, and the algæ and the mosses are devoid of such constituents.

Two chief views have been held as to the function of alkaloids in plants: (1) that they are ultimate products of metabolism, and (2) that they are plastic materials capable of further utilisation by plants in which they occur; but the whole of the recorded facts cannot be accounted for by either theory.

The proportion of alkaloid generally reaches its maximum when the plant is mature.

Alkaloids are distributed throughout the various members of a plant, being found in the leaves, flowers, and seeds, as well as in the root and bark, but the amounts found in the different parts may show great variation. When a plant dies down after flowering, the alkaloid often accumulates in the root, whilst during the growth of a tree the alkaloids appear to be gradually deposited in the bark, and have, therefore, been compared to the excreta of animals.

Very little is known as to the actual mode in which alkaloids are formed in plants. It has been suggested that they may originate in (1) decomposition of proteins, (2) in the condensation of pyrones with ammonia to form pyridine derivatives, (3) in the condensation of ketones and aldehydes with ammonia. The experimental investigation of the natural mode of formation of alkaloids is beset with the great difficulty that the intermediate compounds, the precursors of alkaloids, are present only in minute quantity, and are hard to separate unchanged from the various plant constituents with which they are associated (*cf.* Czapek, Biochemie der Pflanzen, 1905, ii. 267; Pictet, Arch. Sci. phys. nat. 1905, 243, 329; 1906, 244, 389; Tunmann, Arch. Pharm. 1910, 248, 644; Winterstein und Trier, Die Alkaloide, 1910, 263).

Plants often contain several alkaloids, which, however, are generally found to be more or less closely related in chemical structure.

Method of extraction. Various processes are employed for the extraction of alkaloids from plants, the nature of the process depending partly on the properties of the alkaloid which has to be extracted, and partly on the nature of the other substances which occur with it. In the older processes the finely powdered part of the plant (root, bark, &c.) was exhausted by percolating it with dilute sulphuric or hydrochloric acid, which decomposed the natural organic salt of the alkaloid, forming a sulphate or hydrochloride readily soluble in water. The alkaloid was precipitated by the addition of an alkali to this solution; or the plant was incorporated with lime or magnesia to liberate the alkaloid, and the dry mass exhausted with a suitable solvent, generally alcohol. Now that it is known how readily some alkaloids are hydrolysed and otherwise altered by strong acids, the use of mineral acids has been abandoned except in a few cases, and where extraction with an acid medium must be resorted to, dilute solutions of acetic or tartaric acid are employed. In general the natural alkaloidal salts are now extracted directly with alcohol or other organic solvent, and after the solvent has been distilled off, water or very dilute sulphuric acid is added, and from this solution the alkaloid is liberated by the addition of a weak alkali, and extracted by means of an indifferent solvent, such as chloroform or ether, from which it may be recovered by distilling off the solvent. From such residues the pure alkaloid is obtained by fractional crystallisation of suitable derivatives. In the cases of certain very stable alkaloids admixture of the plant with lime or magnesia and extraction of the dry mixture with an organic solvent can be safely employed, and in other cases (*e.g.* caffeine in tea) extraction with boiling water may be resorted to. Ammonia or an alkali bicarbonate is to be recommended for precipitating alkaloids in place of potash or soda. The use of animal charcoal for decolorising alkaloidal solutions requires caution, since some alkaloids adhere to this substance, more especially when they are in the free state.

When the alkaloid is volatile the parts of the plant are mixed with very dilute alkali and steam distilled; the liberated alkaloid condenses with the steam, and may be extracted with a suitable solvent from the aqueous distillate.

Further information respecting the extraction of alkaloids from plants will be given in connection with the account of each alkaloid. The worker should also consult the original memoirs there referred to.

Purification and separation of alkaloids. An alkaloid having been isolated in a pure state (*i.e.* free from non-alkaloidal substances), it is necessary to obtain evidence of its being a single substance before its composition and properties are investigated. This may be done by crystallising the alkaloid or one of its salts in several fractions, the properties of each fraction being examined; they should, of course, be identical if the alkaloid is homogeneous. The melting-point is conveniently made use of for this purpose, or, when this is not sharply defined, some other physical property, *e.g.* rotatory power, solubility, &c. The so-called colour reactions are of very little value for this purpose.

In cases where a distinctive physical property cannot be found, combustions must be made of the different fractions in order to determine whether their composition is identical. The aurichlorides have frequently proved useful as a means of characterising and purifying alkaloids, since these compounds, as a rule, are easily prepared, crystallise well, and melt sharply, each at a different temperature, even when the alkaloids themselves are closely related. An aurichloride having been obtained of constant melting-point, *i.e.* not changed by recrystallisation, the corresponding alkaloid may be regenerated from it by precipitating the gold from it, suspended or dissolved in water, with the slightest possible excess of hydrogen sulphide, filtering, expelling any trace of hydrogen sulphide, and then recovering the alkaloid from the solution of the hydrochloride in the usual manner. For further information concerning the methods of separating and characterising alkaloids, *see* Dunstan and Read on the alkaloids of Japanese aconite (Chem. Soc. Trans. 1900, 77. 45); Dunstan and Brown on hyoscyamine in *Hyoscyamus muticus* (Linn.) (*ibid.* 1899, 75, 72); Watt on the alkaloids of *Senecio latifolius* (Banks and Soland) (*ibid.* 1909, 95, 466); Jowett on the alkaloid of *Aconitum heterophyllum* (Wall.) (*ibid.* 1896, 69, 1518).

Physical and chemical characters and constitution of the vegetable alkaloids. The vegetable alkaloids are, in general, solid substances, most of them being crystalline. A small number are liquid (coniine, nicotine, pilocarpine, &c.); some of these, being volatile, distil with water, although alone they boil at much higher temperatures, often without appreciable decomposition. The crystalline alkaloids generally melt with decomposition, but sufficiently sharply to permit of the melting-point being used for their identification.

Most of the vegetable alkaloids are optically active. The greater number are lævorotatory. A few are dextrorotatory, notably aconitine, pilocarpine, and cinchonine. A few of the alkaloids are optically inactive, *e.g.* piperine, berberine, and papaverine. The alkaloidal salts generally exhibit the same kind of optical activity as the alkaloids themselves; but the salts of the lævorotatory nicotine and narcotine are dextrorotatory, whilst the dextrorotatory aconitine furnishes lævorotatory salts.

The majority of the vegetable alkaloids are insoluble, or very sparingly soluble in water; their best solvent is alcohol. Usually they are also dissolved by chloroform, less generally by ether, benzene, or amyl alcohol, sometimes by light petroleum. Their aqueous solutions are frequently strongly alkaline to litmus, and precipitate hydroxides from solutions of metallic salts. Certain of the alkaloids, *e.g.* morphine, are soluble in alkali hydroxides.

Like ammonia, the vegetable alkaloids combine directly with acids to form salts, which are usually crystalline, and often soluble in water or alcohol, but generally insoluble in chloroform or ether.

In their combinations with acids the alkaloids nearly always act as monacidic bases, even when they contain two atoms of nitrogen in the molecule, that is to say, they unite in only one proportion with acids to form stable salts. To this rule, however, notable exceptions exist, especially among the cinchona alkaloids; *e.g.* quinine is a diacidic base.[1]

The ordinary salts will be alluded to later in connection with the particular alkaloids. Attention will be directed here to certain alkaloidal compounds, which are important in connection with the detection and identification of the vegetable alkaloids.

Auric chloride $AuCl_3$ combines with the hydrochlorides of the alkaloids, forming well-defined aurichlorides,[2] usually composed of one molecule of the alkaloidal hydrochloride and one molecule of auric chloride, $B\cdot HCl\cdot AuCl_3$. These compounds are frequently sparingly soluble in water, and are thrown down as pale-yellow

---

[1] The nomenclature of alkaloidal salts is in a very unsatisfactory state. They were originally named after the similar compounds of ammonia, viz. hydrochlorate, sulphate, nitrate, etc. These names have long ceased to be used for the ammonia compounds, which are now regarded as salts of 'ammonium,' viz. ammonium chloride, ammonium sulphate, etc. No analogous change has, however, been made in the names of alkaloidal salts, the salts of morphine, for example, being still called morphine hydrochlorate (or hydrochloride), morphine sulphate, etc., and not morphium chloride, morphium sulphate, etc. The only change that has been made is to alter 'hydrochlorate,' not into 'chloride' but into 'hydrochloride,' which has the advantage of indicating that the compound contains the extra molecule of hydrochloric acid, and in this respect differs from the metallic chlorides. This reform has been extended to the 'hydriodates' and 'hydrobromates,' which are now called 'hydriodides' and 'hydrobromides.' It has not, however, been applied to the other salts (sulphate, nitrate, etc.), which, though similarly constituted, are not termed 'hydrosulphates,' 'hydronitrates,' etc.

[2] Compounds of the alkaloidal hydrochlorides with auric chloride will be called *auri-chlorides*, the corresponding compounds with platinic chloride, *platinichlorides*, and with mercuric chloride, *mercuri-chlorides*. A compound of the alkaloid itself with auric chloride will be termed an *auric chloride compound*, or simply (for example) pilocarpine auric chloride, and the similar *mercuric chloride compound*, pilocarpine mercuric chloride.

precipitates, when an aqueous solution of auric chloride is mixed with an aqueous solution of the alkaloidal hydrochloride. Sometimes the aurichlorides are soluble in water. They may be crystallised from their solution in alcohol or water acidulated with hydrochloric acid. As has been pointed out already, these crystalline compounds melt sharply, and are often useful in characterising alkaloids. They are also conveniently employed in ascertaining the formula-weights of the alkaloids, the gold being determined by ignition. In cases where neither the alkaloid nor one of its ordinary salts can be crystallised or readily obtained pure, the percentage composition of the alkaloid may be arrived at from the results of the combustion of the pure aurichloride. When only small quantities of material are available, it is possible to determine the composition of the aurichloride without losing the alkaloid, by the following process. A weighed quantity of the aurichloride (0·5–1 grm.) is dissolved or finely suspended in water, and decomposed by the gradual addition of a very slight excess of aqueous hydrogen sulphide. The resulting precipitate of gold sulphide is washed, dried, ignited, and the residue of gold weighed. The filtrate and washings are made alkaline with ammonia, and the alkaloid extracted by agitation with chloroform or ether; the residue of alkaloid left on the evaporation of the solvent is dried and weighed. The alkaline, aqueous solution is now strongly acidified with nitric acid, and the chlorine precipitated with silver nitrate in the ordinary manner and weighed as silver chloride.

Auric chloride combines with the alkaloids themselves, as well as with their hydrochlorides, forming auric chloride compounds $B{\cdot}AuCl_3$, which are stable crystalline salts composed of one molecule of the alkaloid and one of auric chloride. They are obtained by mixing together alcoholic solutions of the alkaloids and auric chloride. The determination of the melting-point and composition of these compounds furnishes an additional means of characterising certain alkaloids. So far these compounds have only been prepared from a few alkaloids (Dunstan and Ince, Chem. Soc. Trans. 1891, 59, 271; Hardy and Calmels, Bull. Soc. chim, 1887, [ii.] 18, 220), but there is reason to believe that they are obtainable from many of the vegetable alkaloids.

Aurichloro derivatives of caffeine and certain of the benzaoconines have been obtained. They are produced from the aurichlorides by the loss of 2 mol. props. of hydrogen chloride, and may therefore be regarded as derived from the alkaloid by the replacement of one atom of hydrogen by the group $AuCl_2$ (Dunstan and Shepheard, Chem. Soc. Trans. 1893, 63. 201; Dunstan and Harrison, *ibid.* 1893, 63, 443; Dunstan and Read, *ibid.* 1900, 77, 57).

Bismuth iodide or *cadmium iodide* dissolved n aqueous potassium iodide precipitates alkaoids, and may be used as a general alkaloidal eagent like iodine solution or Mayer's reagent *see* below).

Iodine, dissolved in aqueous potassium iodide precipitates the solutions of most alkaloidal alts, and may be used as a general reagent for he detection of alkaloids. The precipitate is eddish-brown when the solution is dilute, but in strong solutions this precipitate at once aggregates to a greenish-black mass. The precipitates consist of the periodides of the alkaloids ($B{\cdot}HI{\cdot}I_2$ or ${\cdot}I_4$). Many of them crystallise well from alcoholic solution, the crystals being green by reflected, and red by transmitted, light. The alkaloids may be recovered from these periodides most safely by dissolving the latter in aqueous sodium thiosulphate, then adding excess of ammonia, and shaking out the alkaloid with ether or chloroform (Dunstan and Ransom, Pharm. J. 1883–4, [iii.] 14, 623).

Mercuric chloride also forms double salts with certain alkaloids.

Mercuric iodide dissolved in aqueous potassium iodide (Mayer's reagent) produces an abundant yellowish-white, flocculent precipitate of indefinite composition, in solutions of nearly all alkaloidal salts, and for this reason is one of the best general reagents for detecting alkaloids (Mayer, Chem. News, 1863, 7, 159). The precipitation of an alkaloid by this reagent is often quite complete if certain precautions are taken, the character of which varies with different alkaloids, some being completely precipitated only when the alkaloidal solution is neutral, others requiring that the solution shall be faintly acid to complete the precipitation, while a few alkaloids are only precipitated by this reagent from a strongly acid solution. Although the precipitates (double iodides of mercury and alkaloids) produced by this reagent have not a constant composition, yet the quantity of a known alkaloid contained in a given solution may be volumetrically estimated by its means, the precipitatory power of a cubic centimetre of the solution under prescribed conditions having been previously found for the alkaloid in question. The alkaloids may be recovered from these precipitates by suspending them in water, and passing hydrogen sulphide through the mixture. After filtering off the mercuric sulphide, a solution of the alkaloidal hydriodide is obtained, from which the alkaloid may be liberated and extracted in the usual way.

Phosphomolybdic acid, prepared by adding excess of nitric acid to a solution of sodium phosphomolybdate, produces a white precipitate with solutions of most alkaloidal salts (Sonnenschein, Annalen, 1857, 104, 45). *Phosphotungstic acid* acts similarly. Alkalis liberate the alkaloids from these precipitates.

Picric acid precipitates the solutions of most alkaloidal salts, and the yellow picrates may often be crystallised; in very acid or dilute solutions the precipitation of the picrate is frequently not observed. The alkaloids may be recovered from the picrates by decomposing them with aqueous alkali, and extracting the liquid with ether or chloroform.

Picrolonic acid (4-nitro-1-*p*-nitrophenyl-3-methyl-5-pyrazolone) in alcoholic solution furnishes with many alkaloids crystalline derivatives of definite melting-point (Warren and Weiss, J. Biol. Chem. 1907, 3, 327), and may be used as a means of identification in such cases.

Platinic chloride combines with alkaloidal hydrochlorides to form platinichlorides

$$(B{\cdot}HCl)_2PtCl_4,$$

which are sometimes precipitated when aqueous solutions of those substances are mixed, but are generally more soluble than the corresponding aurichlorides. They frequently crystallise well, and are useful in determining the formula-weights of the alkaloids, the platinum being estimated by carefully igniting the salt and weighing the metallic residue.

Tannic acid also precipitates solutions of many alkaloidal salts.

For a full discussion of these and other alkaloidal reagents, *see* Allen's Commercial Organic Analysis, 4th ed., vol. vi.

Detection of alkaloids. The presence of an alkaloid may be detected by the use of the general reagents referred to above, which, as a rule, afford most delicate indications when added to a slightly acidified solution. The evidence thus obtained must be supplemented by isolation of the alkaloid and an examination of its chief chemical properties. Many of the alkaloids give characteristic colour reactions when mixed with sulphuric acid and other reagents; these will be alluded to later in connection with each alkaloid. It should, however, be remembered that, with possibly one or two exceptions, colour reactions cannot be relied on as conclusive proof of the presence of a particular alkaloid, since very similar colour reactions are often given by more than one alkaloid, and, on the other hand, distinctive colours are frequently obscured by the presence of impurity.

For the detection and separation of alkaloids in toxicology special processes are used, which in principle are the same as those employed to extract alkaloids from plants, but are longer, and differ somewhat in the mode of procedure. The methods devised by Stas-Otto, by Dragendorff, and by Erdmann and Uslar are those usually resorted to. For details of these methods the following works should be consulted: Husemann, Toxicologie; Dragendorff, Gerichtlich-Chemische Ermittelung von Giften; Taylor's Toxicology, edited by Stevenson; Wynter Blyth, Poisons, their Effects and Detection, 1909; Kippenberger (Zeitsch. anal. Chem. 1895, 34, 294).

It will not be possible within the limits of this article to give an account of every known vegetable alkaloid, but only to allude to most of those which are of practical importance in some connection or another, because they are manufactured on a large scale, or are used largely in medicine, or on account of the familiarity of the plants which yield them, &c. Even in these cases it will be impossible to do much more than afford an outline of the principal properties, reactions, modes of preparation, detection, and estimation of the most important alkaloids. Processes for the extraction, detection, and estimation of important alkaloids, as a rule, will be somewhat fully described, whilst questions relating to their chemical constitution, although not exhaustively discussed, will, in important instances, be dealt with sufficiently to make clear the character of the evidence that has been utilised in effecting the remarkable progress of the last 20 years. References will be given to the original memoirs from which fuller information may be obtained.

Since it is not possible to adopt a chemical classification of more than a few of the vegetable alkaloids, and as a system of classification founded on that of the plants which yield them would be without significance in a chemical dictionary, the principal alkaloid will be considered in alphabetical order, excep in cases where several alkaloids are furnishe by one plant, when these will, as a rule, be con sidered in connection with the principal alkaloid

ACONITINE AND THE ACONITE ALKALOIDS.

The alkaloids of the various species o *Aconitum* which have been examined chemicall fall into two sharply differentiated groups. Th first, of which aconitine itself is the type, include a number of highly toxic alkaloids (*the aconi tines*), which are diacyl esters of a series o polyhydroxy bases containing four methoxy groups (*the aconines*). The following 'aconi tines' are known:—

Aconitine from *Aconitum Napellus* (Linn.),
*Bikh*aconitine from *Aconitum spicatum* (Stapf.),
*Ind*aconitine from *Aconitum chasmanthus* (Stapf.),
*Jap*aconitine from Japanese aconite roots,
*Pseud*aconitine from *Aconitum deinorrhizum*.

It is probable that Rosendahl's *lappa*conitine, Makoshi's *jes*aconitine, and Dragendorff's *lyc*aconitine, which are all toxic, belong to the group of 'aconitines,' but this cannot be definitely stated until they have been furthe investigated.

The second group contains non-toxic alkaloids typified by atisine and comprises the following:—

Atisine from *Aconitum heterophyllum* (Wall.),
*Palm*atisine from *Aconitum palmatum* (D. Don.).

Aconitine, the principal alkaloid of *Aconitum Napellus* (Linn.), the common monkshood or wolfsbane, in which it occurs along with its decomposition products, benzaconine and aconine, was isolated by Geiger and Hesse (Annalen, 1833, 7, 276), but first obtained in a crystalline state by Groves (Pharm. J. 1860, [ii.] 8, 121). Wright and Luff assigned to it the formula $C_{33}H_{43}O_{12}N$ (Chem. Soc. Trans. 1877, 31, 143; 1878, 33, 151, 318), and later Dunstan and his collaborators (*ibid.* 1891, 59, 271; 1892, 61, 385) adopted for it the formula $C_{33}H_{45}O_{12}N$, a slight modification of that used by Wright and Luff (*l.c.*). Until now almost all the work on crystallised aconitine had been done on alkaloid prepared from the roots of *Aconitum Napellus* grown in England. In 1894 analyses of the crystallised aconitine of commerce, probably from roots of *Aconitum Napellus* grown in Germany, were made by Freund and Beck, who assigned to the alkaloid the formula $C_{34}H_{47}O_{11}N$ (Ber. 1894, 27, 433), and their results were confirmed by Schulze (Arch. Pharm. 1906, 244, 167), who preferred the formula $C_{34}H_{45}O_{11}N$.

There are certain slight but well-marked differences in physical constants between aconitine and its derivatives from English aconite roots, as investigated by Dunstan and his predecessors in England, and those from German aconite roots, which make it probable that the two are distinct. These differences are summarised on p. 631.

Schulze has asserted that the alkaloid from German roots must be identical with that from English roots, since the two are crystallographically identical (*l.c.* 169), but it is known that identity of crystalline form is not always a

Source of alkaloid	Aconitine					Benzaconine	
	Composition	M.p.	$[\alpha]_D$	B·HBr, m.p.	$B{\cdot}HAuCl_4$, m.p.	B·HCl, m.p.	B·HBr, m.p.
English roots	$C_{33}H_{45}O_{12}N$	188·5°	+10·47 to 11·1 in alcohol	163°	Three forms α=135·5° β=152·0° γ=176°	268°	282°
German roots	$C_{34}H_{45}O_{11}N$	196°–197°	+12° 32′	163° 206° (anhydrous)	Two forms α=136° β=149°–152°	Two forms α=217° β=268°	273°

guarantee of identity of composition. Indaconitine is almost precisely similar in crystalline form to aconitine (Dunstan and Andrews, Chem. Soc. Trans. 1905, 87, 1622), although there can be no doubt that these two alkaloids are chemically distinct.

The aconitine of commerce of the present day is best represented by Schulze's formula $C_{34}H_{45}O_{11}N$.

Preparation. The finely-powdered root is exhausted with amyl alcohol mixed with three times its volume of wood spirit. From this extract the wood spirit is distilled under reduced pressure, leaving the whole of the alkaloids dissolved in the residue of amyl alcohol from which they are removed by agitation with dilute (1 p.c.) sulphuric acid. This acid aqueous liquid is shaken with ether to remove ether-soluble, non-basic substances, then made alkaline with dilute ammonia and the liberated alkaloids extracted with ether. The aconine remains dissolved in the water, the aconitine with some benzaconine passing into the ether. The ethereal solution is washed with a small quantity of water and evaporated. The residue is converted into hydrobromide by dissolving it in dilute hydrobromic acid, care being taken to avoid excess of acid. The exactly neutral liquid is evaporated to a small volume and allowed to crystallise. The aconitine hydrobromide is recrystallised until of constant melting-point, and then is converted into the alkaloid by the addition of a slight excess of ammonia to its aqueous solution, the alkaloid being extracted by ether in the usual way. The washed ethereal solution is dried by agitation with fused calcium chloride and evaporated. The small crystals, which are deposited as the ether evaporates, may be recrystallised from dry alcohol by the addition of ether.

Properties. Colourless, anhydrous hexagonal prisms, belonging to the rhombic system (Chem. Soc. Trans. 1891, 59, 288; Ber. 1894, 27, 722; Arch. Pharm. 1906, 244, 169). Easily soluble in chloroform or benzene, less readily in absolute alcohol or ether, very slightly soluble in water, almost insoluble in light petroleum. The aqueous solution is alkaline to litmus; m.p. 196°–197°. Dextrorotatory; in alcoholic solution $[\alpha]_D = +12° 32'$. Salts lævorotatory.

Aconitine is a most powerful poison (Cash and Dunstan, Phil. Trans. 1898, 190, 239). Between $\frac{1}{70}$ and $\frac{1}{50}$ of a grain has been recorded as a fatal human dose.

The ordinary salts of aconitine crystallise well. The hydrobromide $B{\cdot}HBr,2\frac{1}{2}H_2O$ is lævorotatory, $[\alpha]_D = -30{\cdot}47°$; m.p. 163° or 206° (anhydrous). The hydriodide, m.p. 226°, is crystalline, and sparingly soluble in water. The aurichloride $B{\cdot}HAuCl_4$ is thrown down as a pale-yellow amorphous precipitate from solutions of the hydrochloride and auric chloride. It crystallises from alcohol with $3H_2O$ and then melts at 135·5°; the anhydrous salt has m.p. 152° (Freund, Ber. 1894, 27, 724).

Reactions. When aconitine is heated at its melting-point it loses 1 mol. of acetic acid and furnishes a new alkaloid *pyraconitine*, and this, on hydrolysis with water or acids, furnishes 1 mol. of benzoic acid and a new base *pyraconine*.

When a salt of aconitine is heated with water, a molecule of acetic acid is split off and the alkaloid *benzaconine*, which also occurs in aconite roots, and has been variously known as *picraconitine*, *isaconitine*, *napelline*, &c., is formed. Benzaconine, in turn, by hydrolysis with alkalis or acids, furnishes 1 mol. of benzoic acid, and the alkaloid *aconine*, which is the final basic product of the hydrolysis. Aconitine is therefore *acetylbenzoylaconine*.

On treatment with acetyl chloride aconitine furnishes a triacetyl derivative (m.p. 207°–208°). When heated with hydriodic acid it yields four mols. of methyl iodide, and must therefore contain four methoxyl groups. It also contains a methyl group linked to nitrogen. On oxidation with acid permanganate aconitine yields acetaldehyde and *oxonitine* $C_{23}H_{29}O_9N$ (Carr, Chem. Soc. Trans. 1912, 101, 3241).

It is probable from the foregoing summary of the chief reactions of aconitine that it may be regarded as derived from a parent base $C_{21}H_{34}N$.

$$\begin{matrix}AcO\\BzO\end{matrix}\!>C_{20}H_{21}NMe<\!\begin{matrix}(OH)_3\\(OMe)_4\end{matrix}$$

Aconitine.

Detection and estimation. The identification of the alkaloid is best accomplished by the determination of the physical constants of its characteristic derivatives, but where minute quantities only are available the characteristic precipitate given with potassium permanganate (Dunstan and Carr, Pharm. J. 1896, [iv.] 2, 122), and the peculiar tingling sensation produced when even very dilute (1 in 4000) solutions of aconitine are applied to the tip of the tongue may be utilised, but these reactions are equally applicable to the 'aconitines' as a class. Various methods for the estimation of aconitine in aconite roots have been proposed, but, as a rule, these estimate some benzaconine and aconine as well as aconitine, and are useless as methods of determining the medicinal value of the roots, since this depends essentially on the amount of aconitine present. Aconitine itself may be estimated by hydrolysing it and determining the amount of acetic acid formed, but this method cannot be used for the estimation of aconitine in the plant since the latter contains other substances which yield acetic acid (Dunstan and Tickle, Pharm. J. 1896, [iv.] 2, 126).

BENZACONINE $C_{32}H_{43}O_{10}N$ has also been called *isaconitine*, *picraconitine*, and *napelline* by various observers. It occurs with aconitine in aconite roots, and may be isolated from the mother liquors from which aconitine hydrobromide has been crystallised, and is also produced by heating an aqueous solution of an aconitine salt in a closed tube.

Properties. Amorphous, dextrorotatory base furnishing crystalline, lævorotatory salts. The hydrobromide crystallises in prisms, m.p. 273° (Schulze, *l.c.*); the hydrochloride occurs in two forms, m.p. 217° and 268° (Freund and Beck, Ber. 1894, 27, 729); the hydriodide has m.p. 204°–205°. The aurichloride has m.p. 135°. According to Schulze (*l.c.*) the tetracetyl derivative of benzaconine is identical with triacetylaconitine.

With the removal of the acetyl group from aconitine the characteristic toxicity disappears and benzaconine is not toxic in the ordinary sense. In some respects its physiological action is antagonistic to that of aconitine (Cash and Dunstan, Phil. Trans. 1898, 190, 239).

ACONINE $C_{25}H_{39}O_9N$, the ultimate basic product of the hydrolysis of aconitine or benzaconine is amorphous and dextrorotatory, but yields hygroscopic lævorotatory salts. It is readily soluble in water, alcohol, or chloroform, but almost insoluble in ether or light petroleum. The hydrochloride $B \cdot HCl, 2H_2O$ has m.p. 175°–176°, and the hydrobromide $B \cdot HBr, 1\frac{1}{2}H_2O$, m.p. 225°. The aurichloride is amorphous. The base furnishes a crystalline tetracetyl derivative. m.p. 231°–232° (Schulze, *l.c.* 1906, 244, 177). On oxidation with permanganate it furnishes acetaldehyde and an amorphous base, but with chromic acid it yields methylamine and two new bases $(OH)_4C_{20}H_{19}O(OMe)_3NMe$ and $C_{19}H_{20}O_4(OMe)_3(NMe) \cdot CO_2H$, the former an amino alcohol and the latter an amino acid (Schulze, Arch. Pharm. 1908, 246, 281; *cf.* Carr, Proc. Chem. Soc. 1912, 28, 253; Brady, *ibid.* p. 289).

Bikhaconitine $C_{36}H_{51}O_{11}N$. The characteristic alkaloid of *Aconitum spicatum* (Stapf.), the roots of which constitute 'bikh'-aconite of North Western India. It may be extracted from the roots by a slight modification of the process described under aconitine. The alkaloid was isolated and characterised by Dunstan and Andrews (Chem. Soc. Trans. 1905, 87, 1636).

Properties. Separates from ether in button-shaped masses, m.p. 118°–123°, or from alcohol on addition of water in white granules containing $1H_2O$, m.p. 113°–116°. Dextrorotatory ($[\alpha]_D^{20°} = +12 \cdot 21°$ in alcohol). The salts are lævorotatory. The hydrochloride $B \cdot HCl, 5H_2O$, m.p. 159°–161° (anhydrous), crystallises and has $[\alpha]_D - 8 \cdot 86°$ (in water); the hydrobromide $B \cdot HBr, 5H_2O$, m.p. 173°–175° (anhydrous) is crystalline and has $[\alpha]_D - 12 \cdot 42°$; the hydriodide $B \cdot HI, 2\frac{1}{2}H_2O$, m.p. 193°–194° (anhydrous), crystallises in needles, and is sparingly soluble in water; the aurichloride $B \cdot HAuCl_4$ crystallises in canary-yellow needles, m.p. 232°–233°. Like all the 'aconitines' bikhaconitine is highly toxic.

Reactions. Bikhaconitine contains six methoxyl groups. When heated at 180° it loses 1 mol. of acetic acid and forms pyrobikhaconitine (amorphous, giving amorphous salts). It undergoes hydrolysis in two stages, thus—

i. $C_{36}H_{51}O_{11}N + H_2O = C_{34}H_{49}O_{10}N + C_2H_4O_2$
Bikhaconitine. Veratroylbikhaconine. Acetic acid.

ii. $C_{34}H_{49}O_{10}N + H_2O = C_{25}H_{41}O_7N + C_9H_{10}O_4$
Veratroylbikhaconine. Bikhaconine. Veratric acid.

Bikhaconitine, therefore, resembles pseudaconitine (*see* p. 634) in furnishing veratric acid in the second stage of its hydrolysis. The alkaloid is, therefore, acetylveratroylbikhaconine, and may be represented thus—

$$[MeO]_4C_{21}H_{27}ON{<}\begin{matrix}OAc\\OVe\end{matrix}$$

VERATROYLBIKHACONINE $C_{34}H_{49}O_{10}N$, the first basic hydrolytic product of bikhaconitine is amorphous and dextrorotatory ($[\alpha]_D = +29 \cdot 9°$ in alcohol). The hydrochloride and hydrobromide are amorphous, but the hydriodide crystallises in rosettes of needles, m.p. 189°–190°. The nitrate forms rosettes of hexagonal prisms, m.p. 175°–178°. The aurichloride forms orange-yellow rosettes of prismatic crystals, m.p. 145°–148° (anhydrous).

BIKHACONINE $C_{25}H_{41}O_7N$, the final basic product of the hydrolysis of bikhaconitine or veratroylbikhaconine. It is dextrorotatory and amorphous, but unlike the 'aconines' as a class, furnishes well-defined crystalline salts. The hydrochloride occurs in rosettes of crystals, m.p. 125°–130°, the hydrobromide in tetragonal prisms, m.p. 145°–150°, and the aurichloride

$$B \cdot HAuCl_4, 3H_2O$$

in glistening rhombic plates, m.p. 129°–132° (hydrated), or 187°–188° (anhydrous).

Indaconitine $C_{34}H_{47}O_{10}N$ is the characteristic alkaloid of *Aconitum chasmanthum* (Stapf.), a species indigenous to India, where it is known as 'Mohri.' It may be extracted from the roots by the process described under aconitine. The alkaloid was isolated and characterised by Dunstan and Andrews (Chem. Soc. Trans. 1905, 87, 1620).

Properties. Indaconitine crystallises in several characteristic forms, but can be obtained in crystals, which are almost identical in form with those of aconitine (*see* above). It has m.p. 202°–203°, and is dextrorotatory $[\alpha]_D = +18° 17'$. The salts crystallise well and are lævorotatory. The hydrochloride $B \cdot HCl, 3H_2O$, m.p. 166°–171° (anhydrous), $[\alpha]_D = -15° 50'$, forms rosettes of silky needles; the hydrobromide, m.p. 183°–187° (anhydrous), $[\alpha]_D = -17° 16'$, crystallises from water in large hexagonal prisms; the aurichloride $B \cdot HAuCl_4, CHCl_3$, m.p. 147°–152°, forms rosettes of needles from chloroform by addition of ether.

Indaconitine gives a characteristic crystalline precipitate with potassium permanganate, the crystals being smaller and less stable than those given by aconitine. Like aconitine, indaconitine is highly toxic (Cash and Dunstan, Proc. Roy. Soc. 1905, B, 76, 468).

Reactions.—Indaconitine contains four methoxyl groups. On hydrolysis it behaves in a manner analogous to aconitine, yielding in the first stage acetic acid and indbenzaconine, the latter, on further hydrolysis, furnishing benzoic acid and pseudaconine. The latter is also the final basic hydrolytic product of pseudaconitine (p. 634), so that pseudaconitine differs only from indaconitine in containing a veratroyl group in place of a benzoyl group. Indaconitine is therefore acetylbenzoylpseudaconine, and may be represented thus—

$$[\mathrm{MeO}]_4\mathrm{C}_{21}\mathrm{H}_{27}\mathrm{O}_2\mathrm{N}{<}\begin{matrix}\mathrm{OAc}\\ \mathrm{OBz}\end{matrix}$$

INDBENZACONINE (Benzoylpseudaconine)

$$C_{32}H_{45}O_9N,$$

the first basic product of the hydrolysis of indaconitine is amorphous and dextrorotatory, $[\alpha]_D = +33° 35'$, but furnishes well crystallised, lævorotatory salts. The hydrobromide

$$B{\cdot}HBr,2H_2O,$$

m.p. 247° (anhydrous) forms rosettes, the hydrochloride $B{\cdot}HCl$, m.p. 242°–244°, octahedra, and the aurichloride, m.p. 180°–182°, orange rosettes. The aurichloro derivative, m.p. 234°–235°, forms minute colourless crystals. On hydrolysis with alkalis indbenzaconine furnishes benzoic acid and pseudaconine (*see* p. 634). As is the case with aconitine the removal of the acetyl group virtually abolishes the toxicity of indaconitine and indbenzaconine is scarcely poisonous in the ordinary sense (Cash and Dunstan, *l.c.*).

PYROINDACONITINE $C_{32}H_{43}O_8N$ exists in two forms. The α- form is produced when the free base, indaconitine, is heated at its melting-point. It is amorphous, but furnishes a crystalline hydrobromide $B{\cdot}HBr$, m.p. 194°–198°, which, like the alkaloid itself, is dextrorotatory. The aurichloride is amorphous. When indaconitine hydrochloride is heated at its melting-point it furnishes β-pyroindaconitine, which is also amorphous, but yields a crystalline hydrobromide, m.p. 248°–250°.

Japaconitine $C_{34}H_{49}O_{11}N$ is the characteristic alkaloid of Japanese aconite roots of commerce. It may be prepared from this source by the method described under aconitine. According to Makoshi the roots of true *Aconitum Fischeri* (Reichb.) contain jesaconitine (*see* below), whilst japaconitine is furnished by the roots of a variety grown in Hondo (Arch. Pharm. 1909, 247, 270), which Holmes regards as *A. uncinatum*, var. *japonicum*. Japaconitine has been frequently investigated, and up to 1900 the balance of evidence was in favour of the view that it was identical with aconitine (Mandelin, Arch. Pharm. 1885, 223, 97, 129, 161; Lübbe, Inaug. Diss. Dorp. 1891; and Freund and Beck, Ber. 1894, 27, 720). The dissimilarity of the two alkaloids had already been asserted by Wright and Luff (Chem. Soc. Trans. 1879, 35, 387), and was finally proved by Dunstan and Read (*ibid.* 1900, 77, 45). Their conclusions have been confirmed by Makoshi (*l.c.*).

Properties. Forms rosettes of prismatic needles, m.p. 204·2°, and is crystallographically distinct from aconitine and pseudaconitine. Dextrorotatory ($[\alpha]_D^{18·5} = +23·6°$ in alcohol), but furnishes lævorotatory salts. The hydrochloride $B{\cdot}HCl,3H_2O$, m.p. 149°–150°, $[\alpha]_D = -23·8°$ in water, crystallises from alcohol and ether in rosettes of hexagonal plates; the hydrobromide $B{\cdot}HBr,4H_2O$, m.p. 172°–173°, crystallises similarly; the aurichloride exists in two modifications, the α- form, m.p. 231° is stable and crystallises in opaque, golden-yellow needles; the β- form, m.p. 154°–160°, is unstable and crystallises in yellow prisms. The physiological action of japaconitine is qualitatively identical with that of aconitine than which it is slightly more toxic (Cash and Dunstan, Proc. Roy. Soc. 1902, 68, 379).

Reactions. Japaconitine, unlike aconitine, reacts with methyl iodide to form a crystalline methiodide, and from this methyljapaconitine $C_{34}H_{48}O_{11}N{\cdot}CH_3$, m.p. 206°, rosettes of colourless needles may be obtained. Japaconitine forms a crystalline triacetyl derivative, m.p. 166°, and contains four methoxyl groups. When heated alone it furnishes 1 mol. acetic acid and 1 mol. pyrojapaconitine (*v. infra*). On hydrolysis it also behaves in a manner analogous to aconitine, giving first 1 mol. each of acetic acid and japbenzaconine. The latter may be further hydrolysed to benzoic acid and japaconine. Japaconitine is therefore acetylbenzoyljapaconine, and may be represented thus (D. a. R.)—

$$\begin{matrix}[\mathrm{HO}]_3\\ [\mathrm{OMe}]_4\end{matrix}{>}\mathrm{C}_{21}\mathrm{H}_{\ 4}\mathrm{NH}{<}\begin{matrix}\mathrm{OAc}\\ \mathrm{OBz}\end{matrix}$$

JAPBENZACONINE $C_{32}H_{47}O_{10}N$, the first basic hydrolytic product of japaconitine, also occurs with this alkaloid in Japanese aconite roots. Unlike the analogous benzaconine, it crystallises, though with difficulty, m.p. 183°. Dextrorotatory ($[\alpha]_D = +40·16°$ in alcohol). The salts crystallise well, and are lævorotatory; the hydrochloride $B{\cdot}HCl,H_2O$, m.p. 253°, forms minute rosettes; the aurichloride $B{\cdot}HAuCl_4$ crystallises from alcohol and then melts at 219°. The colourless aurichloro derivative

$$C_{32}H_{46}O_{10}N{\cdot}AuCl_2,$$

m.p. 178°, forms rosettes of needles (D. a. R. *l.c.*).

JAPACONINE $C_{25}H_{41}O_9N$, the final basic product of the hydrolysis of japaconitine or japbenzaconine, is amorphous, and hygroscopic and yields hygroscopic salts, which crystallise with difficulty. Its solutions reduce gold chloride and Fehling's solution. The base is dextrorotatory (D. a. R. *l.c.*).

PYROJAPACONITINE $C_{32}H_{45}O_9N$ is formed by heating japaconitine at its melting-point when 1 mol. of acetic acid is evolved. Crystallises in colourless needles, m.p. 167°–168°, is lævorotatory ($[\alpha]_D = -65·89°$ in alcohol), and furnishes well-crystallised salts; the aurichloride

$$B{\cdot}HAuCl_4,$$

m.p. 160°–161° (from chloroform), or 188°–189° (from alcohol and ether). On hydrolysis by alkalis the base gives rise to 1 mol. benzoic acid and a new base *pyrojapaconine*, which is amorphous, hygroscopic, and lævorotatory, and furnishes amorphous salts.

Jesaconitine $C_{40}H_{51}O_{12}N$, isolated by Makoshi (Arch. Pharm. 1909, 247, 251) from 'Bushi' roots obtained from a species of aconite, *A. Fischeri* (?), found in the island of Hokkaido or Jeso in Japan. It was not obtained crystalline, but a crystalline triacetyl derivative, m.p. 213°, was prepared. On hydrolysis jesaconitine yielded benzoic acid, anisic acid, and aconine, identical with that obtained from aconitine, so that it is regarded as benzoylanisoylaconine. Jesaconitine is highly toxic (Makoshi, *l.c.*).

Lappaconitine $C_{34}H_{48}O_8N_2$, obtained by Rosendahl (J. Pharm. Chim. 1896, [vi.] 4, 262) from the roots of *Aconitum septentrionale* (Koelle). It crystallises in hexagonal prisms, m.p. 205°, is dextrorotatory, shows a reddish-violet fluorescence in ether, and furnishes crystalline salts. On hydrolysis it yields two bases; one, m.p. 98°, readily soluble, and the other. m.p. 106°, nearly insoluble in ether; at the same time an acid, m.p. 114°, giving a purple colour with ferric chloride, is produced. Lappaconitine is highly toxic. The roots also contain *cynoctonine* $C_{36}H_{55}O_{12}N_2$ (amorphous, bitter, and much less toxic than lappaconitine) and *septentrionaline* $C_{31}H_{48}O_9N_2$, amorphous, bitter, and about equal in toxicity to cynoctonine (*cf.* Orloff, P. Z. f. R. 1907, 36, 213).

Lycaconitine $C_{36}H_{46}O_{10}N_2$, obtained by Dragendorff and Spohn (P. Z. f. R. 1884, 23, 313) and later by Schulze and Bierling (Arch. Pharm. 1913, 251, 8) along with *myoctonine* ($C_{36}H_{42}O_{10}N_2$) and an unnamed base, from the roots of *Aconitum Lycoctonum* (Linn.), is amorphous and dextrorotatory. On hydrolysis with acids it furnishes anthranoyl-lycoctonine (Dragendorff's lycaconine) and succinic acid. On hydrolysis with sodium hydroxide lycoctonine $C_{25}H_{39}O_7N,H_2O$ and lycoctoninic acid $C_{11}H_{15}O_5N$, both crystalline, are formed. Lycoctonine had been found previously by Hübschmann in the roots (J. 1857, 416; 1866, 483; *cf.* Wright and Luff, Pharm. J. 1878–9, [iii.] 8, 169). All the alkaloids described are heart poisons.

Pseudaconitine $C_{36}H_{51}O_{12}N$. The characteristic alkaloid of *Aconitum deinorrhizum*, the roots of which form Nepaul aconite of commerce. It may be extracted from the roots by the process described under aconitine. Pseudaconitine has been frequently examined (Wright and Luff, Chem. Soc. Trans. 1878, 33, 151; Mandelin, Arch. Pharm. 1884, 222, 97, 129, 161), and most recently by Dunstan and Carr (Chem. Soc. Proc. 1895, 154; and Chem. Soc. Trans. 1897, 71, 350).

Properties. Colourless crystals of rhomboidal shape, m.p. 211°–212° (decomp.); $[\alpha]_D = +18° 36'$ in alcohol. Readily soluble in alcohol, less so in ether, very slightly in water, almost insoluble in light petroleum. The salts are lævorotatory; the hydrobromide $B{\cdot}HBr,2H_2O$, m.p. 191° (anhydrous), and the nitrate $B{\cdot}HNO_3,3H_2O$, m.p. 192°, are crystalline. The hydrochloride is amorphous, but the aurichloride, m.p. 235°–236°, may be crystallised from alcohol. Pseudaconitine exerts a physiological action similar to that of aconitine, but is much more toxic (Cash and Dunstan, Proc. Roy. Soc. 1902, 68, 379).

Reactions. On heating an aqueous solution of a neutral pseudaconitine salt in a closed tube at 135° the alkaloid undergoes hydrolysis, yielding 1 mol. acetic acid and 1 mol. veratroylpseudaconine. The latter is hydrolysed in the cold by sodium hydroxide in alcohol, furnishing 1 mol. of veratric acid and 1 mol. of pseudaconine. When heated at its melting-point pseudaconitine loses 1 mol. acetic acid and furnishes pyropseudaconitine. Pseudaconitine, in view of these reactions, is to be regarded as acetylveratroylpseudaconine

$$[MeO]_4C_{21}H_{27}O_2N<\begin{matrix}OVe\\OAc\end{matrix}$$

No relationship has yet been traced between pseudaconine and aconine (D. a. C.; *cf.* Freund and Niederhofheim, Ber. 1896, 29, 6, 852).

VERATROYLPSEUDACONINE $C_{34}H_{49}O_{11}N$. The first basic product of the hydrolysis of pseudaconitine (*see* above) separates in large, irregularly-shaped crystals from ether, m.p. 199°. readily soluble in chloroform or alcohol, nearly insoluble in water or light petroleum, $[\alpha]_D = -38° 18'$ in alcohol. The salts crystallise well; the hydrobromide $B{\cdot}HBr,3H_2O$ in prisms; the nitrate $B{\cdot}HNO_3$ in rosettes of rhombic prisms, m.p. 222° and 232°; the aurichloride $B{\cdot}HAuCl_4$ is amorphous (D. a. C.). Veratroylpseudaconine is not toxic (Cash and Dunstan, *l.c.*).

PSEUDACONINE $C_{25}H_{41}O_8N$, the ultimate basic product of the hydrolysis of pseudaconitine and indaconitine (p. 632), forms large colourless crystals, m.p. 94°–95°, containing 1 mol. alcohol of crystallisation. Dextrorotatory ($[\alpha]_D = 38° 12'$ in water). The salts are amorphous.

PYROPSEUDACONITINE $C_{34}H_{47}O_{10}N$. Formed by heating pseudaconitine at its melting-point, when 1 mol. acetic acid is evolved; it is amorphous, but yields a hydriodide, crystallising in prisms (D. a. C. *l.c.*).

Atisine $C_{22}H_{31}O_2N$, the characteristic alkaloid of *Aconitum heterophyllum* (Wall.) of Northern India. It was first isolated by Broughton in 1873, and was subsequently examined by Wasowicz (Arch. Pharm. 1879, 214, 193), Wright (Year Book Pharm. 1879, 422), and later by Jowett (Chem. Soc. Trans. 1896, 69, 1518). Atisine is amorphous, readily soluble in water, alcohol, ether, or chloroform, lævorotatory ($[\alpha]_D^{19°} = -19{\cdot}6°$ in alcohol). It yields crystalline, dextrorotatory salts; $B{\cdot}HCl$, prisms, m.p. 296° (decomp.); $B{\cdot}HI$, tablets, m.p. 279°–281° (decomp.); $B_2{\cdot}H_2PtCl_6$, crystalline yellow powder, m.p. 229° (decomp.). When heated with water in a closed tube atisine furnishes a *hydrate* $C_{22}H_{33}O_3N$, which is amorphous, and yields amorphous salts. Atisine is non-toxic (Jowett, *l.c.*).

Palmatisine. A colourless, crystalline, non-toxic alkaloid, m.p. 285°, found in the roots of *Aconitum palmatum* (D. Don.), a species indigenous to India (Dunstan and Carr).

Adenine. *See* under *Caffeine* (p. 642).

Adlumine $C_{39}H_{41}O_{12}N$, crystals, m.p. 188°, occurs in *Adlumia cirrhosa* (Rafin.) with *adlumidine* $C_{30}H_{29}O_9N$, plates, m.p. 234°, protopine (p. 665), and β-homochelidonine (p. 645) (Schlotterbeck and Watkins, Ph. Ar. 1903, 6, 17).

Agmatine. *See* p. 653.

Alstonine. One of a series of ill-defined alkaloids occurring in *Alstonia* spp. (Hesse, Annalen, 1880, 203, 147; 205, 360), including *alstonamine*, *alstonidine*, *ditaine*, *ditamine*, &c.

Angeline $C_{10}H_{13}O_3N$ (surinamine, geoffroyine, andirine, rhatanine) is a methyltyrosine (Hiller-Bombien, Arch. Pharm. 1892, 230, 513; Goldschmidt, Monatsh. 1913, 33, 1379; 34, 659), widely distributed in plants.

Anhalonamine, Anhalonidine, and **Anhalonine.** *See* under *Mezcaline* (p. 656).

Aporeine. *See* under *Rheadine* (p. 674).

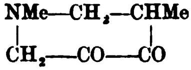
Arachine $C_5H_{14}ON_2$, an alkaloid occurring with choline and betäine in earth-nut (ground-nut, monkey-nut) meal (*Arachis hypogea* (Linn.)). Syrup; the aurichloride and platinichloride are crystalline. Produces somnolence in frogs and rabbits (Mooser, Landw. Versuch-Stat. 1904, 60, 321).

ARECOLINE AND THE ALKALOIDS OF ARECA NUTS.

Arecoline $C_8H_{13}O_2N$ is the chief alkaloid of areca nuts (*Areca Catechu* (Linn.)). It is a strongly alkaline liquid, b.p. 220°, which furnishes crystalline salts. On hydrolysis by alkalis or acids it gives methyl alcohol and arecaïdine (*v. infra*). Arecoline is highly toxic (Meier, Biochem. Zeitsch. 1907, 2, 415).

Arecaïdine $C_7H_{11}O_2N,H_2O$ occurs in areca nuts, and is produced by the hydrolysis of arecoline. It is crystalline, m.p. 222°–223°, yields a crystalline aurichloride, and is non-toxic. In constitution arecaïdine is N-methyl-Δ^3-tetrahydronicotinic acid, and has been synthesised by Jahns (*see* below).

Arecaine $C_7H_{11}O_2N,H_2O$, the third alkaloid of areca nuts, is isomeric with arecaïdine. It is crystalline, m.p. 213° (decomp.), neutral, and gives crystalline salts. It has the following constitution :—



$$\begin{array}{ccccc} NMe & - & CH_2 & - & CHMe \\ | & & & & | \\ CH_2 & - & CO & - & CO \end{array}$$

Arecaine.

Guvacine $C_6H_9O_2N$, the fourth alkaloid of areca nuts, is crystalline, m.p. 271°–272° (decomp.), and neutral in reaction. On methylation it furnishes arecaine in part, whence the latter is regarded as the N-methyl derivative of guvacine.

Our knowledge of the areca-nut alkaloids is chiefly due to Jahns (Ber. 1888, 21, 3404; 1890, 23, 2972; 1891, 24, 2615; Arch. Pharm. 1892, 229, 669; *cf.* Willstätter, Ber. 1897, 30, 729; and Meyer, Monatsh. 1902, 23, 22; Wohl and Johnson, Ber. 1907, 40, 4712).

Arginine $C_6H_{14}O_2N_4$ is α-amino-δ-guanino-*n*-valeric acid (Sörensen, Ber. 1910, 43, 643). Occurs frequently in etiolated embryos of plants (Schulze and others, *ibid.* 1886, 19, 1177; 1891, 24, 1098, 2701; 1897, 30, 2880; 1899, 32, 3191; Ellinger, *ibid.* 1898, 31, 3183; 1899, 32, 3542) (*v.* Vol. I. p. 289).

Aricine $C_{23}H_{26}O_4N_2$ is an alkaloid found in cusco and cuprea barks derived from plants closely allied to the cinchonas. Crystals, m.p. 188°; lævorotatory $[\alpha]_D = -58{\cdot}18°$ in alcohol. The salts are crystalline and dextrorotatory (Hesse, Annalen, 1877, 185, 320; Moissan and Landrin, Compt. rend. 1890, 110, 469).

Aristinic acid $C_{18}H_{13}O_7N$, greenish-yellow needles, m.p. 275° (decomp.). Occurs with *aristidinic acid* $C_{19}H_{13}O_7N$, and *aristolic acid* $C_{15}H_{11}O_7N$, in *Aristolochia argentina* (Griseb.) (Hesse, Arch. Pharm. 1895, 233, 684).

Aristolochine $C_{32}H_{22}O_{13}N_2$, orange-yellow needles, decomposing at 215°. Occurs in *Aristolochia Clematitis* (Linn.) and *A. rotunda* (Linn.). It is a weakly acid base (Pohl, Arch. expt. Path. Pharm. 1891, 29, 282). According to Hesse (Arch. Pharm. 1895, 233, 684) aristolochine has the formula $C_{17}H_{11}O_7N$ and is a homologue of aristolic acid (*see* under *Aristinic acid*). The alkaloid is highly toxic.

Aspidospermine $C_{22}H_{30}ON_2$ and **aspidospermatine** $C_{22}H_{28}O_2N_2$ are two of a number of alkaloids found in quebracho bark (*Aspidosperma Quebracho* (Schlecht.)) (Fraude, Ber. 1878, 11, 2190; 1879, 12, 1560; Hesse, Annalen, 1882, 211, 249).

Atisine. *See* under *Aconitine* (p. 634).

Atropamine. *See* under *Atropine* (p. 637).

Atroscine. *See Scopolamine*, under *Atropine* (p. 639).

ATROPINE AND THE SOLANACEOUS ALKALOIDS.

This group comprises the following members, and possibly others not yet fully examined :—

Atropine and hyoscyamine $C_{17}H_{23}O_3N$;
*nor*Hyoscyamine $C_{16}H_{21}O_3N$;
Apoatropine and belladonnine $C_{17}H_{21}O_2N$;
Tropacocaine $C_{15}H_{19}O_2N$ (*see* p. 647) ;
Scopolamine $C_{17}H_{21}O_4N$;
Meteloidine $C_{13}H_{21}O_4N$.

These are all tertiary bases except *nor*-hyoscyamine, and on hydrolysis furnish an acid and an amino alcohol. Of the eight alkaloids only three are of importance in medicine, viz. atropine, hyoscyamine, and scopolamine. The best known sources of the three alkaloids are belladonna (*Atropa Belladonna* (Linn.)), henbane (*Hyoscyamus niger* (Linn.)), and stramonium (*Datura Stramonium* (Linn.)), all of which are used in medicine. Other plants which contain them in important quantities, and either are or may be used commercially as sources of the alkaloids, are *Hyoscyamus muticus* (Linn.), *H. albus* (Linn.), and *H. reticulatus* (Linn.), *Datura Metel* (Linn.), *D. arborea* (Linn.), *D. quercifolia* (H. B. and K.), *Duboisia myoporoides* (R.Br.), *Scopolia carniolica* (Jacq.), and *S. japonica* (Maxim.) and *Mandragora officinarum* (Linn.). As a rule, at least two of the alkaloids, usually hyoscyamine and scopolamine, are found together in each plant, but *H. muticus* is remarkable in containing hyoscyamine without any admixture of atropine or scopolamine. It is probable that atropine rarely, if ever, occurs pre-formed in plants, and the traces generally found in the extracted alkaloids are due to isomerisation of hyoscyamine either by drying the plant or by the action of chemical agents used for extraction. In general, the alkaloids are present in the stem, leaves, root, and seed, and the amount of total alkaloid present in each of these parts shows great variation with the time of collection and the climatic conditions under which the plant was grown.

Preparation. The method used for the extraction of these alkaloids varies to some extent with the material employed, but the following general process gives good results as a rule. The finely-ground, air-dry drug is exhausted by percolation with cold 90 p.c. alcohol. and the greater part of the solvent removed by distillation under reduced pressure. In the case of seeds, percolation with alcohol should be preceded by percolation with light petroleum to remove oil. The semi-solid extract is then treated with dilute (0·5 p.c.) hydrochloric or sulphuric acid, until no more alkaloid is removed. This acid liquid is filtered, shaken with small quantities of chloroform, if necessary, to remove traces of chlorophyll, oil, or other soluble non-basic matters, then made slightly alkaline with dilute ammonia, and the alkaloid extracted by means of chloroform. The latter is distilled off, leaving, as a rule, a clean gum-like residue. From this, by solution in chloroform and careful addition of light petroleum, hyoscyamine may be caused to separate in crystalline form. If scopolamine is present it remains dissolved in the chloroform, and may be caused to separate by further addition of light petroleum. The alkaloids may be purified by re-crystallisation from alcohol by addition of water, when hyoscyamine separates first. The best source of hyoscyamine is the Egyptian plant, *Hyoscyamus muticus*, since this contains no scopolamine.

ESTIMATION OF TOTAL ALKALOIDS. Dunstan and Ransom have devised the following methods:

For the root. Exhaust by hot percolation 20 grms. of the finely-powdered root with a mixture of equal parts of chloroform and absolute alcohol, which readily dissolves the alkaloidal salts. Agitate the solution with 25 c.c. of water, when the salts pass into the aqueous layer, and the resin, fat, colouring matter, &c., remain dissolved in the chloroform. Repeat this extraction with water. Wash the 50 c.c. of water with a little pure chloroform to remove adhering impurity, then add ammonia in slight excess, and dissolve out the liberated alkaloids by agitation with chloroform in the usual way. The residue of alkaloid left on the evaporation of the chloroform is dried at 100° and weighed (Pharm. J. 1883–4, [iii.] 14, 623).

For the leaves. 20 grms. of the finely-powdered dry leaves are exhausted with absolute alcohol. The liquid is largely diluted with water, acidified with hydrochloric acid, and repeatedly extracted by agitation with chloroform until the whole of the chlorophyll, fat, &c., has been removed. The liquid is then made alkaline with ammonia, and extracted with chloroform, which, on evaporation, leaves a residue of alkaloid. This must be dried at 100° before being weighed. This process answers equally well for stems or fruit capsules, and for seeds, if the latter are first extracted with light petroleum to remove oil (Pharm. J. 1885–6, [iii.] 16, 237).

Extract of the leaves. From 1 to 2 grms. of the extract are dissolved, as far as possible, in warm dilute hydrochloric acid, any residue being extracted with the dilute acid until all the alkaloid has been dissolved. The acid liquid is then extracted with chloroform until nothing further is removed, and, after this treatment, is made alkaline with ammonia, and the free alkaloid removed by agitating again with chloroform, which on evaporation leaves a residue of alkaloid that is dried at 100°C. and weighed (*ibid.* 1885–6, [iii.] 16, 238).

Alcoholic extract of the root. 2 grms. of this extract are dissolved as far as possible in dilute hydrochloric acid. This solution is then treated as described under the leaf extract (*ibid.* 1885–6, [iii.] 16, 777).

No method is yet available for the quantitative separation and estimation in mixtures of the individual mydriatic alkaloids, but the approximate amounts of each present may sometimes be determined by careful fractionation with gold chloride.

Atropine $C_{17}H_{23}O_3N$ was first obtained by Mein (Annalen, 1833, 6, 67) from the root of *Datura Stramonium* (Linn.), and called by him *daturine*. Geiger and Hesse obtained it independently (*ibid.* 1833, 5, 43; 6, 44; 7, 269) from belladonna root, and their material was analysed by Liebig, who assigned to it the empirical formula now in use. Atropine is stated to occur with hyoscyamine and a little scopolamine in belladonna and stramonium and with more scopolamine in *Scopolia japonica* (Maxim), but there is reason to believe that the alkaloid does not exist pre-formed in plants, although it may be produced in the course of preparation by the action of alkalis on hyoscyamine. In any case, the commercial alkaloid is now obtained invariably by conversion of hyoscyamine by the action of very dilute alkali (Will and Bredig, Ber. 1888, 21, 2797; *cf.* Gadamer, Arch. Pharm. 1901, 239, 294).

Properties. Prismatic crystals, m.p. 115·5°. Readily soluble in alcohol or chloroform, less soluble in ether or hot water, sparingly soluble in cold water. The aqueous solution is alkaline to litmus, and has a very bitter taste. Atropine is optically inactive. It is slightly volatile with steam (Dragendorff). One of the most remarkable properties of atropine is that of causing dilation of the pupil of the eye, a property which is often made use of in detecting it and other alkaloids of this group, several of which exert this mydriatic action. A drop or two of an aqueous solution, containing 1 part of atropine in 130,000 parts of water, when introduced into the eye of a cat is sufficient to produce this effect. When taken internally atropine is highly poisonous; some of the alkaloid is apparently excreted unchanged in the urine.

The ordinary salts of atropine are crystalline and soluble in water. The sulphate

$$B_2 \cdot H_2SO_4, H_2O$$

is commonly used in medicine; it forms colourless needles, m.p. 187°–188°, 194° (dry). The aurichloride $B \cdot HAuCl_4$ appears as an oily precipitate when produced in the ordinary manner. This soon solidifies to a crystalline mass, which may be re-crystallised from water, acidified with hydrochloric acid. The crystals melt at 135° (Ladenburg, Annalen, 1880, 206, 274); near 138° (Hesse, *ibid.* 1892, 271, 100). This salt and the picrate, m.p. 175°–176°, are useful for the identification of the alkaloid, since the corresponding salts of the other alkaloids of this group melt at different temperatures.

Reactions and constitution. Among the characteristic qualitative reactions of atropine may be mentioned the production of an odour of heliotrope or of bitter almond oil, when a solution of the alkaloid is warmed with sulphuric acid and a fragment of potassium dichromate or permanganate. When the alkaloid is evaporated to dryness with a few drops of fuming nitric acid a residue is obtained which turns violet (changing to red) when it is moistened with alcoholic potash (Vitali, Zeitsch. anal. Chem. 1881, 20, 563). Other characteristic colour reactions are described by Reichard (Chem. Zeit. 1904, 28, 1048). Many alkaloids form white, insoluble compounds with mercuric chloride, but when a solution of this salt is added to a dilute alcoholic solution of atropine (not a salt) and the mixture is warmed, a yellowish-red precipitate of mercuric oxide is thrown down, and after a time a colourless crystalline double salt separates from the solution (Gerrard, Pharm. J. 1883–4, [iii.] 14, 718).

Atropine yields an anhydride (*apoatropine*) (*see* below) when heated with dilute nitric acid (Pesci, Gazz. chim. ital. 1881, 11, 538; 1882, 12, 60), which Hesse subsequently isolated from belladonna root and named atropamine (Annalen, 1892 271 124; *cf.* Merck, Zeitsch. anal. Chem.

1892, 31, 229; and Hesse, Annalen, 1893, 277, 290). Apoatropine is not mydriatic. Atropine readily undergoes hydrolysis when warmed with alkalis or strong acids. By heating it with concentrated hydrochloric acid in a closed tube at 130°, or with baryta water at 60°, it is completely resolved into *tropine* $C_8H_{15}ON$, and *tropic acid* (α-phenyl-β-hydroxypropionic acid)

$$CH_2(OH)\cdot CH(C_6H_5)COOH$$

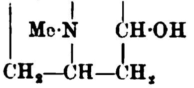
$$C_{17}H_{23}O_3N+H_2O=C_8H_{15}ON+C_9H_{10}O_3$$

Atropine. Tropine. Tropic acid.

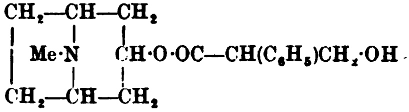
At higher temperatures than these, or after prolonged heating, the tropic acid suffers dehydration, forming, when alkalis are used, atropic acid $CH_2:C(C_6H_5)COOH$.

TROPINE $C_8H_{15}ON$ forms large, colourless tablets, m.p. 63°; b.p. 229°; sp.gr. 1·0392 at 76°/4°, soluble in water, alcohol, or ether. It is a strong base, which forms crystalline salts. It is poisonous, but does not dilate the pupil of the eye. Tropine and tropic acid unite to form tropine tropate $C_8H_{15}NO\cdot C_9H_{10}O_3$, and this salt, when heated with dilute hydrochloric acid, loses water and furnishes atropine, identical with the natural alkaloid (Ladenburg, Annalen, 1883, 217, 74). Similarly, by heating other organic salts of tropine with dilute hydrochloric acid, dehydration occurs, with production of the acyl derivative of tropine. The bases thus formed have been called by Ladenburg *tropeïnes.* In this way *l*-atropine (*l*-tropyltropeine), *d*-atropine (*d*-tropyltropeine), *pseudo*atropine (atrolactyltropeine), and atropamine (apoatropine, atropyltropeïne) have been prepared (*cf.* Wolffenstein and Mamlock, Ber. 1908, 41, 723; and Wolffenstein and Rolle, *ibid.* 1908, 41, 733). Several of the tropeines exert a mydriatic action. *Phenylglycollytropeine* $C_{16}H_{21}O_3N$ has been used in medicine under the name *homatropine.* Its mydriatic effect is less persistent than that of atropine. As a result of Ladenburg's work it has been generally assumed that only those tropëines produce a mydriatic effect which contain an alcoholic (not phenolic) hydroxyl in the aromatic acid residue, thus acetyl-, benzoyl-, and salicyl-tropeines are not mydriatic, whilst mandelyltropeine is mydriatic. Jowett and Pyman find that this is not strictly true, mydriasis being produced by terebyltropeine (Chem. Soc. Trans. 1906, 89, 360), and only slightly by *o*-carboxyphenylglyceryltropeine (*ibid.* 1907, 91, 93; 1909, 95, 1020; and Proc. Int. Cong. Appl. Chem. 1909) which should be very active. Certain tropeines containing a lactone group become less active when the lactonic grouping is opened by the action of alkali.

Tropine has been the subject of numerous investigations especially by Ladenburg, Merling and Willstätter culminating in its synthesis by the last-named from suberone as a starting-point (Ber. 1901, 34, 3163; Annalen, 1903, 326, 23). On the basis of these results tropine and atropine are now generally represented by the following formulæ—



Tropine.



Atropine (tropyltropeïne).

Tropine undergoes a series of interesting decompositions under the action of various reagents. The most interesting of these are as follows: When heated with dehydrating agents it furnishes *tropidine* $C_8H_{13}N$ (Ladenburg, Annalen, 1883, 217, 177), a strongly alkaline oil, b.p. 162°–163°, sp.gr. 0·9467 at 19°/4°, which has an odour recalling that of coniine. On oxidation with chromic acid tropine yields in turn *tropinone* $C_8H_{13}ON$ (Willstätter, Ber. 1896, 29, 396), m.p. 41°–42°, b.p. 224°–225°, *tropinic acid* $C_8H_{13}O_4N$ (Merling, Annalen, 1883, 216, 348; Willstätter, *l.c.*), and finally *ecgoninic acid* $C_7H_{11}O_3N$ (*see* under *Cocaine*), which was shown by Willstätter and Bode to be N-methylpyrrolidine-2-acetic acid (Ber. 1901, 34, 519), thus proving the presence of a pyrrolidine ring in tropine. For a detailed account of the important researches in the tropine series, Schmidt's Über die Erforschung der Konstitution und die Versuche zur Synthese wichtiger Pflanzenalkaloide, i. 1900; ii. 1904 (Enke, Stuttgart), should be consulted.

Apoatropine (*Atropamine*) $C_{17}H_{21}O_2N$. This base was first prepared by Pesci (Gazz. chim. ital. 1881, 11, 538; 1882, 12, 60) by the action of nitric acid on atropine, and was subsequently isolated by Hesse from belladonna under the name atropamine, the identity of the two bases being established by Merck (Arch. Pharm. 1891, 229, 134; 1893, 231, 110; *cf.* Hesse, Annalen, 1891, 261, 87; 1893, 277, 290). It is also formed by the action of cold sulphuric acid on atropine or hyoscyamine, and may be isolated by pouring the solution into water immediately. By prolonged action of the acid apoatropine is converted into belladonnine (*v. infra*). Apoatropine crystallises in prisms, m.p. 60°, and furnishes crystalline salts; the hydrochloride B·HCl, m.p. 237°–239°, forms leaflets, and the aurichloride $B\cdot HAuCl_4$, needles, m.p. 110°–112°. On hydrolysis with baryta water it furnishes tropine and atropic acid, and it has been synthesised by Ladenburg from these two substances and called atropyltropëine (Annalen, 1883, 217, 102).

Belladonnine $C_{17}H_{21}O_2N$. This alkaloid is stated to occur in the leaves and root of *Atropa Belladonna* (Linn.) (Hübschmann, J. 1858, 376; Kraut, Ber. 1880, 13, 165; Dürkopf, *ibid.* 1889, 22, 3183; Hesse, Annalen, 1891, 262, 100). According to Merling (Ber. 1884, 17, 381) it has the formula $C_{17}H_{21}O_2N$, and is isomeric with anhydro-atropine (apoatropine), and this was confirmed by Hesse (*l.c.* 1892, 271, 123; 1893, 277, 295), who stated that it can be prepared by the action of (1) sulphuric acid on atropine or hyoscyamine, or (2) hydrochloric acid on atropamine (apoatropine). Belladonnine is a resinous, uncrystallisable base, which is hydrolysed with much greater difficulty than the other solanaceous alkaloids, yielding tropine $C_8H_{15}ON$ and atropic acid (Merling). It appears to be devoid of mydriatic power.

Hyoscyamine $C_{17}H_{23}O_3N$. An isomeride of atropine. It is the most common of the solanaceous alkaloids, being the principal alkaloid in *Atropa Belladonna* (Linn.) (Schmidt, Arch. Pharm. 1905, 243, 303), *Hyoscyamus niger* (Linn.), and *H. albus* (Linn.), the sole mydriatic alkaloid in *H. muticus* (Linn.) (Dunstan and Brown, Chem. Soc. Trans. 1899, 75, 74; 1901, 79, 72), and the chief alkaloid in *Datura Stramonium* (Linn.), *Duboisia myoporoides* (R. Br.), *Scopolia carniolica* (Jacq.) (Dunstan and Chaston, Pharm. J. 1889–1890, [iii.] 20, 461), and *S. japonica* (Maxim.) (Schmidt, Arch. Pharm. 1888, [iii.] 26, 185, 214), and in other similar plants; it exists in minute quantities in lettuce, *Lactuca virosa* (Linn.) and *L. Scariola* (Linn.) (Dymond, Chem. Soc. Trans. 1892, 61, 90).

Preparation. Hyoscyamine may be extracted from the various plants containing it by means of the process described in the introduction to this section. The best source of the alkaloid is the stem and leaves of *Hyoscyamus muticus*, since this material is free from other mydriatic alkaloids of this group. It may also be obtained from henbane or stramonium. In preparing the alkaloid great care must be taken not to leave it in contact with alkalis, since these readily convert it into atropine. Hyoscyamine is but little used in medicine, and is generally used merely as a source of atropine. When atropine and scopolamine are also present in the plant these alkaloids are obtained with the hyoscyamine. The isolation of pure hyoscyamine from the mixture of the alkaloids is a difficult operation. The greater part of the atropine may be removed by repeated crystallisation from dilute alcohol, the hyoscyamine for the most part remaining dissolved. The isolation of pure hyoscyamine can only be certainly accomplished by converting the alkaloid into the aurichloride and repeatedly crystallising this salt from dilute hydrochloric acid until it melts at the proper temperature. The alkaloid may be regenerated from the aurichloride by decomposing it with hydrogen sulphide in the usual manner.

Properties. Long, silky crystals, m.p. 108·5°; lævorotatory $[\alpha]_D = -14{\cdot}5°$ (Ladenburg, Annalen, 1880, 206, 274); $[\alpha]_D = -20{\cdot}97°$ (Will, Ber. 1888, 21, 1717); $[\alpha]_D = -20{\cdot}3°$ (Hesse, Annalen, 1892, 271, 100); $[\alpha]_D = -22{\cdot}06°$ (in alcohol) Carr and Reynolds (Chem. Soc. Trans. 1910, 97, 1331). Readily soluble in benzene, chloroform, or alcohol, less readily in ether or cold water. When heated the alkaloid sublimes, with partial decomposition, and it is said to be slightly volatile with steam. When hyoscyamine is heated to a temperature slightly higher than its melting-point, it is converted into atropine (Schmidt, Ber. 1888, 21, 1829). This conversion also takes place with great facility when hyoscyamine is warmed or even allowed to stand in the cold, with caustic alkalis or alkali carbonates, but it only takes place extremely slowly in presence of ammonia (Will, Ber. 1888, 21, 1717, 2777). Hyoscyamine exerts a strong mydriatic action, and is a powerful poison.

Many of the ordinary salts of hyoscyamine are crystalline and soluble in water. The sulphate $B_2{\cdot}H_2SO_4$, crystallises well from alcohol and melts at 206°. The aurichloride $B{\cdot}HAuCl_4$ is best crystallised from dilute hydrochloric acid. It melts at 159°–160° (Ladenburg, *l.c.*); 162° (Will, *l.c.*); 159° (Hesse, *l.c.*); but, unlike atropine aurichloride, it does not melt when heated under water. This salt is less soluble in acidified water than atropine aurichloride, from which it may be separated by repeated crystallisation.

Reactions. The qualitative reactions of hyoscyamine are, for the most part, identical with those of atropine. When heated with acids or alkalis, like atropine, it undergoes hydrolysis into *tropine* and *tropic acid.* On reversing this reaction by heating together the tropine and tropic acid, atropine and not hyoscyamine is formed. According to Gadamer (Arch. Pharm. 1901, 239, 294) hyoscyamine is, in the first place, converted by alkalis into atropine, and it is really this alkaloid which is hydrolysed. The same author states that by the action of water at atmospheric temperature hyoscyamine is resolved into *r*-tropine and *l*-tropic acid, and consequently hyoscyamine must be *l*-tropyl-*r*-tropine; Amenomiya (*ibid.* 1902, 240, 498) has synthesised *l*-hyoscyamine and *d*-hyoscyamine. Ladenburg and Hundt's *d*- and *l*-atropines (Ber. 1889, 22, 2590) are regarded as mixtures of *d*- and *l*-hyoscyamine with atropine.

Detection. Hyoscyamine may be detected by its mydriatic action and by most of the reactions described under atropine. Its partial separation from atropine may be effected by recrystallisation from dilute alcohol, but it can only be completely separated and identified by preparing its aurichloride, which is characterised by its melting-point (for details *see* Dunstan and Chaston, Pharm. J. 1889–1890, [iii.] 20, 461).

Mandragorine was obtained by Ahrens (Ber. 1889, 22, 2159) from *Mandragora officinarum* (Linn.), and from the same source by Hesse (J. pr. Chem. 1901, [iii.] 64, 274), along with hyoscyamine, scopolamine, and pseudohyoscyamine. According to Thoms and Wentzel (Ber. 1901, 34, 1023), Ahrens' mandragorine is merely a mixture of hyoscyamine with scopolamine and possibly a third alkaloid (*v.* MANDRAGORA ROOT, vol. iii. p. 391).

Meteloidine $C_{13}H_{21}O_4N$ was obtained by Pyman and Reynolds (Chem. Soc. Trans. 1908, 93, 2077) from *Datura meteloides* (DC.) along with atropine, and hyoscine (scopolamine) to the extent of 0·07 p.c. It crystallises in tabular needles, m.p. 141°–142°, and furnishes a crystalline, optically inactive hydrobromide $B{\cdot}HBr,2H_2O$, m.p. 250° (anhydrous), and an aurichloride, m.p. 149°–150°. On hydrolysis by baryta water meteloidine furnishes tiglic acid $CHMe:CMe{\cdot}COOH$ and a new base *teloidine* $C_8H_{15}O_3N$, which crystallises with $1H_2O$ and has m.p. 168°–169° (anhydrous); the aurichloride $B{\cdot}HAuCl_4,\frac{1}{2}H_2O$ has m.p. 225°, and crystallises in hexagonal plates.

Norhyoscyamine $C_{16}H_{21}O_3N$ occurs in *Scopolia japonica* (Maxim.) and *Datura Metel* (Linn.) and other solanaceous plants. On treatment with methyl iodide it yields hyoscyamine, which is its nitrogen methyl derivative. Lævorotatory: mydriatic but less so than hyoscyamine (Carr and Reynolds, Trans. Chem. Soc. 1912, 101, 946). Dilute alkalis racemise it to noratropine.

Pseudohyoscyamine $C_{17}H_{23}O_3N$ occurs, according to Merck (Arch. Pharm. 1893, 231, 117), in *Duboisia myoporoides* (R. Br.) along with hyoscyamine and scopolamine, and according to Hesse in mandragora root. It crystallises in needles, m.p. 133°–134° (decomp.), is lævorotatory $[\alpha]_D = -21{\cdot}15°$, and is hydrolysed by baryta water into tropic acid and a base $C_8H_{15}ON$ not identical with tropine or pseudotropine. According to Carr and Reynolds, pseudohyoscyamine is impure norhyoscyamine (*v. supra*).

Scopolamine (*Hyoscine*) $C_{17}H_{21}O_4N$. This alkaloid was isolated by Ladenburg (Annalen, 1880, 206, 299) from the 'amorphous hyoscyamine' remaining in the mother liquors resulting from the preparation of hyoscyamine from *Hyoscyamus niger* (Linn.), and was named by him 'hyoscine.' Some years later Schmidt obtained from *Scopolia japonica* (Maxim.) and *S. carniolica* (Jacq.) a new crystalline alkaloid, which he named scopolamine (Arch. Pharm. 1890, 228, 139, 435), and which he afterwards proved to be the principal constituent of Ladenburg's amorphous hyoscine (*ibid.* 1892, 230, 207; 1894, 232, 409; *cf.* Hesse, Annalen, 1892, 271, 120; 1893, 276, 84). Schmidt subsequently obtained scopolamine from *Hyoscyamus niger* (Linn.), *Atropa Belladonna* (Linn.), *Datura Stramonium* (Linn.), and *Duboisia myoporoides* (R. Br.). The name scopolamine has been adopted generally for this alkaloid although hyoscine is still used in commerce. A further complication in nomenclature was introduced when Hesse isolated from scopolamine hydrobromide of commerce an optically inactive alkaloid, which he named *atroscine* (Annalen, 1892, 271, 121), and which Gadamer showed subsequently was an anhydrous *i*-scopolamine (Arch. Pharm. 1898, 236, 382), Schmidt having previously shown (*ibid.* 1894, 232, 394) that when natural *l*-scopolamine hydrobromide is treated with moist silver oxide it is converted into an optically inactive isomeride (*i*-scopolamine).

Preparation. The total alkaloid is separated from the plant by the method described already. The scopolamine remains in the alcoholic solution when the atropine and hyoscyamine have crystallised out. It may be completely purified by conversion into the aurichloride, which is crystallised until it has the proper melting-point, the alkaloid being regenerated in the usual way. The usual source of the alkaloid is stated to be the mother liquors resulting from the preparation of hyoscyamine from henbane seeds or *Duboisia* roots or leaves, but it is the chief alkaloid in *Datura Metel* (Linn.), and *D. fastuosa* (Linn.) (Schmidt, Arch. Pharm. 1906, 244, 66), and certain species of *Scopolia*, and *D. Metel* especially would form a good source of the alkaloid.

Properties. Crystallises with difficulty in prisms, m.p. 59°. Soluble in alcohol or ether, slightly soluble in water. In alcoholic solution lævorotatory $[\alpha]_D = -13{\cdot}7°$, $-18°$ (Gadamer), $-28°$ in water (Gadamer); the rotation is much diminished by addition of soda (Hesse). Its mydriatic power is stated to be greater than that of atropine. The ordinary salts are crystalline. The hydrobromide $B{\cdot}HBr,3H_2O$ crystallises in rhombic tables, m.p. 187°–191° (anhydrous), $[\alpha]_D = -22{\cdot}5°$ in water (Hesse), $-15{\cdot}72°$ in alcohol (Gadamer). The aurichloride $B{\cdot}HAuCl_4$ is less soluble than the corresponding hyoscyamine compound. It crystallises well from diluted hydrochloric acid, m.p. 198° (Ladenburg, *l.c.*), and is characteristic. The picrate has m.p. 180°–181°.

Reactions. Scopolamine, for the most part, reacts like atropine and hyoscyamine, but it does not precipitate mercuric oxide from mercuric chloride. When treated with moist silver oxide *l*-scopolamine is converted into an optically inactive form, *i*-scopolamine, which crystallises with $1H_2O$ in needles or rhombohedra, m.p. 55°–56°, and yields an aurichloride $B{\cdot}HAuCl_4$, m.p. 208°–210° (Schmidt, *ibid.* 1894, 232, 394). Hesse's atroscine (Ber. 1896, 29, 1776) prepared from commercial scopolamine hydrobromide is, according to Gadamer (Arch. Pharm. 1898, 236, 382; *cf.* Schmidt, *ibid.* 9, 47), *i*-scopolamine crystallised with $2H_2O$; it has m.p. 36°–37°, and furnishes an aurichloride, m.p. 201°–202° (Hesse). When hydrolysed by acids or alkalis scopolamine yields *tropic acid* and *scopoline* (oscine) $C_8H_{13}O_2N$, which crystallises in needles, m.p. 109°, b.p. 241°–243°. Like its analogue tropine, scopoline forms esters with acids and a number of these, known as 'scopoleines,' have been prepared.

Detection. Scopolamine is readily distinguished from its associates by the higher m.p. (198°) of its aurichloride. At present the repeated recrystallisation of this salt, until it has the proper melting-point, is the only known method of purifying the alkaloid.

Baptitoxine. *See Cytisine* (p. 651).

Bebeerine $C_{18}H_{21}O_3N$ is found in bebeeru bark (*Nectandra Rodioei* (Hook.)), and true pareira root (*Chondodendron tomentosum* [Ruiz. and Pav.]), and is probably identical with buxine, contained in *Buxus sempervirens* (Linn.), and probably also with the pelosine of *Cissampelos Pareira* (Linn.). Crystallises from methyl alcohol in colourless prisms, m.p. 214, $[\alpha]_D -298°$. Forms crystalline salts. Contains one —OH and one ·OMe group. Behaves as a tertiary base. Used as a febrifuge, as a substitute for quinine. The subsidiary alkaloid *sepeerine* occurs in bebeeru bark, whilst the leaves of *Buxus sempervirens* (Linn.) also contain *parabuxine*, *buxinidine*, and *parabuxinidine*. The chief papers on the subject are Maclagan, Annalen, 1843, 48, 106; 1845, 55, 105; von Planta, *ibid.* 1851, 77, 333; Walz, J. 1860, 548; Faure, J. 11, 245; Wiggers, Annalen, 1840, 33, 81; Scholtz, Ber. 1896, 29, 2054; Arch. Pharm. 1898, 236, 530; 1906, 244, 555; 1911, 249, 408; 1913, 251, 136; and Hildebrandt, Arch. expt. Path. Pharm. 1907, 57, 279).

Belladonnine. *See* under *Atropine* (p. 637).

Berbamine. *See* under *Berberine* (*v. infra*).

Berberine and the Berberis Alkaloids.

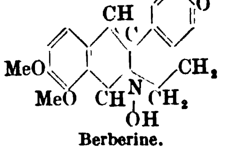
Berberine $C_{20}H_{17}O_4N,H_2O$ is contained in various species of *Berberis*, especially *B. vulgaris* (Linn.) (the barberry), which also contains berbamine $C_{18}H_{19}O_3N$ (Hesse, Ber. 1886, 19, 3193), and oxyacanthine (*v. infra*), in *Hydrastis canadensis* (Linn.), along with hydrastine (*see* p. 654), in *Coptis Teeta* (Wall.), which contains as much as 8 p.c., and in many other plants, but not in calumba root (Gordin, Arch. Pharm. 1902, 240, 146).

Preparation. The best available material from which to extract berberine is the root of *Hydrastis canadensis* (Linn.), which contains about 4 p.c. of the alkaloid. The finely-powdered hydrastis root is exhausted with alcohol, the greater part of the alcohol removed by distillation, and the alkaloid converted into sulphate or nitrate by the addition of sufficient dilute sulphuric acid or nitric acid. The crude berberine salt which separates is collected, dissolved in water, and sodium hydroxide and acetone added, whereby the alkaloid is precipitated in the form of its crystalline additive product with acetone, from which it is recovered as the hydrochloride by prolonged ebullition with chloroform and alcohol. The berberine is finally crystallised from water or alcohol.

Detection and estimation. For the detection of berberine in plants, *see* Gordin, Arch. Pharm. 1902, 240, 146. The same author recommends for estimation the precipitation of the alkaloid as sulphate from its alcohol solution, the decomposition of the sulphate by potassium iodide and the titration of the sulphuric acid liberated by means of N/40 potassium hydroxide (*ibid.* 1901, 239, 638).

Properties. Long, silky, yellow, needle-shaped crystals. Crystallised from water the substance contains $5\frac{1}{2}H_2O$; dried at 100° the crystals retain $2\frac{1}{2}H_2O$ (Perkin, Chem. Soc. Trans. 1889, 55, 63); m.p. 160° (decomp.). Slightly soluble in cold water or alcohol, but freely soluble in the hot liquids, slightly soluble in benzene or chloroform, insoluble in ether or light petroleum. Its aqueous solution is neutral to litmus, optically inactive, and has a bitter taste. The alkaloid is not poisonous to man, and is used medicinally, like preparations of the plants containing it, as a tonic. The ordinary salts of berberine crystallise well, and are of a yellow or red colour. They are sparingly soluble in water, especially in presence of mineral acids or salts.

Reactions. On adding excess of hydrochloric, sulphuric, or nitric acid, to a solution of berberine the salts separate as crystalline precipitates. Alkalis colour berberine brown. Chlorine water gives with a solution of the hydrochloride a bright-red coloration even in very dilute solutions. With alkaline permanganate berberine yields as chief products *berberal* $C_{20}H_{17}O_7N$ and *berberilic acid* $C_{20}H_{17}O_9N$. The former on hydrolysis gives noroxyhydrastinine and ψ-opianic acid. These reactions indicate that berberine has the following constitution (*cf.* Perkin, Chem. Soc. Trans. 1889, 55, 63; 1890, 57, 1081; 1910, 97, 305; Tinkler, *ibid.* 1911, 99, 340; Gadamer, Chem. Zeit. 1902, 26. 291, 385; Arch. Pharm. 1905, 243, 31; 1910, 248, 43). A synthesis of berberine has been effected by Pictet and Garus (Compt. rend. 1911, 152, 1102; 153, 386):—



Berberine.

Berberine is therefore closely allied to hydrastine, which occurs with it in *Hydrastis canadensis* (Linn.), and also to the two opium alkaloids, papaverine and narcotine.

Oxyacanthine $C_{19}H_{21}O_3N$ accompanies berberine in *Berberis vulgaris* (Linn.) (Polex, Arch. Pharm. 1836, 45, 271; Hesse, Ber. 1886, 19, 3190; Rüdel, *ibid.* 1891, 229, 631), and may be obtained by precipitating with soda the mother-liquor from which all the berberine salt has crystallised (Hesse). It crystallises with difficulty from alcohol or ether, m.p. 208°–214° (Hesse), is insoluble in water, easily soluble in chloroform, less so in alcohol. The alcoholic solution is dextrorotatory, alkaline to litmus, and has a bitter taste. The ordinary salts crystallise.

Betäine $C_5H_{11}O_2N$ (*lycine, oxyneurine*) (*v.* also vol. i. p. 452) occurs in sugar-beet and in numerous other plants. Crystalline, m.p. 293° (dry), optically inactive. Sweet taste. The hydrochloride has been used in medicine. It is formed by the oxidation of choline (p. 645), and by the action of trimethylamine on chloroacetic acid

$$CH_2Cl\cdot COOH + NMe_3 \rightarrow Cl\cdot NMe_3\cdot CH_2\cdot COOH$$

Chloroacetic acid. Trimethylamine. Betäine hydrochloride.

$$\rightarrow NMe_3\cdot CH_2\cdot CO\cdot O$$

Betäine.

The special anhydride grouping (betāine grouping) characteristic of betāine occurs in several natural alkaloids, *e.g.* chrysanthemine (p. 645), strychnine (p. 676), and trigonelline (p. 680).

Brucine. *See* under *Strychnine* (p. 678).

Bulbocapnine. *See* under *Corydaline* (p. 650).

Buxine, Buxinidine, Parabuxine, &c. *See Bebeerine* (p. 639).

Caffearine $C_{14}H_{16}O_4N_2$, an alkaloid occurring with caffeine (*see* below) in coffee berries. Hygroscopic needles, m.p. 140° (decomp.). Optically inactive. Weakly alkaline (Palladino, Chem. Soc. Abstr. 1894, 66, [i.] 214; 1895, 68, [i.] 629). According to Gorter (Annalen, 1910, 372, 237) caffearine is identical with trigonelline.

Caffeine and the Alkaloids of Tea, Coffee and Cocoa.

These bases are nearly related to uric acid, a substance only found in the animal organism.

Caffeine (*Theine*) $C_8H_{10}O_2N_4$, the principal alkaloid of tea and coffee, is also found in guarana, maté or Paraguay tea, kola nuts, and in small amounts in cocoa (Schmidt, Annalen, 1883, 217, 306). Coffee beans are stated to contain an average of about 1 p.c. of caffeine, and tea leaves 1–4·8 p.c. (Stenhouse, *ibid.* 1853, 89, 244; 102, 124; Chem. Soc. Mem. 1, 215; Chem. Soc. Trans. 1856, 9, 33; *cf.* Bull. Imp. Inst. 1908, 6, 1). More recent determinations conducted with improved methods have shown that ordinary samples of tea leaves contain from 3–4 p.c. of caffeine, whilst commercial samples of coffee show a remarkable uniformity in containing less than 1·5 p.c. of the alkaloid (Paul and Cownley, Pharm. J. 1886–1887, [iii.] 17, 565, 821, 921; 1890–1891, [iii.] 21, 61; Dvorkovitch, Ber. 1891, 24, 1945; *cf.* Bull. Imp. Inst. 1908, 6, 1, and Coffee. Vol. II. p. 97).

According to Kossel (Zeitsch. physiol. Chem. 1889, 13, 298) tea also contains small quantities of *theophylline* (*see* p. 642), *hypoxanthine*, or *sarcine* ($C_5H_4ON_4$), *iminosarcine* or *adenine* ($C_5H_5N_5$), and *xanthine* ($C_5H_4O_2N_4$), of which caffeine is the trimethyl derivative.

Preparation. Tea is heated for about an hour with four times its weight of boiling water, the solution is filtered and mixed with a weight of lime equal to that of the tea taken, and the mixture dried on the water-bath. The powdered residue is exhausted with boiling chloroform, which dissolves the caffeine. The alkaloid is purified by crystallisation from alcohol or water (Cazeneuve and Caillol, Bull. Soc. chim. 1877, [ii.] 27, 199; *cf.* Paul, Pharm. J. 1890–1891, [iii.] 21, 882). Or the methods described for the extraction of theobromine (*see* below) may be employed. Caffeine may be extracted from coffee and the other substances which contain it by similar methods.

Properties. Silky needles, containing $1H_2O$ from water, anhydrous from alcohol, chloroform, or benzene. The hydrate loses its water at 100°, and the anhydrous caffeine melts at 234°–235° (Strecker, Annalen, 1861, 118, 170; Dunstan and Shepheard, Chem. Soc. Trans. 1893, 63, 197). Sublimes without decomposition. Soluble in cold water (1 in 80 at 15°), readily soluble in boiling water. Sparingly soluble in ether or absolute alcohol, more soluble in aqueous alcohol. Very soluble in chloroform (13 in 100 at 16°). The aqueous solution is neutral and has a bitter taste.

Caffeine is a very weak, monacidic base. It dissolves in aqueous acids forming salts which crystallise, but are decomposed on evaporation of their aqueous solutions, which, indeed, would seem to contain free alkaloid under ordinary conditions, since caffeine can be extracted from them by shaking with chloroform. The salts of caffeine with organic acids are particularly unstable. The double salts are more stable. The aurichloride $B{\cdot}HAuCl_4$ and mercuric chloride compound $B{\cdot}HgCl_2$ crystallise well (Nicholson, Annalen, 62, 71; Schmidt, *ibid.* 1883, 217, 283; Ber. 1881, 14, 814). The aurichloride melts at 242·5°, and is soluble in alcohol, and to a smaller extent in water. It is decomposed when its aqueous solution is warmed, with loss of two molecular proportions of hydrochloric acid, forming aurichlorcaffeine $C_8H_9(AuCl_2)O_2N_4$, m.p. 207°, insoluble in water or alcohol: this dissolves in aqueous hydrochloric acid, reproducing the aurichloride (D. and S.). Caffeine does not unite directly with auric chloride, but it combines with potassium auric chloride, forming a red crystalline compound $B{\cdot}KAuCl_4$, m.p. 208°. This is precipitated by mixing a solution of caffeine in chloroform with an alcoholic solution of potassium auric chloride, and is resolved into its constituents on solution in water or acetone (D. and S. *l.c.* 205). The 'citrate' $B{\cdot}C_6H_8O_7$ is a colourless powder, soluble in water (1 in 3; more water dissociates the salt forming caffeine which re-dissolves in excess of water, 1 in 32). This salt, as well as caffeine itself, is used in medicine.

For information concerning other caffeine salts, the papers of Nicholson and Schmidt, referred to above, should be consulted.

Reactions. Caffeine is precipitated by several of the alkaloidal reagents, notably tannic acid and iodine solution in presence of acid, but not by Mayer's solution. It exhibits the murexide reaction (p. 642), the oxidation being best effected by evaporating a solution of caffeine in hydrochloric acid with a crystal of potassium chlorate.

Caffeine is methyltheobromine and consequently trimethylxanthine (Fischer, Ber. 1898, 31, 2563). It may be prepared by heating silver theobromine with methyl iodide (Strecker, Annalen, 1861, 118, 170). The constitution of caffeine and its relationship to other alkaloids of this group is discussed below.

Estimation of caffeine in tea and coffee. A number of methods have been proposed for this purpose. Allen's modification of Stahlschmidt's process gives good results: 6 grms. of the finely-powdered tea are boiled under a reflux apparatus during 6–8 hours with 500 c.c. of water. The filtered extract is diluted to 600 c.c., heated almost to boiling, 4 grms. of lead acetate added, and the boiling continued for 10 mins. 500 c.c. of the filtrate are evaporated to 50 c.c., and the excess of lead removed by adding sodium phosphate. The filtrate is concentrated to 40 c.c., and the caffeine extracted by shaking at least 4 times with chloroform. The total chloroformic solution is run into a tared flask, the solvent distilled off and the residue dried by a current of warm, dry, filtered air and weighed. Its weight multiplied by 20 gives the percentage of caffeine in the tea. (For other processes, *see* Paul and Cownley, Pharm. J. 1887–1888, [iii.] 18, 417; Vité, Chem. Zentr. 1890, ii. 274; Dvorkovitch, Ber. 1891, 24, 1945.) These methods also answer for coffee if a larger quantity of the material is taken.

Theobromine $C_7H_8O_2N_4$ occurs in cocoa beans (*Theobroma Cacao* [Linn.]), and is also stated to be present in minute amounts in tea leaves and kola nuts (*cf.* Dekker, Rec. trav. chim. 1903, 22, 143). Cocoa beans usually contain 1–2 p.c. of theobromine; the nibs or shells of the beans contain about 0·5 p.c. *V.* also Cocoa, vol. ii. p. 91.

Preparation. Finely-powdered cocoa beans are exhausted with boiling water. Lead acetate solution is then added until no further precipitate is obtained. By this means tannin, organic acids, and colouring matter are removed. The filtrate is freed from lead by hydrogen sulphide, and evaporated to dryness. The residue is boiled with alcohol to dissolve the theobromine, which crystallises when the alcoholic solution is evaporated. Or the powdered beans may be mixed with about half their weight of quicklime, and the mixture boiled with alcohol (80 p.c.), which dissolves the theobromine (Schmidt and Pressler, Annalen, 1883, 217, 288; Dragendorff, Ber. 1878, 11, 1689).

Estimation. The method described by Dekker (Rec. trav. chim. 1903, 22, 143) is stated to give good results.

Properties. Microscopic needles which sublime when heated at 290°–295°, m.p. 329° (under pressure) (Keller, Annalen, 1854, 92, 71, 329; Michael, Ber. 1895, 28, 1629). Slightly soluble in water (1 in 1600 at 17°; 1 in 148·5 at 100°) or ether, rather more soluble in chloroform (1 in 105 at 62°). Very slightly soluble in absolute alcohol, more soluble in aqueous alcohol (rectified spirit, 1 in 47 at b.p.). Theobromine possesses both acid and feebly basic properties. It dissolves in aqueous alkalis, and the solution yields metallic derivatives, which crystallise with difficulty and are decomposed by carbon dioxide, theobromine being liberated. The silver compound

$AgC_7H_7O_2N_4,1\frac{1}{2}H_2O$

is insoluble in water. It is produced as a semi-crystalline precipitate when silver nitrate is added to a solution of theobromine in aqueous ammonia (Schmidt, Annalen, 1883, 217, 282).

Theobromine acts as a monacidic base. It unites with acids, forming crystalline salts, which, as a rule, are decomposed by boiling with water (Schmidt and Pressler, *ibid.* 1883, 217, 289).

Reactions. Theobromine is precipitated by several of the alkaloid reagents, but not by Mayer's solution. It is most easily detected by a reaction which is very similar to the murexide reaction for uric acid. The theobromine is first oxidised by warming it with chlorine water, or a drop of nitric acid, and evaporating to dryness. The residue consists chiefly of amalic acid (tetramethylalloxantin $C_8(CH_3)_4O_7N_4$). The residue is coloured violet by potash and bright red by ammonia, owing to the formation of tetramethylmurexide. This reaction is very delicate, but it is also exhibited by the other alkaloids of this group.

The constitution of theobromine and its relation to other alkaloids of this group is discussed below.

Theobromine is dimethylxanthine and may be prepared from xanthine (*see* below) by heating its lead or silver derivative with methyl iodide at 100° (Fischer, Annalen, 1882, 215, 311).

Theophylline $C_7H_8O_2N_4$, an isomeride of theobromine, which occurs in small quantity in tea leaves (Kossel, Zeitsch. physiol. Chem. 1888, 13, 298; Ber. 1888, 21, 2164).

Preparation. A large quantity of tea is exhausted by extraction with alcohol, and the solution evaporated to a syrup, from which the greater part of the caffeine will crystallise out. This is removed, and the liquid residue diluted with water acidified with sulphuric acid. After having stood for some hours the liquid is filtered, the filtrate made alkaline with ammonia, and precipitated by solution of silver nitrate. After the lapse of 24 hours the precipitate is filtered off, washed, and dissolved in a little warm nitric acid (sp.gr. 1·1). On cooling the silver derivatives of sarcine and adenine crystallise out, leaving the silver theophylline dissolved. The acid filtrate is made alkaline with ammonia, and the precipitate of silver theophylline, &c. collected, washed, suspended in water acidified with nitric acid, and decomposed by hydrogen sulphide. By evaporating the filtrate crystals of xanthine separate, and afterwards the theophylline crystallises. A further quantity may be obtained from the mother liquor by precipitation with mercuric nitrate and decomposition of the precipitate with hydrogen sulphide (Kossel, *l.c.*).

Properties. Tabular crystals, with $1H_2O$, m.p. 264°. Readily soluble in boiling water. Slightly soluble in cold alcohol. Like theobromine, it affords the 'murexide' reaction, and in general its decomposition products are similar. When silver theophylline is heated with methyl iodide caffeine is formed.

Constitution of caffeine and the related alkaloids. Alkaloids of this type are somewhat widely distributed in plants and animals. Thos occurring in plants are as follows:—

Adenine $C_5H_5N_5$ in tea and beetroot.

Guanine $C_5H_5ON_5$ in many leguminos plants, and as its pentoside *vernine* $C_{10}H_{13}O_5N_5$ in the seeds of *Vicia sativa* (Linn.), &c. (Schulz and Castoro, Zeitsch. physiol. Chem. 1904, 41, 463); also in guano.

Hypoxanthine $C_5H_4ON_4$ in black pepper, and as its pentoside *inosine* $C_{10}H_{12}O_5N_4$ in yeas and beetroot, and in meat extract (Haiser an Wenzel, Monatsh. 1908, 29, 157).

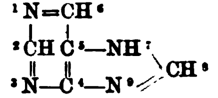
Xanthine $C_5H_4O_2N_4$ in tea.

Theophylline $C_7H_8O_2N_4$ in tea.

Theobromine $C_7H_8O_2N_4$ in cocoa.

Caffeine $C_8H_{10}O_2N_4$ in tea, coffee, kola.

Certain of these also occur in animals and uri acid, $C_5H_4O_3N_4$ is found in animals only. All these compounds may be regarded as derived from a parent substance purine (Fischer, Ber. 1899, 32, 435), which has so far not been found occurring naturally.



Purine.

The substances of practical importance are caffeine, theobromine, and theophylline, to which may be added uric acid, since it occurs in guano and is prepared from that source to be used as a raw material in the industrial manufacture of the three alkaloids just named. The constitution of uric acid is established by its synthesis accomplished by the following series of reactions (Fischer and Ach, Ber. 1895, 28, 2473):—

(1) Condensation of malonic acid with carbamide (urea) to form malonylcarbamide.

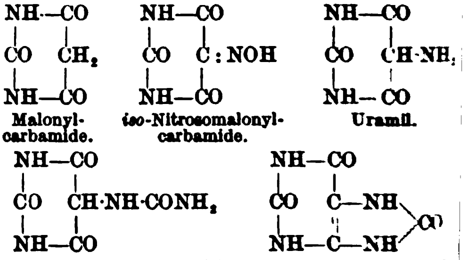
(2) Conversion of malonylcarbamide into its *iso*nitroso- derivative (violuric acid) by the action of nitrous acid.

(3) Reduction of *iso*nitrosomalonylcarbamide to the corresponding amino derivative (uramil).

(4) Conversion of uramil into *pseudo*uric acid by the action of potassium cyanate.

(5) Transformation of *pseudo*uric acid into uric acid by the action of hot dilute acid.

This series of changes may be represented thus—



Malonyl-carbamide. *iso*-Nitrosomalonyl-carbamide. Uramil.

pseudo-Uric acid. Uric acid (2:6:8-Trioxypurine).

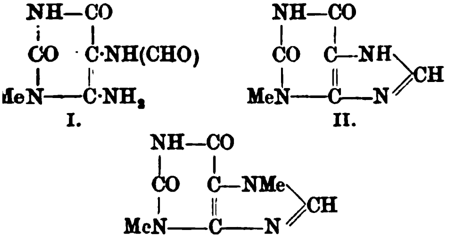
Adenine $C_5H_5N_5,3H_2O$, long needles, m.p. 360°–365°, is 6-aminopurine (p. 47, vol. i.).

Guanine $C_5H_5ON_5$, colourless amorphous powder, is 2-amino-6-oxypurine (p. 12, vol. iii.)

Hypoxanthine $C_5H_4ON_4$, microscopic needles, decomposes at 150°, is 6-oxypurine (p. 91, vol. iii.).

Xanthine $C_5H_4O_2N_4$, colourless powder, is 2:6-dioxypurine (p. 791, vol. v.).

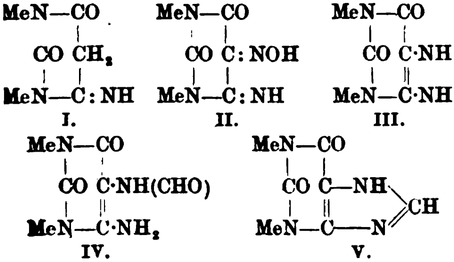
Theobromine $C_7H_8O_2N_4$ (for description, *see* bove). The synthesis of this alkaloid has been ccomplished by a series of reactions analogous o that described for theophylline (*v. infra*). 'or this purpose methylcarbamide is used as a tarting-point, leading eventually to the formyl lerivative of 4 : 5-diamino-2 : 6-dioxypyrimidine I) ; this, on loss of water, forms 3-methyl-anthine (II) ; which, on methylation, gives heobromine (3 : 7-dimethylxanthine or 3 : 7-limethyl-2 : 6-dioxypurine) (III)—



I. II.

III. (Theobromine).

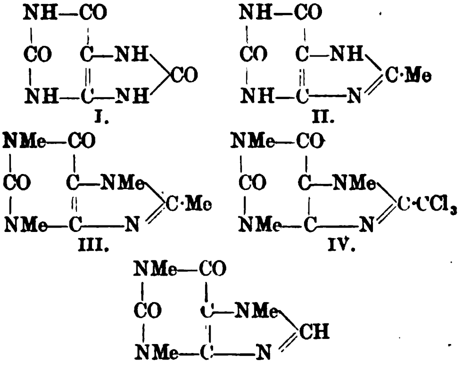
Theophylline $C_7H_8O_2N_4$ (for description, *see* above). This alkaloid has been synthesised by a series of reactions similar to those described for uric acid, and it may also be prepared from the latter. It is prepared commercially from uric acid or from dimethylcarbamide (Traube, Ber. 1900, 33, 3035). Dimethylcarbamide is condensed with cyanoacetic acid in presence of phosphorus oxychloride forming dimethylimino-barbituric acid (I), which by the action of nitrous acid is converted into the oximino compound (II). The latter on reduction forms 1 : 3-dimethyl-4 : 5-diamino-2 : 6-dioxypyrimidine (III), which with formic acid yields a formyl-derivative (IV); this on heating loses 1 mol. of water forming theophylline (V) (1 : 3-dimethyl-2 : 6-dioxypurine or 1 : 3-dimethylxanthine).



I. II. III.

IV. V.

Caffeine $C_8H_{10}O_2N_4$ (for description, *see* above). This alkaloid results from the methylation of xanthine, theophylline, or theobromine, so that the synthetic processes already described for the two latter alkaloids are also suitable for caffeine, provided the product obtained is methylated. Caffeine is therefore 1 : 3 : 7-trimethylxanthine (1 : 3 : 7-trimethyl-2 : 6-dioxypurine). Synthetic caffeine is manufactured chiefly from uric acid (I) by heating this with acetic anhydride (Böhringer and Söhne, D. R. P. 121224), when it is converted into 8-methylxanthine (II), which is then methylated completely, forming 1 : 3 : 7 : 8-tetramethylxanthine (III). The latter is fully chlorinated in the 8th position, and the resulting 1 : 3 : 7-trimethyl-8-trichloroxanthine (IV) treated with potash when caffeine (V) results.



I. II.

III. IV.

V. (Caffeine).

Calabarine. *See* under Physostigmine.

Calycanthine $C_{11}H_{14}N_2$, crystals, m.p. 243°–244° (dry), occurs with *iso*calycanthine, prisms, m.p. 235°–236° (dry), in the seeds of *Calycanthus glaucus* (Wild.). One nitrogen is secondary, the other tertiary. Toxic (Gordin, J. Amer. Chem. Soc. 1905, 27, 144, 1418 ; 1909, 31, 1305 ; 1911, 33, 1626).

Canadine. *See* under *Hydrastine* (p. 655).

Carpaine $C_{14}H_{25}O_2N$ occurs in papaw leaves (*Carica Papaya* (Linn.)). It forms glancing prisms, m.p. 121°, $[\alpha]_D + 21° 55'$, and has a bitter taste. A heart poison (Greshoff, 1890, Med. s'Lands Plantentuin, Java, No. 7, 5 ; van Rijn, Arch. Pharm. 1893, 231, 184 ; 1897, 235, 332). According to Barger (Chem. Soc. Trans. 1910, 97, 466) it is a lactone of carpamic acid $C_{14}H_{27}O_3N$.

Casimiroine $C_{24}H_{20}O_8N_2$, rosettes of colourless needles, m.p. 196°–197°, occurs in the seeds of *Casimiroa edulis* (LaLlave); the picrate, m.p. 165°, and aurichloride, m.p. 195°–196°, are crystalline. Contains two methoxyl groups, and on hydrolysis by alkalis yields *casimiroitine* $C_{23}H_{22}O_7N_2$, m.p. 171°, apparently by loss of CO_2 and absorption of H_2O. The seeds also contain *casimiroedine* $C_{17}H_{24}O_5N_2$, aggregates of small needles, m.p. 222°–223°, $[\alpha]_D - 36{\cdot}5°$ (in acid solution). Casimiroine and casimiroedine are physiologically inactive (Power and Callan, Chem. Soc. Trans. 1911, 99, 1993 ; *cf.* Bickern, Arch. Pharm. 1903, 241, 166 ; and Vincent, Bl. Gen. Ther. 1909, 158, 16, 96, 193, 241).

Cephaeline. *See* under *Emetine* (p. 652).

CEVADINE AND THE ALKALOIDS OF VERATRUM SPP.

The species principally concerned are the seeds of *Schoenocaulon officinale* (A. Gray) [*Asagræa officinalis* (Lindley)], and the rhizomes of *Veratrum viride* (Ait.) (green hellebore) and *Veratrum album* (Linn.) (white hellebore), all of which belong to the N. O. *Liliaceæ*, and have nothing in common with the hellebores proper, which belong to the N. O. *Ranunculaceæ*. The alkaloids present in these three drugs are as follows :—

Sabadilla seeds	Cevadine (crystallised veratrine) Veratridine (amorphous veratrine) Sabadilline (cevadilline) Sabadine Sabadinine

White Hellebore	Protoveratrine Jervine Pseudojervine Rubijervine Protoveratridine Veratralbine
Green Hellebore	Cevadine Veratridine Jervine Pseudojervine Veratralbine

It should be noted that there has been considerable confusion in the nomenclature of these alkaloids. Commercially the name 'veratrine' is applied to an amorphous mixture of alkaloids obtained from sabadilla seeds. The name veratrine is also frequently applied to veratridine, usually, however, with the prefix 'amorphous.' The name veratridine was also applied by Robbins (Pharm. J. 1877–1878, [iii.] 8, 316) to a crystalline alkaloid contained in green hellebore, and which, in some respects, resembles protoveratrine. It is not identical with Bossetti's veratridine isolated from sabadilla seed (Ber. 1883, 16, 1384).

Alkaloids of Sabadilla Seeds.

Cevadine (*crystallised veratrine*) $C_{32}H_{49}O_9N$ is the chief alkaloid of sabadilla or cevadilla seeds (*Schoenocaulon officinale* [A. Gray]).

Preparation. The finely-powdered seeds are extracted with alcohol, containing 1 p.c. of tartaric acid. The acid liquid is evaporated and diluted with water to precipitate resin. To the clear solution soda is added in slight excess, and the mixture completely extracted by repeatedly shaking with ether. The ethereal solution is mixed with light petroleum and the filtrate allowed to evaporate spontaneously. Crystals of cevadine separate from the syrup, and are recrystallised from their solution in alcohol. The remaining syrup contains veratridine (amorphous veratrine) and sabadilline (Wright and Luff, Chem. Soc. Trans. 1878, 33, 338).

Sabadilla seeds contain about 0·1 p.c. of cevadine.

'Commercial veratrine' is amorphous and appears to be a mixture of cevadine with amorphous alkaloids.

Properties. Rhombic prisms, containing $2C_2H_5OH$ when crystallised from alcohol. The alcohol is lost at 130°–140°, and the anhydrous alkaloid then melts at 205° with decomposition. Nearly insoluble in water, soluble in alcohol or ether. Optically inactive. Acts as a monacidic base, forming salts, some of which are crystalline (Merck, Annalen, 1855, 95, 200; Schmidt, Annalen, 1877, 185, 224).

The aurichloride, m.p. 182° (decomp.), and the mercurichloride, m.p. 172° (decomp.), are characteristic crystalline compounds (Ahrens, Ber. 1890, 23, 2700).

Cevadine and its salts are intensely poisonous.

Reactions. When warmed with concentrated hydrochloric acid cevadine produces a fine purplish-red colour, which is a somewhat delicate test for the alkaloid. Concentrated sulphuric acid produces a carmine-red coloration, or, if the alkaloid is previously mixed with a little sugar, a blue.

Cevadine is a monacidic tertiary base. The alkaloid unites with bromine to form a dibromide and a tetrabromide. It contains no methoxyl groups and no :NMe group; one HO· group is present.

When allowed to stand with aqueous alkalis or when heated with alcoholic potash, cevadine undergoes hydrolysis furnishing *cevine*

$$C_{27}H_{42}O_8N$$

and angelic and tiglic acids $C_5H_8O_2$ (Wright and Luff, Chem. Soc. Trans. 1878, 33, 338; 18 35, 405; Bosetti, Arch. Pharm. 1883, [iii.] 2 81; Ahrens, Ber. 1890, 23, 2700; Freund and collaborators, *ibid.* 1899, 32, 801; 1904, 3 1964). Cevine crystallises with $3\frac{1}{2}H_2O$ from dilute alcohol, m.p. 195°–200° (anhydrous), and yields derivatives both with metals and acids. It is less toxic than cevadine (Freund, *l.c.*).

When oxidised by permanganate cevadine yields acetic and oxalic acids, or when chromic acid is used, principally acetaldehyde and carbon dioxide.

When anhydrous cevadine is distilled β-picoline is obtained with tiglic acid.

Veratridine (*amorphous veratrine*) $C_{37}H_{53}O_{11}N$ is found in sabadilla seeds, and is isolated from the amorphous alkaloids precipitated in the earlier stages of the preparation of cevadine (*see* above) by treating this with ether when it separates into insoluble matter (sabadilline) and soluble matter (veratridine). The latter is purified by conversion into the sparingly soluble crystalline nitrate. Veratridine is said to be sternutatory. On hydrolysis by alkalis it yields *verine* $C_{28}H_{45}O_8N$, which closely resembles cevine (*see* above) and veratric acid (3 : 4 dimethoxylbenzoic acid).

Sabadilline (*cevadilline*) $C_{34}H_{53}O_8N$ is a second amorphous alkaloid occurring in sabadilla seeds. It yields amorphous salts (W. and L. *l.c.*).

Sabadine $C_{29}H_{51}O_8N$, crystals, m.p. 238°–240°, also occurs in sabadilla seeds; the salts are crystalline (Merck, Arch. Pharm. 1891, 229, 164).

Sabadinine $C_{27}H_{45}O_8N$ (?), crystals; found in sabadilla seeds; yields a crystalline aurichloride and sulphate (M. *l.c.*).

Sabadilline, sabadine, and sabadinine all resemble cevadine in action, but are less toxic.

Alkaloids of White Hellebore Rhizome.

Protoveratrine $C_{32}H_{51}O_{11}N$ is the characteristically toxic alkaloid of white hellebore 'roots.' It crystallises in thin four-sided tablets from alcohol, m.p. 245°–250°, 239°–241° (Bredemann) and dissolves in sulphuric acid with a green coloration, which gradually passes into deep blue. It is readily decomposed by acids yielding *iso*butyric acid as one product.

Protoveratrine is accompanied in white hellebore rhizomes by

Jervine $C_{26}H_{37}O_3N$, prismatic crystals, m.p. 238°–242°; toxic.

Pseudo*jervine* $C_{29}H_{42}O_7N$, six-sided tablets, m.p. 300°–307°; not poisonous.

Rubijervine $C_{26}H_{43}O_2N$, long prisms, m.p. 240°–246°, 234° (Bredemann); not poisonous.

Protoveratridine $C_{24}H_{45}O_8N$, four-sided plates, m.p. 265°; not poisonous.

The chief papers relating to protoveratrine and its congeners are Wright and Luff (Chem. Soc. Trans. 1879, 35, 405), Salzberger (Inaug.

Diss. Erlangen, 1890; Arch. Pharm. 1890, 228, 162), Pehkschen (Inaug. Diss. Dorpat, 1890; J. Pharm. Chim. 1890, [v.] 22, 265), and Bredemann (Apoth. Zeit. 1906, 21, 41, 53).

Alkaloids of Green Hellebore Rhizome.

The chief alkaloids occurring in this drug have been described already, viz. cevadine (*see* under *Alkaloids of sabadilla seeds*), jervine, and pseudojervine (*see* under *Alkaloids of white hellebore rhizome*). Veratridine (*see* under *Alkaloids of sabadilla seeds*) occurs only in traces in green hellebore. Robbins isolated from green hellebore rhizomes (Pharm. J. 1877–1878, [iii.] 8, 316) a crystalline alkaloid which he called veratridine, and which, like protoveratrine of white hellebore, gives a green coloration with sulphuric acid. The amorphous alkaloid veratralbine was also obtained by Wright and Luff from this source (Chem. Soc. Trans. 1879, 35, 421).

Cheirinine. *See* under *Cheiroline.*

Cheiroline $C_5H_9O_2NS_2$, colourless prisms, m.p. 47°–48°, optically inactive, occurs in wallflower seeds (*Cheiranthus Cheiri* [Linn.]) and *Erysimum nanum* (Boiss. & Hohen.). On hydrolysis by dilute alkalis it yields carbon dioxide, hydrogen sulphide, and a substance $C_4H_{11}O_2NS$. It is stated to possess antipyretic properties (Wagner, Chem. Zeit. 1908, 32, 76; Schneider, Ber. 1908, 41, 4466; 1909, 42, 3416). From wallflower leaves or seeds Reeb has obtained *cheirinine* $C_{18}H_{35}O_{17}N_3$, which resembles quinine in physiological action (Arch. expt. Path. Pharm. 1898. 41, 302; 1899, 43, 130) and a glucoside cheiranthin.

Chelerythrine $C_{21}H_{17}O_4N$ occurs in various Papaveraceous plants, *e.g. Chelidonium majus* (Linn.), *Glaucium flavum* (Crantz.), *Sanguinaria canadensis* (Linn.) (Probst, Annalen, 1839, 29, 120, 250), *Bocconia* spp. Forms colourless rhombohedra with $1H_2O$ or $1C_2H_5OH$, m.p. 203°, $[\alpha]_D=0°$. Salts intensely yellow and well crystallised. Contains two methoxyl groups, and may be a methyl ether of sanguinarine (p. 675). Narcotic (König and Tietz, Arch. Pharm. 1893, 231, 145, 161; Murrill and Schlotterbeck, Ber. 1900, 33, 2802; Fischer, Arch. Pharm. 1901, 239, 409, 426, 438).

Chelidonine $C_{20}H_{19}O_5N,H_2O$ occurs with protopine, chelerythrine, sanguinarine, and α-, β-, and γ-homochelidonines in the root of the common celandine (*Chelidonium majus* [Linn.]), and with one or more of the same alkaloids in *Stylophorum diphyllum* (Nutt.) (Selle, Arch. Pharm. 1890, 228, 96), *Adlumia cirrhosa* (Rafin.) (*see* under *Adlumine*), and possibly in *Sanguinaria canadensis* (Linn.) (König and Tietz, Arch. Pharm. 1893, 231, 145, 161). It crystallises in monoclinic tablets, m.p. 135°–136°, $[\alpha]_D+115°24'$. Yields a benzoyl derivative, m.p. 217°, and when heated with zinc-dust furnishes ammonia and a substance with a phenanthrene-like odour (Schlotterbeck and Watkins, Pharm. Arch. 1903, 6, 141). Salts crystallise well (Wintgen, *ibid.* 1901, 239, 438). It is slightly toxic, resembling morphine in its action.

Chloroxylonine $C_{22}H_{23}O_7N$, an alkaloid occurring in East Indian satinwood (*Chloroxylon Swietenia* (DC.)). It crystallises from alcohol in colourless prisms, m.p. 182°–183°, $[\alpha]_D^{18}-9°18'$, in chloroform, is soluble in excess of ammonia solution, and is neutral to litmus. The salts are crystalline and dissociate in water; aurichloride $B\cdot HCl\cdot AuCl_3$ groups of reddish-yellow needles, m.p. 70°. Chloroxylonine contains four ·OMe but no hydroxyl groups (Auld, Chem. Soc. Trans. 1909, 95, 964). It produces dermatitis when applied to the skin and is the cause of the dermatitis sometimes experienced by satinwood workers (Cash, Brit. Med. J. 1911, Oct. 7; and Bull. Imp. Inst. 1911, 9, 351).

Choline $C_5H_{15}O_2N$ is an amine found in many plants, *e.g.* oats, lupins, barley, hops, potatoes, beetroot, scopolia, ipecacuanha, &c., and has long been known as a decomposition product of a number of substances occurring in the animal organism (lecithin, bile-acids, &c.). It reacts with acids like ammonium hydroxide, the acid radicle taking the place of hydroxyl. Choline is hydroxyethyltrimethylammonium hydroxide $N(C_2H_4OH)(CH_3)_3OH$; its chloride may be produced by the action of trimethylamine on ethylene chlorohydrin; *v.* also vol. ii. p. 48.

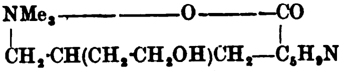
Chrysanthemine $C_{14}H_{28}O_3N_2$, crystals, occurs in *Chrysanthemum cinerariaefolium* (Vis.) flowers used under the name 'Dalmatian insect powder.' Forms crystalline salts; aurichloride

$$B\cdot 2HCl\cdot AuCl_3,$$

golden-yellow prisms. On oxidation with sodium hypobromite it forms oxychrysanthemine

$$C_{14}H_{26}O_4N_2,$$

which is a carboxylic acid. The potassium salt of this when heated with caustic potash solution gives trimethylamine, piperidinecarboxylic acid, and succinic acid, whence the following formula has been assigned to the alkaloid :—



$$\begin{array}{lcr} NMe_3 \text{———————} & O & \text{———————}CO \\ | & & | \\ CH_2\cdot CH(CH_2\cdot CH_2OH)CH_2 & \text{—} & C_5H_9N \end{array}$$

Chrysanthemine.

The alkaloid is relatively inactive physiologically (Marino-Zuco, Chem. Soc. Abstr. 1891, 60, 333; 1892, 62, 84).

Cinchonidine and **Cinchonine.** *See* under *Quinine* (p. 665).

Clavine. *See* under *Ergotoxine* (p. 652).

COCAINE AND THE COCA ALKALOIDS.

The coca leaves of commerce are derived from three varieties of the coca plant, *Erythroxylon Coca* (Lam.), viz. *E. Coca*, var. *Bolivianum* (Burck.) *E. bolivianum* (Rusby), cultivated in Bolivia; *E. Coca* var. *Truxillense* (Rusby), cultivated in Peru; and *E. Coca*, var. *spruceanum* (Burck.), cultivated in Java. *E. Coca*, var. *Novo-granatense* (Morris), and *E. Coca*, var. *Bolivianum*, are also cultivated in Ceylon and the Federated Malay States. Bolivian leaves rarely appear in European markets. The Peruvian leaves are known as Truxillo leaves. The Ceylon leaves may be either Truxillo (probably from *E. Coca*, var. *Novo-granatense*) or Bolivian (Huanuco) in character, and the Java leaves are distinct from any of these types in appearance, and in the fact that they contain little or no cocaine (*cf.* Holmes, Pharm. J. 1901, [iv.] January 5th and 26th, and Bull. Imp. Inst. 1912, 10, 37). Coca leaves contain alkaloids of four types—

1. *Cocaines;* alkyl acyl derivatives of ecgonine.

2. *Acylecgonines;* acyl derivatives of ecgonine.

3. *Pseudotropeines;* acyl derivatives of pseudotropine.

4. *Hygrines.*

The first and second types of alkaloid can be employed as commercial sources of ecgonine, and consequently can be used for the manufacture of crystalline cocaine which is readily prepared from ecgonine. The coca leaves derived from South America contain up to 1 p.c. of total alkaloids soluble in ether (mostly cocaine), the Ceylon and Federated Malay States leaves contain up to 1·6 p.c. of total alkaloid soluble in ether, of which two-thirds may be cocaine, whilst Java leaves contain 1·6, or sometimes more total alkaloids, little or none of which is cocaine, but from which a large proportion of cocaine can be prepared.

Estimation of total alkaloids in coca leaves. The following process is given in the United States Pharmacopeia, 8th ed.: 10 grms. of coca leaves in No. 60 powder are mixed with 50 c.c. of a mixture of chloroform 1 vol., ether 4 vols., in a stoppered Erlenmeyer flask and set aside during 10 mins. Two c.c. of ammonia solution diluted with 3 c.c. of water are then added and the flask shaken at intervals during 1 hour. A small glass percolator with the lower end obstructed by a wad of cotton wool is then placed in the neck of a separating funnel containing 6 c.c. of N-sulphuric acid, diluted with 20 c.c. of water and the contents of the flask poured into the percolator. When all the liquid has passed the contents of the percolator are packed in firmly by means of a glass rod, and then the flask is rinsed out with 10 c.c. of the chloroform-ether mixture, followed by several successive washings with 5 c.c. quantities of the same mixture, the percolation being continued with this liquid until 50 c.c. have been used in all. The separator is now shaken during one minute, the acid liquid drawn off, and the extraction repeated twice, using each time 10 c.c. of acid (6 c.c. N-acid with 20 c.c. of water); the combined acid liquors are made distinctly alkaline with ammonia solution and the alkaloids extracted with successive portions of ether (25, 20, and 15 c.c.). The ether is allowed to evaporate spontaneously and the residue dissolved in 4 c.c. of N/10 sulphuric acid, and the excess of acid determined by N/50 potassium hydroxide, using cochineal or iodeosin as indicator. This process gives the amount of ether-soluble alkaloids in the drug. No satisfactory process is yet available for the estimation of cocaine in the 'total alkaloids.'

Cocaine $C_{17}H_{21}O_4N$ occurs to a variable extent in the different varieties of coca leaves (*see* above).

Preparation. The coca leaves are exhausted by maceration and agitation with a mixture of aqueous sodium carbonate and petroleum, whereby the cocaine with cinnamyl cocaine, &c., passes into solution in the petroleum. The latter is shaken with dilute hydrochloric acid, when cocaine hydrochloride crystallises out and is collected, pressed, and dried. This crude salt is purified by solution in water, liberation of the free base by ammonia and solution of this in alcoholic hydrogen chloride, when the hydrochloride crystallises out. The mother-liquors contain the other coca alkaloids. If Java coca leaves are used the coca alkaloids other than cocaine alone are obtained, and these and the residual coca alkaloids referred to above are converted into cocaine by heating with boiling hydrochloric acid and pouring into water, when truxillic acids separate and may be filtered off. The filtrate is concentrated until ecgonine hydrochloride crystallises out. The ecgonine is recovered, and then benzoylated and methylated in turn to produce cocaine.

The crude cocaine manufactured in Peru and imported to Europe for the preparation of cocaine salts is said to be obtained by extracting the leaves with 0·5 p.c. sulphuric acid, making the filtrate alkaline with sodium carbonate and extracting with petroleum. The latter is again shaken out with dilute sulphuric acid and the crude alkaloid precipitated from this as a white, bulky powder by sodium carbonate. The powder is washed with water and dried by exposure to air for export.

Properties. Monoclinic prisms, m.p. 98°; at higher temperatures it sublimes with decomposition. Lævorotatory $[\alpha]_D -15·8°$; slightly soluble in cold water, more soluble in hot water. Readily soluble in alcohol, ether, benzene, light or heavy petroleum, or carbon disulphide. The aqueous solution is alkaline to litmus, has a bitter taste, and produces a tingling and numbness of the tongue and lips, or, more generally, local anæsthesia of the surface to which it is applied. On this account it is largely employed in minor surgical operations, although in recent years it has been replaced to some extent by synthetically prepared anæsthetics, such as eucaine, stoväine, novocaine, &c. The alkaloid also causes dilatation of the pupil of the eye, but is not so powerfully mydriatic as some of the solanaceous alkaloids. When administered internally in small doses it acts as a stimulant, and diminishes the feeling of fatigue consequent on muscular exertion. Coca leaves have long been known to possess this property, and in places where the plant is abundant a mixture of lime and coca leaves is chewed by the natives before engaging in severe exertion. Larger doses of the alkaloid are poisonous.

The ordinary salts of cocaine are crystalline. The hydrochloride B·HCl, which is used in medicine, has m.p. 189·9°, and crystallises anhydrous from alcohol, or with $2H_2O$ from water. The chromate $B·H_2CrO_4,H_2O$ is thrown down as a pale-yellow precipitate when potassium chromate is added to an acid solution of the hydrochloride. This salt is very slightly soluble in cold water, m.p. 127°. The aurichloride $B·HAuCl_4$ is crystalline and sparingly soluble in water. When aqueous mercuric chloride is mixed with a solution of cocaine hydrochloride a bulky precipitate of the mercurichloride $B·HCl·HgCl_2,2H_2O$ is formed. This salt may be crystallised from alcohol, m.p. 124°.

d-Cocaine was obtained by Liebermann and Giesel (Ber. 1890, 23, 508, 926) from coca leaves, but was probably formed by the racemisation of *l*-cocaine by the action of alkalis; it has been synthesised from *d*-ecgonine. *dl*-Cocaine, m.p. 80°, was prepared from *dl*-ecgonine by Willstätter and Bode (*ibid.* 1901, 34, 1457).

Detection. In isolating cocaine the aqueous solution should not be heated for any length of ime, and not at all in presence of acids or lkalis. For the liberation of the alkaloid from ts salts, ammonia, and not caustic alkalis, should e employed. Cocaine may be detected by its haracteristic action on the tongue (*see* above). The following reactions are useful for the detection of the alkaloid: One c.c. of a 3 p.c. solution f potassium permanganate gives a violet preipitate with 0·01 grm. of the hydrochloride lissolved in two drops of water (Chem. Zeit. 886, 10, 71). The hydrochloride heated with lcoholic potash gives off an odour of methyl enzoate. Schaefer has suggested (J. Amer. Chem. Soc. 1899, 21, 634) that the differences n solubility of the chromates might be used for he detection of amorphous coca alkaloids in ocaine and its salts. The purity of cocaine ydrochloride may be roughly gauged by Maclagan's test (*cf.* B. Ph. G. 1899, 9, 38), which consists in dissolving 0·06 grm. of the ydrochloride in 60 grms. of water and adding 2 drops of 10 p.c. ammonia solution. A crystalline precipitate indicates that the hydrochloride s reasonably free from amorphous alkaloids, whilst a milky precipitate indicates the presence f amorphous coca bases.

REACTIONS AND CONSTITUTION. Cocaine exhibits most of the general reactions of the vegetable alkaloids. When boiled with water t is gradually hydrolysed into methyl alcohol and *benzoylecgonine* (*see* below)

$$C_{17}H_{21}O_4N+H_2O=C_{16}H_{19}O_4N+CH_3OH$$

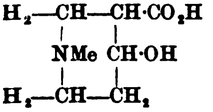
Paul, Pharm. J. 1887–1888, [iii.] 18, 781; Einhorn, Ber. 1888, 21, 47), and the same hange gradually occurs if the alkaloid remains n contact with an alkaline liquid. With alkalis r mineral acids methyl alcohol and benzoylcgonine are first formed, but the latter undergoes further hydrolysis into *benzoic acid* and *cgonine* (*see* below)

$$C_{17}H_{21}O_4N+2H_2O$$
$$=CH_3OH+C_7H_6O_2+C_9H_{15}O_3N.$$

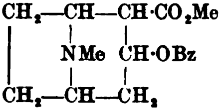
Natural cocaine is therefore methylbenzoyl-*l*-cgonine.

l-Ecgonine $C_9H_{15}O_3N$. This base does not ccur as such in coca leaves, but is the ultimate asic product of hydrolysis of cocaine, cinnamylocaine, the truxillines and benzoylecgonine. t crystallises from dry alcohol in monoclinic risms with $1H_2O$, m.p. 140°, or 198°–199° anhydrous); lævorotatory. It is readily esteried by alcohols yielding a series of alkyl esters, nd by acid chlorides or anhydrides, giving the cylecgonines from which the corresponding cocaines' are obtained by alkylation.

Ecgonine is now known, principally as the esult of the researches of Einhorn, Liebermann, Willstätter and their collaborators (*see* below), be closely related to tropine, the ultimate asic hydrolytic product of atropine and yoscyamine (p. 636), and may be regarded as opine-β-carboxylic acid. Ecgonine and its ost important derivative *l*-cocaine may be presented by the following formulæ:—



Ecgonine.



Cocaine.

Some of the chief papers bearing on the constitution of ecgonine are: Einhorn, Ber. 1889, 22, 399; 1890, 23, 1338; 1893, 26, 324; 1894, 27, 2823; Annalen, 1894, 280, 96; Liebermann, Ber. 1890, 23, 2518; 1891, 24, 606; Willstätter, *ibid.* 1897, 30, 702; 1898, 31, 1546, 2500, 2655; 1901, 34, 519; Annalen, 1903, 326, 79.

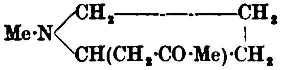
***l*-Benzoylecgonine** $C_{16}H_{19}O_4N$ is the first product of the hydrolysis of cocaine; it occurs in coca leaves from which it was isolated almost simultaneously by Skraup (Monatsh. 1885, 6, 556), and by Merck (Ber. 1885, 18, 1594). The base crystallises from water in needles, m.p. 86° (anhydrous 195°), and is hydrolysed by hydrochloric acid to benzoic acid and ecgonine. On methylation it furnishes cocaine.

***l*-Cinnamylcocaine** $C_{19}H_{23}O_4N$. This alkaloid is now known to occur in all varieties of coca leaves, but is found in largest proportion in the Java leaves, whence it was isolated by Giesel (Pharm. Zeit. 1889, 34, 516). It forms needles, m.p. 121°, from benzene on addition of light petroleum. Lævorotatory. On hydrolysis it furnishes cinnamic acid, methyl alcohol, and *l*-ecgonine, and is therefore methylcinnamyl-*l*-ecgonine. The *d*-isomeride has been prepared (Einhorn and Deckers, Ber. 1891, 24, 7).

Truxillines $C_{38}H_{46}O_8N_2$. Two of these, *α*- and *β*-, occur in coca leaves; the former is methyl-*α*-truxillyl-*l*-ecgonine, and the second the corresponding *β*-truxillyl compound (Hesse, Pharm. Zeit. 1887, 32, 407, 668; Liebermann, Ber. 1888, 21, 2342; 1889, 22, 130, 680). They are amorphous, and, according to von Liebrich, are heart poisons, and exert no local anæsthetic action.

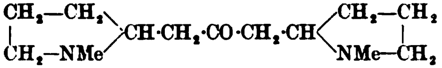
Tropacocaine (*Benzoylpseudotropeïne*) $C_{15}H_{19}O_2N$ was isolated by Giesel (Ber. 1891, 24, 2336) from Java coca leaves. It crystallises from ether, has m.p. 49°, is optically inactive, and distils unchanged. The salts are crystalline; the aurichloride has m.p. 208°. On hydrolysis tropacocaine furnishes benzoic acid and pseudotropine (Liebermann, *ibid.* 1891, 24, 2336, 2587; 1892, 25, 927); the latter is a physical isomeride of tropine (p. 636), and has been synthesised by Willstätter (Ber. 1896, 29, 936; 1901, 34, 129, 3163), who assigns to it the same structural formula as to tropine, and states that since tropine and pseudotropine are optically inactive the isomerism appears to be of the *cis-trans* type, a view subsequently confirmed by Barrowcliff and Tutin (Chem. Soc. Trans. 1909, 95, 1970). Tropacocaine, like the pseudotropeines as a class, is almost devoid of mydriatic action, but like cocaine (p. 646) is a local anæsthetic, though the effect is more transitory.

Hygrines. These secondary alkaloids were discovered by Lossen in Peruvian coca leaves (Annalen, 1862, 121, 374; 1865, 133, 352), and investigated by Liebermann and collaborators (Ber. 1889, 22, 675; 1891, 24, 407; 1893, 26, 851; 1895, 28, 578; 1896, 29, 2050; 1897, 30, 1113), who showed that Lossen's supposed homogeneous material contained two liquid alkaloids, one boiling at 193°–195° and having the formula $C_8H_{15}ON$, which makes it isomeric with tropine (p. 636), and a second having the composition $C_{14}H_{24}ON_2$, b.p. 215°, under 50 mm. pressure. The low boiling alkaloid is that now known as hygrine. Willstätter and Ettlinger's synthesis of hygrinic acid shows that hygrine probably has the following constitution (Annalen, 1903, 326, 91):—



Hygrine (Willstätter and Ettlinger).

From "cusco" leaves Liebermann and Cybulski isolated a third substance of this type, viz. cuscohygrine $C_{13}H_{24}ON_2$, b.p. 185° under 32 mm. pressure, which forms a crystalline hydrate $B,3\frac{1}{2}H_2O$, m.p. 40°. It probably has the constitution (L. a. C. Ber. 1895, 28, 578)—



Codeine. *See* under *Morphine* (p. 658).

Colchicine $C_{22}H_{25}O_6N$, an alkaloid existing in the seeds of the 'autumn crocus,' *Colchicum autumnale* (Linn.); *see* also COLCHICUM, vol. ii. p. 111.

Properties. A yellowish varnish, soluble in water, alcohol, or chloroform. It unites with chloroform forming a crystalline compound $B,2CHCl_3$. Lævorotatory. The aqueous solution has a very bitter taste. Colchicine is poisonous, causing death by vaso-motor paralysis (Dixon and Malden, J. Physiol. 1908, 37, 50). The alkaloid dissolves in sulphuric acid, forming a yellow solution, which becomes green, violet, and finally red on the addition of a drop of nitric acid. It contains three methoxyl groups and one acetyl group, and when treated with hydrochloric acid gives 3 mols. methyl chloride, 1 mol. acetic acid, and 1 mol. colchicinic acid $C_{15}H_{11}N(OH)_3COOH$. When heated with hydriodic acid colchicine furnishes one molecular proportion of methyl iodide, together with *colchiceine* $C_{21}H_{23}O_6N$, an alkaloid, which also occurs in *Colchicum autumnale* (Linn.). When a solution of colchicine is boiled with dilute sulphuric acid colchiceine and methyl alcohol are formed. Colchiceine crystallises with $\frac{1}{2}H_2O$, and melts at 139° or 172° (anhydrous). It is lævorotatory. Unlike colchicine, colchiceine is not poisonous (*cf.* Fühner Arch. expt. Pharm. 1913, 72, 228). Colchicine may be reproduced from colchiceine by heating it with methyl iodide and a solution of caustic soda in methyl alcohol (Zeisel, Monatsh. 1886, 7, 568; 1888, 9, 4, 868). According to Windaus colchicine is an enol methyl ether of colchiceine (Chem. Soc. Abstr. 1911, 100, i. 904), and may be represented by the formula

$$C_6H(OMe)_3{:}C_{10}H_8O(OMe)NH{\cdot}COMe.$$

Columbamine $C_{21}H_{21}O_5N$ occurs in calumba root (*Jateorrhiza columba* [Miers]) (vol. i. p. 615) along with *jateorrhizine* $C_{20}H_{19}O_5N$, and a third alkaloid *palmatine*. Columbamine is only known in the form of its salts which are all yellow. On reduction the hydriodide yields the colourless tetrahydrocolumbamine hydriodide (Günzel, Arch. Pharm. 1906, 244, 257). Columbamine contains a —OH and four —OMe groups. On methylation it furnishes a methylcolumbamine identical with the dimethyl ether similarly obtained from jateorrhizine, and this on oxidation with permanganate gives corydaldine (an oxidation product of corydaline) and 3 : 4 : 5-trimethoxy-*o*-phthalic acid (?), so that these two alkaloids are closely related to corydaline and berberine (Feist, *ibid.* 1907, 245, 586). Palmatine $C_{21}H_{21}O_6N$ is yellow, and on reduction yields a colourless tetrahydride; its relationship to its associates is unknown (Feist, *l.c.*). The statement frequently made that calumba root contains berberine is inaccurate (Gordin, *ibid.* 1902, 240, 146).

Conessine or **Wrightine** $C_{24}H_{40}N_2$ exists in *Wrightia antidysenterica* and in *Holarrhena africana* (A. DC.) and *H. antidysenterica* (Wall.). Crystals, m.p. 122° (Polstorff, Ber. 1886, 19, 78, 1682; Warnecke, *ibid.* 1886, 19, 60; Arch. Pharm. 1888, [iii.] 26, 248, 281).

Conhydrine (*Conydrine*). *See* under *Coniine*, below.

Coniceine. *See* under *Coniine*, below.

CONIINE AND THE ALKALOIDS OF HEMLOCK.

Coniine $C_8H_{17}N$ is one of several poisonous, volatile alkaloids found in hemlock, *Conium maculatum* (Linn.). A similar mixture of alkaloids occurs in fool's parsley (*Aethusa cynapium* [Linn.]) (Power and Tutin, J. Amer. Chem. Soc. 1905, 27, 146). Besides coniine, hemlock contains N-*methyl*-d-*coniine*, N-*methyl*-l-*coniine*, γ-*coniceine*, *conhydrine*, and *pseudoconhydrine*.

Preparation. Coniine is most readily separated from the crushed, unripe hemlock seeds by digesting them with water made alkaline with sodium carbonate, to decompose the coniine malate, and distilling the mixture in a current of steam. The distillate contains the coniine, together with much ammonia derived from the ammonium salts present in the seeds. The liquid is neutralised with hydrochloric acid and evaporated to dryness. The dry residue is extracted with absolute alcohol, when most of the ammonium chloride remains undissolved, whilst the alkaloidal hydrochlorides go into solution. If ether is added to the alcoholic solution a further quantity of ammonium chloride is separated. The residue left by the evaporation of the alcoholic solution is dissolved in cold water, ether added, and the coniine liberated by the addition of potash. The ethereal layer is decanted, washed, dried with potassium carbonate and distilled at a low temperature, when the coniine remains as an oily liquid. It may be purified from the accompanying conhydrine by fractional distillation: the coniine passes over first. So prepared the coniine contains γ-coniceine from which it may be freed by conversion into the hydrochlorides and extracting these when dry with acetone, in which the γ-coniceine salt is soluble and the coniine salt insoluble.

Properties. Colourless, alkaline liquid, having a remarkable, penetrating odour and a burning taste; b.p. 166°–167°, m.p. −2°; rel. den. 0·8626 at 0°, dextrorotatory $[\alpha]_D = +13{\cdot}79°$.

Coniine is slightly soluble in cold water, but less so in hot water, so that a clear, cold solution becomes turbid when warmed. It dissolves about one-quarter of its own volume of water at the ordinary temperature. When boiled with water the alkaloid distils with the steam. Coniine mixes with alcohol in all proportions, and is also readily soluble in ether, but only sparingly so in chloroform or carbon disulphide. Exposed in the air it darkens and slowly resinifies. When administered internally coniine acts as a powerful poison. It is a monacidic base.

The ordinary salts are crystalline and soluble in water or alcohol. The hydrochloride B·HCl forms rhombic crystals and melts at 220°. The aurichloride $B \cdot HAuCl_4$, m.p. 77°, forms minute yellow needles.

Reactions. Coniine is a strong base, which precipitates many metallic hydroxides from solutions of their salts.

It is a secondary amine. When oxidised with nitric acid it yields *normal butyric acid* among other products. When permanganate is used *a-pyridinecarboxylic acid* (*picolinic acid*) is obtained. On distillation with zinc-dust coniine is decomposed into hydrogen and *a-n*-propylpyridine.

Ladenburg has inferred from these and other reactions that coniine is a-propylpiperidine and has confirmed this by effecting the synthesis of the alkaloid by hydrogenating (with sodium in alcoholic solution) a-allylpyridine

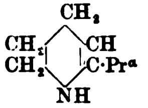
$$C_5H_4N(C_3H_5)+4H_2=C_5H_{10}N(C_3H_7).$$

The liquid thus produced possesses all the chemical and physical properties of the natural alkaloid except one; it is optically inactive (Ber. 1886, 19, 2579; 1906, 39, 2486). Ladenburg has also succeeded in resolving the inactive coniine into dextrorotatory and lævorotatory forms and has shown the dextro compound to be identical with the natural alkaloid. This was the first synthesis of a natural alkaloid.

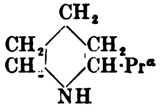
N-Methyl-*d*-coniine $C_8H_{16}(CH_3)N$ is stated to occur in hemlock (*v.* Planta and Kekule, Annalen, 1854, 89, 150), and remains with γ-coniceine when this is separated from coniine by fractional crystallisation of the acid tartrates. It has been synthesised by methylating coniine with potassium methyl sulphate (Wolffenstein, Ber. 1894, 27, 2611; *cf.* Passon, *ibid.* 1891, 24, 1678). It is a colourless, oily liquid, b.p. 173°–174°, closely resembling coniine.

N-methyl-*l*-coniine was obtained by Ahrens (*ibid.* 1902, 35, 1330) from residues accumulated in the preparation of coniine.

Coniceines. This name has been applied to a series of isomeric bases, $C_8H_{15}N$, obtained in various ways from the hemlock alkaloids. Only one of them γ-coniceine (2-propyl-Δ′-tetrahydropyridine) occurs in hemlock and was isolated from crude coniine obtained therefrom by Wolffenstein (Ber. 1895, 28, 302). This base was first prepared by Hofmann by the action of alkalis on bromoconiine. It strongly resembles coniine in odour and appearance, boils at 171°–172° under 746 mm. pressure, yields crystalline salts, and furnishes coniine on reduction. It has the constitution



γ-Coniceine.



Coniine.

Cf. Hofmann, Ber. 1885, 18, 16, 27, 112; Lellmann, Annalen, 1890, 259, 127; Löffler and colleagues, Ber. 1909, 42, 94, 107, 116, 124, 948, 3420; Gabriel, *ibid.* 1909, 42, 4059.

Conhydrine $C_8H_{17}ON$, also found in hemlock, may be separated from coniine with which it occurs either by cooling the concentrated ethereal solution of the two alkaloids, when the conhydrine crystallises out, or it may be obtained by distilling the crude coniine, when it remains behind in the retort, if the temperature has not exceeded 180°.

Conhydrine is a crystalline, basic substance, m.p. 121°, b.p. 226°, $[a]_D+10°$. On reduction it furnishes a mixture of coniceines (*see* above). According to Willstätter it is 2 : β-hydroxypropylpiperidine (Ber. 1901, 34, 3166; cf., however, Löffler and Tschunke, *ibid.* 1909, 42, 929).

Pseudoconhydrine $C_8H_{17}ON$, which is also found in hemlock, closely resembles conhydrine. It is a crystalline, strongly basic substance, m.p. 105°–106°; b.p. 236°. It is a secondary base and forms crystalline salts (Ladenburg and Adam, Ber. 1891, 24, 1671). Engler and Baur regard it as 2 : a-hydroxypropylpiperidine (*ibid.* 1894, 27, 1777), and Löffler has suggested that it is 4-hydroxy-2-propylpiperidine (*ibid.* 1909, 42, 116).

Conquinamine. *See* under *Quinine* (p. 673).

Cornutine. *See* under *Ergotoxine* (p. 653).

CORYDALINE AND THE CORYDALIS ALKALOIDS.

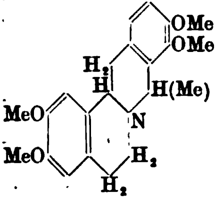
These alkaloids occur in the roots of *Corydalis tuberosa* (DC.). Certain of them possess a narcotic action, but they are not used in medicine, though corydalis tubers have been used as a drug. The chief alkaloids of the group are as follows:—

Corydaline $C_{22}H_{27}O_4N$,
Dehydrocorydaline $C_{22}H_{23}O_4N$,
Corybulbine $C_{21}H_{25}O_4N$,
*iso*Corybulbine $C_{21}H_{25}O_4N$.
Bulbocapnine $C_{19}H_{19}O_4N$,
Corytuberine $C_{19}H_{21}O_4N$,
Corydine $C_{20}H_{23}O_4N$,
*iso*Corydine $C_{20}H_{23}O_4N$.
Corycavine $C_{23}H_{23}O_6N$,
Corycavamine $C_{21}H_{21}O_5N$,
Corycavidine $C_{22}H_{25}O_5N$.

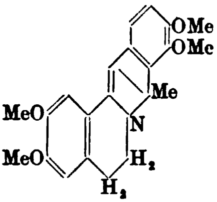
They fall naturally into 3 sub-groups of alkaloids closely related in chemical constitution and physiological action, and which may be called the corydaline, bulbocapnine, and corycavine sub-groups, as shown by the bracketing in the above table. According to Peters (Arch. expt. Path. Pharm. 1904, 51, 130) and Gadamer (Arch. Pharm. 1905, 243, 147) the corydaline sub-group produces paralysis of the spinal cord, the bulbocapnine sub-group gives rise to increased reflex action, whilst the corycavine sub-group stimulates the motor centres; all except corytuberine induce in frogs narcosis like that due to morphine. A method of isolation and separation of these alkaloids has been described by Gadamer, Ziegenbein and Wagner (Arch. Pharm. 1902, 240, 19).

Corydaline sub-group. The chief member *corydaline* $C_{22}H_{27}O_4N$ occurs in *Corydalis tuberosa* (DC.) and *C. ambigua* (Cham. and Schlecht.) (Makoshi, *ibid.* 1908, 246, 381). It crystallises from alcohol in hexagonal prisms, m.p. 134°–135°, $[a]_D^{16°}+300{\cdot}1°$ in chloroform, and furnishes well-crystallised salts; aurichloride $(B \cdot HCl)_2AuCl_3$, orange needles, m.p. 207°; platinichloride, m.p. 227°; ethyl sulphate $B \cdot C_2H_5HSO_4$, large prisms, m.p. 152°. On oxidation with iodine in alcohol it yields *dehydrocorydaline*, which occurs with it in *Corydalis tuberosa* (Schmidt, Arch. Pharm. 1908, 246, 575), *C.*

ambigua, and possibly *C. Vernyi* (Makoshi, *ibid.* 1908, 246, 381, 401). On oxidation by permanganate it gives eventually a mixture of hemipinic and *meta*hemipinic acids, and with nitric acid *meta*hemipinic and pyridine-2 : 3 : 4 : 6-tetracarboxylic acids, and from these results, and a study of the intermediate oxidation products, Dobbie and Lauder have assigned the following constitutional formulæ to corydaline and dehydrocorydaline (Chem. Soc. Trans. 1902, 81, 145; 1903, 83, 605; *cf.* Haars, Arch. Pharm. 1905, 243, 165)—



Corydaline.



Dehydrocorydaline.

which bring these alkaloids into close relationship with tetrahydroberberine and berberine respectively (p. 639).

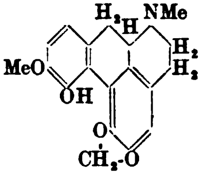
Corybulbine $C_{21}H_{25}O_4N$ crystallises in pale-yellow needles, m.p. 238°–240°, is dextrorotatory, $[\alpha]_D^{20}+303°$ (Bruns, *ibid.* 1903, 241, 634), and forms well-crystallised salts; the hydrochloride B·HCl forms yellowish prisms, m.p. 245°–250° (*l.c.*). On oxidation with iodine in alcohol corybulbine forms *dehydrocorybulbine* $C_{21}H_{21}O_4N$, m.p. 210°–211°, and on treatment with hydriodic acid furnishes 3 mols. methyl iodide. On methylation with methyl iodide in presence of potassium hydroxide it yields corydaline, so that it differs from the latter only in containing an —OH group in place of an —OMe group, probably in the *iso*quinoline nucleus (Dobbie and Lauder, Chem. Soc. Trans. 1895, 67, 25; and with Paliatseas, *ibid.* 1901, 79, 87).

*iso*Corybulbine $C_{21}H_{25}O_4N$, first obtained by Gadamer, Zeigenbein and Wagner (Arch. Pharm. 1902, 240, 19), crystallises in voluminous leaflets, m.p. 179°–180°, $[\alpha]_D+299·8°$, and on oxidation with iodine in alcohol yields *dehydro-isocorybulbine* $C_{21}H_{21}O_4N$, which resembles dehydrocorydaline and dehydrocorybulbine. The alkaloid contains three methoxyl groups (*cf.* Bruns, *ibid.* 1903, 241, 634).

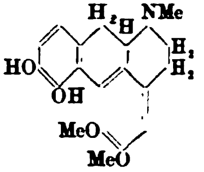
Bulbocapnine sub-group. The typical member of this group bulbocapnine $C_{19}H_{19}O_4N$ first obtained by Freund and Josephi (Annalen, 1893, 277, 10) separates from alcohol in rhombic needles, m.p. 199°, $[\alpha]_D+237·1°$ in chloroform, and yields crystalline salts. Bulbocapnine has until recently been regarded as a demethylated corydaline thus—

$C_{18}H_{15}(OMe)_4N$	$C_{18}H_{13}(OMe)(OH)_3N$
Corydaline.	Bulbocapnine.

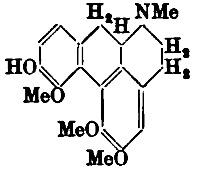
There was, however, very little evidence for this view, and Gadamer and Kuntze have shown that the alkaloid does not contain three OH groups. The oxygen atoms are present as methoxyl, hydroxyl, and dioxymethylene respectively. Further, 'exhaustive methylation' gives rise to 3 : 4-dimethoxy-5 : 6-dioxymethylene-8-vinylphenanthrene, which brings bulbocapnine into close relationship with apomorphine (p. 657). The same authors have investigated the other members of this group, and assign the following formulæ to the four alkaloids concerned (Arch. Pharm. 1911, 249, 503, 598, 641):—



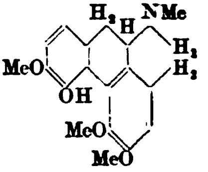
Bulbocapnine.



Corytuberine.



Corydine.



iso-Corydine

Corytuberine $C_{19}H_{21}O_4N$ crystallises with $5H_2O$ in colourless leaflets, m.p. 240°, $[\alpha]_D^{20°}+282·6°$, in alcohol and yields crystalline salts (Dobbie and Lauder, Chem. Soc. Trans. 1893, 63, 485; and Gadamer, Arch. Pharm. 1902, 240, 81; 1911, 249, 503, 641). *Corydine* $C_{20}H_{23}O_4N$ (crystals, with ½EtOH, m.p. 124°–125°, 149° anhydrous) has been described by Merck, and later by Gadamer, Ziegenbein and Wagner (*ibid.* 1902, 240, 81; 1911, 249, 669). On methylation with diazomethane corytuberine yields corydine and *iso*corydine (crystals, m.p. 185°, $[\alpha]_D^{20°}+195·3°$ in chloroform). The constitutional formulæ assigned by Gadamer (*l.c.*) to these three bases are given above.

Corycavine sub-group. The typical member of this group Corycavine $C_{23}H_{23}O_6N$, first obtained by Freund and Josephi (Annalen, 1893, 277, 15), crystallises in rhombic tablets, m.p. 218°–219°, and is optically inactive; it contains a dioxymethylene, but no ·OH or ·OMe group (Ziegenbein, Arch. Pharm. 1896, 234, 523; and Gaebel, *ibid.* 1910, 248, 207).

Corycavamine $C_{21}H_{21}O_5N$ is crystalline, m.p. 147°–148°, $[\alpha]_D^{20°}+166·6°$ in chloroform, and yields crystalline salts (Gadamer, Ziegenbein and Wagner, *ibid.* 1902, 240, 81).

Corycavidine $C_{22}H_{25}O_5N$, belonging to this sub-group, has been described by Gadamer (*ibid.* 1911, 249, 30). It is crystalline, has m.p. 212°–213°, $[\alpha]_D^{20°}+203·1°$ in chloroform, and, like corycavamine, is converted into the inactive form on heating at its melting-point. It appears to be corycavamine, in which a dioxymethylene group is replaced by two methoxyl groups.

Other alkaloids, including glaucine (p. 653) and protopine (p. 665) derived from *Corydalis* spp. have been referred to by Gadamer and others, *l.c.* and Arch. Pharm. 1911, 249, 224, 680; Haars, *ibid.* 1905, 243, 154; Makoshi, *ibid.* 1908, 246, 381, 401; Heyl, Apoth. Zeit. 1910, Nos. 5 and 17.

Cryptopine $C_{21}H_{23}O_5N$ occurs in opium, and is found in commercial papaverine; hexagonal prisms or plates, m.p. 218°, optically inactive, the aurichloride, m.p. 205° (decomp.), and the picrate, m.p. 215°, are crystalline; gives a bluish-violet coloration with sulphuric acid.

Exerts a narcotic action in small doses, but large doses paralyse the central nervous system (T. and H. Smith, Pharm. J. 1867, [ii.] 8, 595, 716; Pictet and Kramers, Ber. 1910, 43, 1329; Danckwortt, Arch. Pharm. 1912, 250, 590).

Cupreine. *See* under *Quinine* (p. 673).

Curarine. The drug known as 'curare' is a dry aqueous extract prepared from various species of *Strychnos*, indigenous in South America, where it was used by the natives as an arrow poison. Three kinds have appeared in commerce, viz. 'tube curare' in bamboo tubes, 'calabash curare' in small gourds, and 'pot curare' in unbaked clay jars. The first, also known as 'Para curare,' alone comes into commerce now, *v.* also vol. ii. 178. The drug has been examined by Roulin and Boussingault (Berz. J. 1829, 216), Buchner (*ibid.* 1861, 767), Preyer (*ibid.* 1865, 455), and Sachs (Annalen, 1878, 191, 254), who agree in stating that the intensely poisonous action is due to a basic substance, though they disagree as to whether this is amorphous or crystalline. Boehm (Arch. Pharm. 1897, 235, 660) has examined all three varieties of curare, and the following is a brief summary of his results :—

'TUBE CURARE.' This yields *tubocurarine* $C_{19}H_{21}O_4N$, an amorphous, bitter, intensely poisonous substance, and *curine* $C_{18}H_{19}O_3N$, a crystalline substance, m.p. 212°, crystallised from methyl alcohol, which is comparatively inactive physiologically.

Buraczewski and Zbijewski (Bull. Acad. Sci. Crac. 1910, 352) point out that these two bases give characteristic precipitates with iodine.

'CALABASH CURARE' yields *curarine*

$$C_{19}H_{26}ON_2,$$

which is amorphous, bitter, and poisonous.

'POT CURARE' furnishes *protocurarine* $C_{19}H_{23}O_2N$, poisonous; *protocurine* $C_{20}H_{23}O_3N$, crystalline, m.p. 306°, slightly toxic, and *protocuridine* $C_{19}H_{21}O_3N$, also crystalline, m.p. 275°, but physiologically inactive.

Curare is usually employed as such. It paralyses the motor nerve endings without, however, impairing the excitability of muscle, and on this account is largely employed in physiological research (*cf.* Edmund and Roth, Amer. J. Physiol. 1908, 23, 28, 46). *Delphocurarine* (*see* under *Delphinine*, below) exerts a similar action.

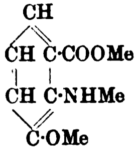
Cusconine $C_{23}H_{26}O_4N_2$, isomeric with aricine, which it accompanies in cusco bark (*Cinchona pubescens*). Crystals, m.p. 110° (Hesse, Annalen, 1877, 185, 301).

Cusparine $C_{19}H_{17}O_3N$ is found with *galipine* $C_{20}H_{21}O_3N$, *cusparidine* $C_{19}H_{17}O_3N$, *cuspareine* $C_{18}H_{13}N(OMe)_2$, *galipidine* $C_{19}H_{19}O_3N$, and *galipoidine* $C_{19}H_{15}O_4N$ in angostura bark (*Cusparia febrifuga*) [Hamb.]. Needle-shaped crystals, m.p. 90°–91°, or 110°–122°. Moderately soluble in ether, very soluble in alcohol (Körner and Böhringer, Gazz. chim. ital. 1883, 13, 363; Beckurts and Nehring, Arch. Pharm. 1891, 229, 591; Beckurts and Frerichs, Apoth. Zeit. 1903, 18, 697; Arch. Pharm. 1905, 243, 470; Tröger and others, *ibid.* 1910, 248, 1; 1911, 249, 174; 1912, 250, 494; 1913, 251, 246). *See* also CUSPARIA BARK, vol. ii. 180.

Cynoctonine. *See* under *Aconitine* (p. 634).

Cytisine $C_{11}H_{14}ON_2$ is contained in laburnum (*Cytisus Laburnum* [Linn.]), *Ulex europæus* (Linn.), *Sophora* spp., *Baptisia tinctoria* (R.Br.), *Euchresta Horsfieldii* (Benn.), and *Anagyris fœtida* (Linn.), from which it has been isolated under various names: ulexine, sophorine, baptitoxine (Husemann, Zeitsch. Chem. 1869, 5, 677; Gerrard, Pharm. J. 1886–87, [iii.] 17, 101, 229; Partheil, Ber. 1890, 23, 3201; 1891, 24, 634; Buchka and Magalhaës, *ibid.* 1891, 24, 253, 674). Prisms, m.p. 153°, which sublime without decomposition. Soluble in water, alcohol, or chloroform, insoluble in light petroleum. Cytisine usually behaves as a diacidic base: salts crystalline. The aurichloride $B{\cdot}HAuCl_4$ melts at 220°. In aqueous solution cytisine is lævorotatory, $[\alpha]_D^{17°} = -120°$, and gives with ferric chloride a red coloration, which is discharged by a few drops of aqueous hydrogen peroxide, a blue coloration being subsequently observed. Cytisine is a violent poison. For recent work on the chemistry of cytisine, *see* Freund and others, Ber. 1901, 34, 615; 1904, 37, 16; 1906, 39, 814; Maass, *ibid.* 1908, 41, 1635; Ewins, Chem. Soc. Trans. 1913, 103, 97. *Caulophyllum thalictroides* (Linn.) contains methylcytisine (Power and Salway, Chem. Soc. Trans. 1913, 103, 194).

Damascenine $C_{10}H_{13}O_3N$ occurs in the seed-coats of *Nigella damascena* (Linn.) and *N. arvensis* (Linn.). Crystalline mass, m.p. 26°, b.p. 270° under 750° mm. pressure. The solutions show blue fluorescence. The salts crystallise well. The alkaloid is narcotic. On treatment with acids or alkalis damascenine is hydrolysed into methyl alcohol and damasceninic acid, m.p. 144°, which with hydriodic acid yields 2-methylamino-3-hydroxybenzoic acid and methyl iodide, so that damasceninic acid appears to be 2-methylamino-3-methoxybenzoic acid, and damascenine itself is probably represented by the following formula :—



(Schneider, Pharm. Centh. 1890, [ii.] 173; Pommerehne, Arch. Pharm. 1899, 237, 475; 1900, 238, 531; 1904, 242, 295; Keller, *ibid.* 299; 1908, 246, 1; 1910, 248, 463 (Ewins, Chem. Soc. Trans. 1912, 101, 544).

Daucine $C_{11}H_{1}$[illegible]N_2, colourless, oily base, b.p. 240°–250°, occurring in carrot leaves (Pictet and Court, Ber. 1907, 40, 3771).

Delphinine $C_{31}H_{49}O_7N$ is one of a series of ill-defined alkaloids, including *delphisine*, *delphinoidine*, *staphisagroine*, and *staphisagroidine*, found in stavesacre seeds (*Delphinium Staphisagria* (Linn.)). (Kora-Stojanoff, Chem. Zentr. 1890, [ii.] 628, and Ahrens, Ber. 1899, 32, 1581, 1669.) *Delphinium consolida* and *D. ajacis*, according to Keller (Arch. Pharm. 1910, 248, 468; 1913, 251, 207), also contain alkaloids. From various *Delphinium* spp. Heyl has obtained 'delphocurarine,' an amorphous mixture of bases, including a crystalline substance, m.p. 184°–185° (Chem. Soc. Asbtr. 1903, i. 650).

'Delphocurarine' resembles curarine (*see* above) in physiological action (Lohmann, Pflug. Arch. 1902, 92, 398).

Dicentrine $C_{20}H_{21}O_4N$ occurs with protopine in *Dicentra pusilla* (Sieb. and Zucc.) and possibly in *D. formosa* (Walp.). Prismatic crystals, m.p. 168°–169°, $[\alpha]_D + 62°$ in chloroform. Salts crystalline (Heyl, Arch. Pharm. 1903, 241, 313; Asahina, *ibid.* 1909, 247, 201). Produces slight narcosis (Iwakawa, Arch. expt. Path. Pharm. 1911, 64, 369). Gadamer has stated (Arch. Pharm. 1911, 249, 680) that dicentrine resembles glaucine in its properties, and suggests that it is glaucine (p. 653) in which the two —OMe groups in positions 5 and 6 are replaced by a dioxymethylene group.

Dioscorine, $C_{13}H_{19}O_2N$, greenish-yellow plates, m.p. 43·5°, occurs in *Dioscorea hirsuta* (Blume) tubers. Bitter and poisonous (Gorter, Rec. Trav. Chim. 1911, 30, 161).

Ecgonine. *See* under *Cocaine* (p. 647).

EMETINE AND THE ALKALOIDS OF IPECACUANHA.

Emetine $C_{30}H_{44}O_4N_2$ occurs with *cephaeline* $C_{25}H_{40}O_4N_2$ and *psychotrine* in ipecacuanha root (*Psychotria Ipecacuanha*), (Stokes) which contains up to 2·5 p.c. of total alkaloids.

Preparation. The emetine may be extracted from ipecacuanha by moistening the finely-powdered root with ammonia and extracting with alcohol. From the total alkaloids so isolated emetine is separated by extraction with ether in presence of alkali.

Properties. Amorphous, colourless, m.p. 68°, yielding crystalline salts. In minute doses emetine produces local irritation resulting in emesis; in large doses it affects the central nervous system causing collapse and death.

Cephaeline $C_{25}H_{40}O_4N_2$ crystallises in colourless needles, m.p. 96°–102°, and exerts a physiological action similar to that of emetine.

Psychotrine is crystalline, m.p. 140°, and is physiologically inactive (Kunz-Krause, Arch. Pharm. 1887, 225, 461; 1894, 232, 466; Paul and Cownley, Pharm. J. 1894–1895, [iii.] 25, 373, 641, 690; Keller, Arch. Pharm. 1911, 249, 512).

DETECTION OF IPECACUANHA ALKALOIDS. The mixed ipecacuanha alkaloids have occasionally been mistaken for morphine. They may be distinguished by the fact that with Fröhde's reagent they give a violet coloration, changing to deep blue on addition of hydrochloric acid. Further, the alkaloidal residue from ipecacuanha readily develops microscopic crystals of psychotrine under the influence of ammonia gas (*cf.* Allen and Scott-Smith, Analyst, 1902, 27, 345).

ESTIMATION OF TOTAL ALKALOIDS IN IPECACUANHA. This is best accomplished, according to Flückiger, by extracting the finely-powdered root with boiling chloroform to which about 1 p.c. of aqueous ammonia has been added. Ransom finds it is better to exhaust the root with chloroform made alkaline with ammonia by shaking with aqueous ammonia and then withdrawing the layer of water. The solution in chloroform is shaken with dilute sulphuric acid, and the quantity of 'emetine' in the acid solution determined by titration with Mayer's solution (Pharm. J. 1887–1888, [iii.] 18, 241).

These processes were devised for the estimation of 'emetine' when the 'total alkaloid' of the root was regarded as consisting solely of emetine. Since Paul and Cownley have shown that the total alkaloids include three substances, emetine, cephaeline, and psychotrine, of which only the first two are active, these processes require some modification in order to give a correct idea of the medicinal value of the root. Frerichs and Fuentes Tapis (Arch. Pharm. 1902, 240, 390) and Keller (*ibid.* 1911, 249, 512) have employed ether in place of chloroform, since this extracts emetine and cephaeline, but not psychotrine (*cf.* U.S. Pharmacopeia, 8th ed.).

Ephedrine $C_{10}H_{15}ON$, crystals, m.p. 39°, b.p. 225°, occurs in *Ephedra vulgaris.* It is a secondary base, furnishes crystalline salts, and on 'exhaustive methylation' yields eventually trimethylamine and α-phenylallyl alcohol $C_9H_{10}O$. On distillation the hydrochloride furnishes methylamine and propiophenone. When heated with hydrochloric acid, ephedrine undergoes isomerisation to ψ-ephedrine (*iso*ephedrine), crystals, m.p. 117°, which also occurs with it in *E. vulgaris.* Both bases are poisonous and ephedrine hydrochloride has been used as a mydriatic (Ngai, Chem. Zentr. 1894, i. 470; Merck's Bericht, 1893, 13; Ladenburg and Oelschälgel, Ber. 1889, 22, 1823; Miller, Arch. Pharm. 1902, 240, 481; Flaecher, *ibid.* 1904, 242, 380; Schmidt and collaborators, *ibid.* 1905, 243, 73; 1906, 244, 239, 241, 269; 1908, 246, 210; 1909, 247, 141; 1911, 249, 305; 1913, 251, 320; Apoth. Zeit. 1911, No. 37; Fourneau, J. Pharm. Chim. 1904, [vi.] 20, 481; Emde, Arch. Pharm. 1907, 245, 662; Gadamer, *ibid.* 1908, 246, 566; Calliess, Apoth. Zeit. 1910, 25, 677). According to Rabe (Ber. 1911, 44, 824) the ammonium base of ephedrine decomposes into water, trimethylamine and α-phenylpropylene-αβ-oxide, and he regards ephedrine and ψ-ephedrine as optically isomeric β-methylamino-α-phenylpropane-α-ols $OH{\cdot}CHPh{\cdot}CHMe{\cdot}NHMe$ (*cf.* Emde, *l.c.*).

The name ephedrine has also been applied by Spehr to a crystalline alkaloid $C_{13}H_{19}ON$, m.p. 112°, obtained from *Ephedra monostachya*, a drug used as a remedy for syphilis and gout in Bessarabia and Wallachia. Ordinary ephedrine is known commercially as 'ephedrine (Merck)' and the second species as 'ephedrine (Spehr).'

ERGOTOXINE AND THE ALKALOIDS OF ERGOT.

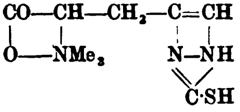
Commercial ergot consists of the mycelia of the fungus *Claviceps purpurea*, which occurs on rye and occasionally on other cereals. It is of considerable importance owing to its use in obstetric medicine, and to the fact that chronic poisoning due to the use of rye grain containing ergot as food was at one time not uncommon. Much confusion has been introduced into the chemistry of ergot by the characterisation of impure substances, often merely by physiological tests, but this has now largely disappeared as a result of the work done by Barger and collaborators, Kraft, Kutscher, and others, who have corrected and largely extended the pioneer work done by Tanret in 1875–1878. It is now known with certainty that ergot contains a crystalline, but physiologically inert, alkaloid *ergotinine*, an amorphous alkaloid *ergotoxine* (hydroergotinine), and a series of physiologically active amino acids, which appear to result mainly from putrefactive changes, and also occur in putrid flesh.

Ergotoxine $C_{35}H_{41}O_6N_5$ was first obtained in a pure state by Barger and Carr (Rept. Brit. Assoc. 1906, 526; Chem. News, 1906, 94, 89), and was fully described by them in 1907 (Chem. Soc. Trans. 1907, 91, 337). The same substance was obtained by Kraft independently in 1906 (Arch. Pharm. 1906, 244, 336) and called hydroergotinine, since it was converted into ergotinine by loss of 1 mol. H_2O. It seems clearly established that Tanret's 'amorphous ergotinine' (Compt. rend. 1875, 81, 896; 1878, 86, 888), and Jacobi's 'sphacelotoxine' (Arch. expt. Path. Pharm. 1897, 39, 104) consisted of impure ergotoxine, and that Kobert's 'cornutine' (*l.c.*) probably contained some ergotoxine. The alkaloid is a bulky, colourless, powder, m.p. 162°–164°, which shows varying dextrorotation. It gives colour reactions like those referred to under ergotinine (*see* below), and yields crystalline salts; the phosphate $B{\cdot}H_3PO_4,H_2O$, colourless needles, being that most easily obtained. On boiling with methyl alcohol (Kraft) or with acetic anhydride (Barger and Carr) ergotoxine is converted into ergotinine. On destructive distillation both ergotoxine and ergotinine yield *iso*butyrylformamide (Barger and Ewins, Chem. Soc. Trans. 1910, 97, 284). Ergotoxine produces in very small doses the effects characteristic of ergot, including gangrene (Barger and Dale, Bio-Chem. J. 1907, 2, 240; Dale, J. Physiol. 1913, 46, 291).

Ergotinine $C_{35}H_{39}O_5N_5$ was first isolated by Tanret (Compt. rend. 1875, 81, 896), who assigned to it the formula $C_{35}H_{40}O_6N_4$. The formula now accepted for the alkaloid $C_{35}H_{39}O_5N_5$ is due to Barger and Carr (Chem. Soc. Trans. 1907, 91, 337; *cf.* Tanret, J. Pharm. Chim. 1906, [vi.] 24, 397). Ergotinine crystallises in long, colourless needles, melts indefinitely at about 229° (corr.), has $[\alpha]_D^{10}$ +338° in alcohol, and does not give crystalline salts. Sulphuric acid with ergotinine in ether yields an orange coloration changing to blue, and ferric chloride produces a succession of colours—yellow, orange, crimson, green, dark blue—when added to a solution of the alkaloid in sulphuric acid. On standing in acetic acid at atmospheric temperature (Kraft) ergotinine is converted into ergotoxine. Ergotinine exercises little or no physiological activity (Barger and Dale, Arch. Pharm. 1906, 244, 554; *cf.* Kobert, Arch. expt. Path. Pharm. 1884, 18, 316).

Other Basic Constituents of Ergot.

Ergothioneine $C_9H_{15}O_2N_3S,2H_2O$, m.p. 290°, was obtained by Tanret (Compt. rend. 1909, 149, 222); it crystallises in colourless, monoclinic lamellæ. According to Barger and Ewins (Chem. Soc. Trans. 1911, 99, 2336) it is a thiolglyoxaline derivative of the following formula:—



A considerable number of amino bodies have been isolated from ergot from time to time, and recently several physiologically active substances of this kind have been prepared from the drug and characterised.

'**Clavine**' (Vahlen, Arch. expt. Path. Pharm. 1906, 55, 136; 1908, 60, 42), according to Barger and Dale (Bio-Chem. J. 1907, 2, 240), is a mixture of leucine and aspartic acid.

Aminosecalesulphonic acid

$$NH_2{\cdot}C_{15}H_{27}O_5{\cdot}HSO_3$$

(Kobert's 'ergotic acid'), obtained by Kraft (*l.c.*), is described by Vahlen (*l.c.*) as physiologically inactive.

p-**Hydroxyphenylethylamine** was shown by Barger (Chem. Soc. Trans. 1909, 95, 1123) to be present in ergot in small quantity, and to be responsible in part for the rise in blood pressure produced by aqueous extracts of ergot (Barger and Dale, Proc. Physiol. Soc. 1909). The same authors have shown that *iso*amylamine is probably present in ergot in minute quantity.

(4- or 5)-β-**Aminoethylglyoxaline** was isolated almost simultaneously from ergot by Kutscher (Z. P. 1910, 24, 163), and by Barger and Dale (Chem. Soc. Trans. 1910, 97, 2592), and shown to possess great physiological activity, producing marked contraction of the isolated uterus even when applied in very minute amounts (*cf.* Dale and Laidlaw, J. Physiol. 1910, 41, 318).

Agmatine (*aminobutyleneguanidine*)

$$NH_2{\cdot}C(NH)NH[CH_2]_4{\cdot}NH_2$$

was prepared from ergot by Engeland and Kutscher (Z. P. 1910, 24, 479); this also causes contraction of the isolated uterus and induces a rise in blood pressure.

Erythrophleine $C_{28}H_{43}O_7N$, an amorphous alkaloid found in sassy bark (*Erythrophleum guineense* (G. Don)). It resembles digitalin in physiological action (Gallois and Hardy, Bull. Soc. chim. 1876, 26, 39; Harnack, Chem. Zentr. 1897, [i.] 301).

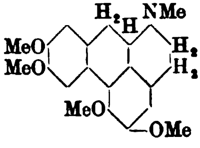
Eseramine. *See* under *Physostigmine* (p. 663).

Galipine and **Galipoidine.** *See* under *Cusparine* (p. 651).

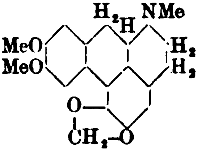
Gelsemine $C_{20}H_{22}O_2N_2$, a crystalline alkaloid occurring in the root of American wild jasmine *Gelsemium sempervirens*, (Ait.) along with gelseminine and a third alkaloid, the two latter being amorphous and yielding amorphous derivatives (Wormley, Amer. J. Pharm. 1870, 42, 1; Sonnenschein, Ber. 1876, 9, 1182; Gerrard, Pharm. J. 1882–1883, [iii.] 13, 502, 641; Thompson, *ibid.* 1886–1887, [iii.] 17, 805; Spiegel, Ber. 1893, 26, 1045; Cushny, *ibid.* 1725; Goeldner, B. Ph. G. 1895, 5, 330). The roots have been thoroughly re-examined by Moore (Chem. Soc. Trans. 1910, 97, 2223; 1911, 99, 1231).

Properties. Crystallises from acetone in handsome, glistening prisms containing 1 mol. of acetone, melts at 178°, and has $[\alpha]_D$ +15·9° in chloroform. The salts crystallise well, $B{\cdot}HCl$, m.p. 300°, small prisms; $B{\cdot}HNO_3$, m.p. 280°, glistening prisms. Gelsemine hydrochloride is physiologically inactive to mammals, but produces strychnine-like effects in frogs. The characteristic physiological action of gelsemium roots is due to the two amorphous alkaloids, to one of which the name 'gelseminine' has been applied. In general their physiological action resembles that of coniine; they are highly toxic and also exert a mydriatic action on the eye (Cushny, *l.c.*; Moore, *l.c.*).

Glaucine $C_{21}H_{25}O_4N$ occurs in *Glaucium flavum* (Crantz) along with protopine (Battandier, Chem. Soc. Abstr. 1892, 62, i. 893). Crystallises in rhombic prisms, m.p. 119°–120°, $[\alpha]_D$ +113·3° in alcohol, is a tertiary base and contains four ·OMe groups (Fischer, Arch. Pharm. 1901, 239, 426). It has been synthesised by Gadamer (*ibid.* 1911, 249, 680) and shown to be phenanthreno-N-methyltetrahydropapaverine, and therefore is closely related to dicentrine (p. 652).



Glaucine.



Dicentrine.

Glaucine is tasteless and induces narcosis, accompanied by some tetanising action.

Gnoscopine. *See Narcotine* (p. 659).

Guanine. *See* under *Caffeine* (p. 642).

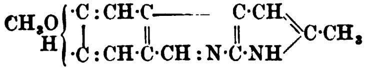
Guvacine. *See* under *Arecoline* (p. 635).

Harmaline $C_{13}H_{14}ON_2$ occurs along with *harmine* $C_{13}H_{12}ON_2$ and *harmalol* $C_{12}H_{12}ON_2$ as a phosphate in the seeds of *Peganum Harmala* (Linn) (Göbel, Annalen, 1841, 38, 363; Fritzsche, *ibid.* 1847, 64, 360; O. Fischer, Ber. 1885, 18, 400; 1889, 22, 637; 1897, 30, 2481; 1905, 38, 329; 1912, 45, 1930; Chem. Zentr. 1901, i. 957; and Hasenfratz, Compt. rend. 1912, 154, 215, 704, 1520).

Properties. Small tabular crystals, m.p. 238° (decomp.), $[\alpha]_D=0°$. Very slightly soluble in water, more soluble in alcohol or ether. A monacidic base; the salts are yellow, and their aqueous solutions exhibit a green fluorescence.

Reactions and constitution. On oxidation harmaline is converted into *harmine* $C_{13}H_{12}ON_2$, a crystalline alkaloid, m.p. 256°, also found in small quantity in peganum seeds. Its salts are colourless, but show a blue fluorescence in aqueous solution. Both harmaline and harmine contain one methoxyl group, and when heated with hydrochloric acid furnish methyl chloride harmalol $C_{12}H_{12}ON_2$ (m.p. 212°, slender red needles) and harmol $C_{12}H_{10}ON_2$ (m.p. 321°, greyish needles) respectively; ahrmalol also occurs in *Peganum* seeds. Oxidation with nitric acid converts harmine and harmol into harmic acid $C_{10}H_8O_6N_2$ and 1-methoxy-2-nitro-3:4-phthalic acid, whence it appears that this group of bases must contain the complex $OMe\cdot C_6H_3(C\cdot)C\cdot$ in which $\cdot OMe$, (C.), and C. occupy positions 1 : 3 : 4 or 1 : 4 : 5.

Perkin and Robinson (Chem. Soc. Trans. 1912, 101, 1775) have assigned the following formula to harmine:—



$$\begin{matrix}CH_3O\\H\end{matrix}\left\{\begin{matrix}\cdot C:CH\cdot C\text{———}\qquad C\cdot CH\\ |\qquad\quad \|\qquad\qquad\qquad \|\\ \cdot C:CH\cdot C\cdot CH:N\cdot C\cdot NH\end{matrix}\right.\!\!>C\cdot CH_3$$

Harmine and harmaline cause convulsions, increase of saliva, interference with respiration, and depression of temperature in warm-blooded animals (Gunn, T. E. 1910, 47, 245; Flury, Arch. expt. Path. Pharm. 1910, 64, 105). In Turkey peganum seeds are used as an anthelmintic, and Flury (*l.c.*) ascribes this action to the paralysis of the musculature of the parasites caused by harmaline.

Histidine $C_6H_9O_2N_3$, 4- (or 5-)glyoxaline-α-amino-propionic acid, occurs in various plant seedlings (Schulze, Zeitsch. physiol. Chem. 1899, 28, 465); needles or leaflets, m.p. 253°, $[\alpha]_D$ −39·74° (Kossel, Chem. Soc. Abstr. 1896, 70, 582). *V.* vol. iii. p. 41.

Homoquinine. *See Cupreine* (p. 673).

Hordenine $C_{10}H_{15}ON$ occurs in barley germs. Crystallises in orthorhombic prisms, m.p. 117·8°, sublimes at 140°–150°, b.p. 173°–174°/11 mm., is optically inactive, yields crystalline salts and behaves as a tertiary base. It has the constitution $OH\cdot C_6H_4\cdot CH_2\cdot CH_2\cdot NMe_2[OH:CH_2 etc. = 1:4]$ (Léger, Compt. rend. 1906, 142, 108, 143; 234, 916; 1907, 144, 488; Gaebel, Arch. Pharm. 1906, 244, 435), and has been synthesised by Barger (Chem. Soc. Trans. 1909, 2193), and by Rosenmund (Ber. 1910, 43, 306). It is slightly toxic (Camus, Compt. rend. 1906, 142, 110, 237, 350). *V.* vol. iii. p. 46.

HYDRASTINE AND THE ALKALOIDS OF HYDRASTIS CANADENSIS.

Hydrastine $C_{21}H_{21}O_6N$, an alkaloid occurring together with berberine (*see* p. 639), and canadine in the root of *Hydrastis canadensis* (Linn.) to the extent of about 1·5 p.c.

Preparation and estimation. Hydrastine may be isolated from the mother-liquid from which the berberine salt has crystallised (p. 639). This is largely diluted with water, and almost neutralised with ammonia. On evaporation, ammonium sulphate, resin, &c., separate out; these are removed, and the hydrastine precipitated from the cold liquid by ammonia. The coloured precipitate is dissolved in alcohol, and the colouring matter removed by digestion with animal charcoal; the alkaloid crystallises from the concentrated solution. In order to purify it the hydrastine is repeatedly crystallised from alcohol.

According to Freund and Will (Ber. 1886, 19, 2797) hydrastine is most readily obtained by percolating finely-powdered hydrastis root with ether, and crystallising the ethereal residue from alcohol.

A method for the estimation of hydrastine and berberine separately in hydrastis rhizome has been proposed by Gordin and Prescott (Arch. Pharm. 1899, 237, 499; 1901, 239, 638).

Properties. Colourless, rhombic prisms, m.p. 132°. Insoluble in water; readily soluble in chloroform or benzene; less soluble in ether or alcohol. The alcoholic solution is alkaline to litmus and lævorotatory; in chloroform $[\alpha]_D = -67·8°$. The ordinary salts of hydrastine are soluble in water but do not crystallise well. They are poisonous to animals (Perrins, Pharm. J. 1861–1862, [ii.] 3, 546; Mahla, Amer. J. Sci. 36, 57; Lloyd, Proc. Am. Pharm. Assoc. 26, 805; Power, Pharm. J. 1884–1885, [iii.] 15, 297; 1885–1886, [iii.] 16, 1092; Schmidt and Kerstein, Arch. Pharm. 1890, [iii.] 28, 49).

Reactions. When permanganate is added to an acid solution of hydrastine sulphate in water a blue fluorescence is observed. Iodine solution gives a characteristic periodide. For other colour reactions of hydrastine, *see* Lyons, Pharm. J. 1885–1886, [iii.] 16, 880; and Labat, Bull. Soc. chim. 1909, [iv.] 5, 742, 745.

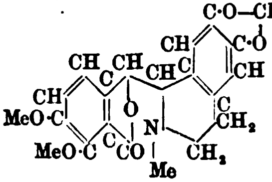
The principal products of the oxidation of hydrastine by nitric acid are opianic acid and hydrastinine $C_{11}H_{13}O_3N$, thus—

$$\underset{\text{Hydrastine.}}{C_{21}H_{21}O_6N}+H_2O+O=\underset{\text{Opianic acid.}}{C_{10}H_{10}O_5}+\underset{\text{Hydrastinine.}}{C_{11}H_{13}O_3N}.$$

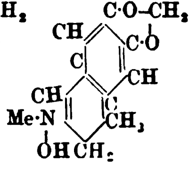
Opianic acid has the constitution

$$C_6H_2(OMe)_2(COOH)(CHO)$$
$$[OMe:OMe:COOH:CHO=1:2:3:4].$$

HYDRASTININE, m.p. 116°–117°, crystallises from light petroleum in glancing crystals easily soluble in alcohol or ether, sparingly in water. It is used in medicine as an internal styptic. On 'exhaustive methylation' hydrastinine gives trimethylamine and hydrastal $C_{10}H_8O_3$: the latter on oxidation gives hydrastic acid (4:5-dioxymethylenephthalic acid). These reactions indicate the following constitution for hydrastine and hydrastinine :—



Hydrastine.



Hydrastinine.

(*cf.* Freund, Annalen, 1892, 271, 320; Fritsch, *ibid.* 1895, 286, 18; Roser, *ibid.* 1889, 254, 357; Dobbie and Tinkler, Chem. Soc. Trans. 1904, 85, 1005).

Canadine $C_{20}H_{21}O_4N$ occurs with crude hydrastine (*see* above), from which it may be isolated by fractional crystallisation of the nitrates, the canadine salt being less soluble. Silky needles, m.p. 132·5° $[\alpha]_D - 298°$ in chloroform (Schmidt, Arch. Pharm. 1894, 232, 136). On treatment with iodine it is converted into berberine. By fractional crystallisation of tetrahydroberberine *d*-camphorsulphonate, Gadamer (*ibid.* 1901, 239, 648) isolated a lævorotatory base identical with canadine, which is therefore *l*-tetrahydroberberine. Jowett and Pyman have found *l*-α-canadine methochloride in *Xanthoxylum brachyacanthum*, Chem. Soc. Trans. 1913, 103, 293.

Hygrine. *See* under *Cocaine* (p. 647).

Hymenodictyonine (*Hymenodictine*) $C_{23}H_{40}N_2$, crystals, m.p. 66°, occurs in the bark of *Hymenodictyon excelsum* (Wall.), used in India as an antipyretic. It is bitter and slightly toxic (Naylor, Pharm. J. 1883, [iii.] 13, 817; 1885, [iii.] 15, 195).

Hyoscine. *See Scopolamine* (p. 639).

Hyoscyamine. *See* under *Atropine* (p. 637).

Hypaphorine $C_{14}H_{18}O_2N_2$, an alkaloid isolated from *Erythrina hypaphorus* (Boerl.) by Greshoff (Med. s'Lands Plant. 1890, 7, 29; Chem. Soc. Abstr. 1891, 60, 335), and subsequently investigated by van Romburgh (Proc. K. Akad. Wetenoch. Amst. 1911, 13, 1177), and by van Romburgh and Barger (Chem. Soc. Trans. 1911, 99, 2068), and shown to be α-trimethyl-β-indolepropiobetaine, since it is produced by the action of methyl iodide on trytophan (β-indole-α-aminopropionic acid) and treating the resulting methiodide with warm dilute alkali. Hypaphorine crystallises as a monohydrate, m.p. 255°, [α] +91·93°, and yields a sparingly soluble nitrate, m.p. 215°–220°. It exhibits no marked physiological action.

Hypoxanthine. *See* under *Caffeine* (p. 642).

Ibogäine $C_{26}H_{32}O_2N_2$ (*Ibogine*), an alkaloid occurring in 'iboga' obtained from the French Congo. Orthorhombic crystals, m.p. 152°, lævorotatory (Dybowski and Landrin, Compt. rend. 1901, 133, 748; Haller and Heckel, *ibid.* 1901, 133, 850). The alkaloid produces anæsthesia, and in large doses causes convulsions and death due to stoppage of respiration (Lambert and Heckel, *ibid.* 1901, 133, 1236).

Imperialine $C_{35}H_{59}O_4N$ (?) occurs in the bulbs of *Fritillaria Imperialis* (Linn.). Short needles, m.p. 254° (approx.), [α] −35·4° in chloroform; yields a crystalline hydrochloride. It slows the action of the heart (Fragner, Ber. 1885, 21, 3284).

Jaborine. *See* under *Pilocarpine* (p. 664).

Jateorrhizine. *See* under *Columbamine* (p. 648).

Jervine. *See* under *Cevadine* (p. 644).

Laudanidine and **Laudanine.** *See* under *Papaverine grout* (p. 661).

Laudanosine. *See* under *Papaverine* (p. 661).

Laurotetanine $C_{19}H_{23}O_5N$ occurs in the bark of *Litsea citrata* (Blume), and in many East Indian lauraceous plants (Greshoff, Ber. 1890, 23, 2546). It crystallises in needles, m.p. 134°, gives crystalline salts, behaves as a secondary amine, contains three ·OMe groups, and probably one hydroxyl group. It exerts a tetanising action in frogs, but is less powerful than strychnine (Filippo, Arch. Pharm. 1898, 236, 601).

Lobeline $C_{18}H_{23}O_2N$, the characteristic alkaloid of *Lobelia inflata*, (Linn.) a drug used as a remedy for spasmodic asthma. Amorphous, viscous, strongly alkaline liquid, soluble in alcohol, sparingly soluble in other solvents; it darkens and resinifies in light and air. The hydrochloride $B{\cdot}HCl,H_2O$, m.p. 129°, and the platinichloride $(B{\cdot}HCl)_2PtCl_4,3H_2O$ are crystalline (Siebert, Inaug. Diss. Marburg, 1891). The alkaloid is highly toxic, exercising in small doses a stimulating, and in large doses a paralysing action on the respiratory centre (Edmunds, Amer. J. Physiol. 1904, 11, 79).

Lophophorine. *See* under *Mezcaline* (p. 656).

Lupanine $C_{15}H_{24}ON_2$ occurs in the *d*- and *dl*-form in the seeds of *Lupinus albus* (Linn.), and in the *d*- form in those of *L. angustifolius* (Linn.) and *L. perennis* (Linn.) The *dl*- form crystallises in needles, m.p. 99°, and furnishes crystalline salts. The *d*- form has m.p. 44°, and yields salts which are less soluble and crystallise more easily than those of the *dl*- form. The *l*- form, which may be separated from racemic lupanine, has m.p. 43°–44°, and crystallises less easily than the *d*-form. It has been suggested from time to time that lupanine is closely related to sparteine, but according to Beckel (Arch. Pharm. 1911, 249, 329; 1912, 250, 700), this is not the case. All the forms of lupanine are bitter and poisonous (Eichhorn, Nobbes Vers. St. 1867, 272; Siebert, Chem. Soc. Abstr. 1892, 62, 223; Soldaini, Boll. Chem. Farm. 1902, 41, 37; Arch. Pharm. 1902, 240, 260; Davis, Apoth. Zeit. 1896, 11, 94).

Lupinidine. *See Sparteine* (p. 676).

Lupinine $C_{10}H_{19}ON$, an alkaloid found with sparteine (p. 676) in the seeds of *Lupinus luteus* (Linn.) and *L. niger*. Rhombic crystals, m.p. 67°–68°. Distils without decomposition in hydrogen at 255°–257°; lævorotatory. It is bitter and slightly toxic. A tertiary, hydroxy base which furnishes crystalline salts (Baumert, Ber. 1881, 14, 1150; 1882, 15, 1951; Hagen, Annalen, 1885, 230, 370; Siebert, Arch. Pharm. 1891, 229, 531; Soldaini, *ibid.* 1892, 230, 16; Berend, *ibid.* 1897, 235, 262; Willstätter and Fourneau, Ber. 1902, 35, 1910).

Lycoctonine. *See* under *Aconitine* (p. 634).

Mandragorine. *See* under *Atropine and the belladonna alkaloids* (p. 638).

Meteloidine. *See* under *Atropine* (p. 638).

MEZCALINE AND THE ALKALOIDS OF ANHALONIUM SPP.

In Mexico several plants belonging to the genus *Anhalonium*, notably *A. Lewinii* (Hennings), are used in Indian religious ceremonies as narcotics, under the name 'pellote.' The dried flowering heads of *A. Lewinii* are chiefly used for this purpose and come into commerce under the name 'mescal buttons.' From this source and from allied plants a series of alkaloids has been isolated, some of which resemble morphine and others strychnine in their physiological action.

Anhalamine $C_{11}H_{15}O_3N$, microscopic needles, m.p. 185·5°. Occurs in *A. Lewinii* (Hennings). It contains two ·OMe groups and one ·OH group, and is a secondary base (Kander, Arch. Pharm. 1899, 237, 190; Heffter, Ber. 1901, 34, 3004).

Anhaline $C_{10}H_{17}O_3N$, prisms, m.p. 115°, occurs in *A. fissuratum* (Engelm.). Exerts a paralysing action on the central nervous system.

Anhalonidine $C_{12}H_{15}O_3N$, crystalline, m.p. 154°, occurs in *A. Lewinii* (Hennings). Contains one —OH and two —OMe groups, and is a secondary base $OH{\cdot}C_{10}H_7(OMe)_2 : NH$ (Heffter, *ibid.* 1894, 27, 2976).

Anhalonine $C_{12}H_{15}O_3N$, long needles, m.p. 85°, occurs in *A. Lewinii* (Hennings). A secondary base, and contains one —OMe group. It resembles strychnine in its physiological action.

Lophophorine $C_{13}H_{17}O_3N$, syrup, yielding crystalline salts. Occurs in *A. Lewinii* (Hennings). It contains one ·OMe group, and is the most toxic of all the anhalonium alkaloids.

Mezcaline $C_{11}H_{17}O_3N$, colourless, strongly alkaline oil, found in 'mescal buttons' (*Anhalonium Lewinii* [Hennings]), which owe their peculiar properties to its presence. It is a secondary base, contains three ·OMe groups, and on oxidation by permanganate yields 2 : 3 : 4-trimethoxybenzoic acid. Its constitution is still doubtful (Heffter, *l.c.*; and Ber. 1905, 38, 3634).

According to Dixon, anhalonidine, anhalonine, lophophorine, and mezcaline exert qualitatively the same physiological action, lophophorine being the most powerful, and mezcaline the most active in producing colour visions. In man the alkaloids produce first excitement and then intoxication, resembling that caused by alcohol, but accompanied by a number of subjective sensations including colour visions and a feeling of dual existence (J. Physiol. 1899, 25, 69).

Pellotine $C_{13}H_{19}O_3N$, colourless tablets, m.p. 110°; occurs in *A. Williamsii* (Lem.) and also in *A. Lewinii* (Hennings). Possesses slightly narcotic action, and has been employed in medicine as a narcotic.

The chief papers relating to the anhalonium alkaloids, in addition to those already quoted, are Lewin (Arch. expt. Path. Pharm. 1888, 24, 401; 1898, 34, 374; and Heffter, Ber. 1894, 27, 2975; 1896, 29, 216; 1898, 31, 1193).

MORPHINE AND THE OPIUM ALKALOIDS (*see* also *Opium*).

Opium, the partially dried juice of the seed-capsules of *Papaver somniferum* (Linn.), contains the salts (sulphates and meconates) of a large number of alkaloids, of which only the more important will be considered here, viz. morphine $C_{17}H_{19}O_3N$, codeine $C_{18}H_{21}O_3N$ thebaine $C_{19}H_{21}O_3N$, papaverine $C_{20}H_{21}O_4N$, narcotine $C_{22}H_{23}O_7N$, narceine $C_{23}H_{27}O_8N$, and certain secondary alkaloids derived from those named.

The quantity of 'total alkaloids' in opium shows great variation with the geographical source of the drug, but on the average the morphine is about 10 p.c., narcotine 6 p.c., papaverine 1 p.c., codeine 0·5 p.c., and thebaine 0·15 p.c. Indian opium is richer in narcotine and codeine than the Asia Minor (Turkish) opium of commerce.

Morphine Group (*Morphine, Apomorphine, Codeine, Thebaine*).

Morphine $C_{17}H_{19}O_3N$, the first known vegetable alkaloid was isolated from opium about the year 1807 by Sertürner. It is contained in minute amounts in several other plants belonging to the natural order *Papaveraceæ*.

The amount of morphine present in opium varies in the different commercial sorts (Persian, Turkish, Indian, &c.) from 3 to 20 p.c. The British Pharmacopœia specifies that the dried opium intended for medicinal use should contain from 9·5 to 10·5 p.c. of morphine.

Preparation. Morphine exists in opium in the form of two soluble salts (meconate and sulphate), so that extraction with water removes the whole of the alkaloid.

Gregory's method for the manufacture of morphine from opium consists in extracting the drug with lukewarm water, mixing the liquid with excess of chalk, and evaporating to a small volume. Slight excess of calcium chloride is now added, the liquid diluted with water, and the precipitated resin, calcium meconate, &c., filtered off. On concentrating the liquid the hydrochlorides of morphine and codeine crystallise out. These are dissolved in water, the solution decolorised with charcoal and decomposed with excess of ammonia, which precipitates morphine containing a little codeine. For complete separation the codeine may be extracted by one of the solvents, in which it is much more soluble than morphine, *e.g.* ether or benzene.

Properties. Small rhombic prisms or silky needles containing $1H_2O$, which is gradually lost at 100°, more rapidly at 120°. At higher temperatures (about 230°) morphine melts with some decomposition, and afterwards a part of the alkaloid sublimes, together with some of its decomposition products. Slightly soluble in water, 1 in 10,000 at 10°; 1 in 5000 at 20° (Chastaing, Bull. Soc. chim. 1882, [ii.] 37, 477); more soluble in boiling water (1 in 500). Soluble in absolute alcohol (1·1 in 100 at 10°; 8·6 in 100 at b.p.), less so in aqueous alcohol (1 in 100 at 15°; 1 in 36 at b.p.). Less soluble in amyl alcohol (1 in 400 at 11°; 1·1 in 50 at 78°). Very slightly soluble, or nearly insoluble in ether, benzene, chloroform, or light petroleum (Florio, Gazz. chim. ital. 1883, 13, 496; *cf.* Müller, Apoth. Zeit. 1903, 18, 257, and U S. Pharmacopeia, 8th ed.). Readily soluble in solutions of fixed alkalis, especially when warm; less soluble in aqueous ammonia (rel. dens. 0·97) (1 in 177 at 15°). Lævorotatory, in methyl alcohol $[\alpha]_D^{23} = 130{\cdot}9°$. in aqueous soda, $[\alpha]_D = -70{\cdot}23°$; more strongly lævorotatory in neutral or acid solution (Hesse, Annalen, 1875, 176, 190).

Morphine is a strong monacidic base; its alcoholic solution is alkaline to litmus. Dilute acids readily dissolve morphine, and the salts are generally easy to crystallise. The hydrochloride $B{\cdot}HCl,3H_2O$ is a well-crystallised salt, soluble in water (1 in 24 at 15°), less soluble in alcohol (Hesse, *l.c.*). This salt and the sulphate, acetate, and tartrate, &c., are used in medicine. The platinichloride $(B{\cdot}HCl)_2PtCl_4$ is crystalline. The alkaloid and its salts have a bitter taste, and when administered in small doses exert a powerful narcotic action; in larger doses they are poisonous.

Reactions and constitution.

Solution of ferric chloride, almost free from acid, produces with the alkaloid, and with neutral solutions of its salts, a deep-blue coloration, which is discharged by strong acids. This reaction is characteristic and delicate in neutral or nearly neutral solutions. Strong sulphuric acid, free from nitric acid, does not colour morphine unless the mixture is warmed, when a brown coloration is produced. Nitric acid dissolves the alkaloid, with the production of a deep-red colour. If the morphine is first dissolved in strong sulphuric acid and then a drop of nitric acid added, a carmine coloration is observed. Morphine is a powerful reducing agent, converting ferric salts into ferrous salts, solution of potassium ferricyanide into potassium ferrocyanide, and precipitating the metals from solutions of silver nitrate, and gold and platinum chlorides. Since it reduces aqueous iodic acid, liberating iodine, this reaction is often utilised as a test for morphine, the iodine being detected in the usual manner. The salts of morphine also liberate iodine from aqueous iodic acid. Morphine is liable to be mistaken for emetine if colour reactions alone are relied on for its identification (*see* under *Emetine* p. 652, and Allen and Scott-Smith, Analyst, 1902, 27, 345).

Morphine is a tertiary base which combines with 1 mol. prop. of alkyl iodide.

A dibenzoyl and a diacetyl derivative (*heroine*) of morphine have been prepared, whence it may be inferred that the alkaloid contains two hydroxyl groups (Wright, Chem. Soc. Trans. 1874, 27, 1031; Wright and Beckett, *ibid.* 1875, 28, 15; Wright and Rennie, *ibid.* 1880, 37, 610). One of these hydroxyl groups is probably attached to a benzene nucleus, since it has phenolic properties; thus morphine dissolves in alkalis, forming metallic derivatives, in which one atom of hydrogen of the morphine is replaced by metals (Chastaing, Compt. rend. 1882, 94, 44).

When morphine is heated with hydrochloric acid (25 p.c.) in a closed tube at 140°–150°, a molecule of water is separated and *apomorphine* $C_{17}H_{17}O_2N$ is produced. It is isolated by adding sodium bicarbonate in excess to the acid liquid, and shaking with ether, which dissolves the 'apomorphine.' The free base is usually amorphous; it is slightly soluble in cold water, and unstable when exposed to air, absorbing oxygen, especially in presence of alkali, with the production of a green, and afterwards a red, colour. The hydrochloride $B{\cdot}HCl$ is crystalline and is used in medicine. The properties of apomorphine appear to show that the base still contains the phenolic hydroxyl present in morphine. Its physiological action differs entirely from that of morphine, since it produces no narcotic effect, but acts as a powerful emetic (Matthiessen and Wright, Proc. Roy. Soc. 1868–1869, 17, 455; Marmé, Zeitsch. anal. Chem. 1885, 24, 643).

Alkaline solutions of morphine absorb oxygen from the air, which converts the morphine into *pseudomorphine* (oxydimorphine) $C_{34}H_{36}O_6N_2$, a base which also results from the action of weak oxidising agents on morphine, and is found in small quantity in opium (Hesse, Annalen, 1867, 141, 87; 1875, 175, 195; 1884, 222, 234; 1886, 234, 255). It is not poisonous.

The reactions, which are of primary importance as regards the constitution of morphine, and the closely related alkaloids, codeine and thebaine, are as follows—

1. Of the three oxygen atoms in morphine one is phenolic, and on methylation gives rise to codeine; the second is alcoholic; the third oxygen atom is non-reactive, and is present in a heterocyclic nucleus.
2. The nitrogen atom is tertiary.
3. On distillation with zinc dust morphine yields phenanthrene.
4. With methyl iodide morphine furnishes codeine methiodide; this on warming with silver hydroxide gives codeine methylhydroxide $MeO(HO){\cdot}C_{16}H_{14}O{\cdot}NMe_2OH$, which immediately decomposes, giving methylmorphimethine

$$MeO(OH){\cdot}C_{16}H_{12}O{\cdot}NMe_2$$

by loss of H_2O. This base when heated with hydrochloric acid or acetic anhydride is decomposed in part, forming methylmorphol and hydroxyethyldimethylamine—

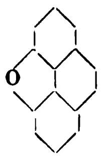
$$\left.\begin{matrix}HO\\OMe\end{matrix}\right>C_{16}H_{12}O{\cdot}NMe_2=\left.\begin{matrix}HO\\OMe\end{matrix}\right>C_{14}H_8+C_4H_{11}ON$$

Methylmorphimethine. Methylmorphol Hydroxyethyldimethylamine.

Methylmorphol is known to be 4-hydroxy-3-methoxyphenanthrene (Pschorr and Sumuleanu, Ber. 1900, 33, 1810). Hydroxyethyldimethylamine probably results from the addition of water to vinyldimethylamine first liberated thus

$$NMe_2{\cdot}CH:CH_2 \rightarrow NMe_2{\cdot}CH_2{\cdot}CH_2OH$$

It follows from the above that morphine must be built up from the complexes



and $—CH_2{\cdot}CH_2{\cdot}NMe—$

The two complexes have been 'assembled' in various ways, but Pschorr's formula is that now generally accepted (*see* p. 659 under *Thebaine*).

Detection. Morphine affords precipitates with most of the alkaloidal reagents. It may be identified by means of the properties and reactions described above. The characteristic reactions of morphine can, however, only be relied on when a nearly pure alkaloid has been experimented with. Unfortunately, morphine is one of the most difficult alkaloids to separate from much organic impurity, especially when it is present only in minute quantity, as is generally the case in toxicology. Since the internal administration of opium, and not of morphine itself, is often the cause of poisoning, the existence of this alkaloid may be confirmed by detecting meconic acid, which is easy to recognise.

For a detailed account of the qualitative reactions of morphine, *see* Marmé, *l.c.*

Estimation. The following method may be adopted for the estimation of morphine in opium: 14 grms. of powdered opium dried at 100° are mixed with 6 grms. of slaked lime, and stirred in a mortar with 40 c.c. of water. The mixture is diluted with 100 c.c. of water and occasionally stirred during about half an hour. The mixture is then filtered into a stoppered bottle, until a volume of 104 c.c., representing 10 grms. of opium, has been obtained. To this filtrate 10 c.c. of 90 p.c. alcohol are added and 50 c.c. of ether and the mixture shaken. In order to precipitate the morphine from its solution in the lime-water, 4 grms. of ammonium chloride are added and the mixture well shaken. After the lapse of 12 hours the morphine will have crystallised out. Decant the ethereal layer and filter it through a small counterbalanced paper. Add 20 c.c. of ether to the contents of the bottle, shake gently, again decant and filter the ethereal layer. Wash the filter paper with 10 c.c. of ether and dry it. Now filter off the crystals which remain in the bottle, using a saturated solution of morphine in water for washing. The crystals of morphine are dried first at 55°–60°, and then at 110° for two hours and weighed. 0·5 grm. of the crystals obtained is then titrated with N/10 sulphuric acid, using litmus paper as indicator. The weight of morphine as determined by titration +0·014 grm. (correction for loss) should be 0·95 to 1·05 grm.

For an account of the different methods which have been proposed, *v.* Allen's Organic Analysis, 4th ed. vol. vi.

For the estimation of morphine in tincture of opium (laudanum) the following method may be employed: 80 c.c. of the laudanum are evaporated to 30 c.c. on the water-bath, and the residue thoroughly mixed with 3 grms. of calcium hydroxide, and diluted to 85 c.c. with water. The liquid is then filtered, and 50 c.c. of the filtrate (representing the same quantity of laudanum) are mixed with 5 c.c. of alcohol (90 p.c.), 30 c.c. of ether, and 2 grms. of ammonium chloride. The mixture is well shaken and allowed to remain for 12 hours. The crystals of morphine, which will have separated, are collected, with the precautions described above for the estimation of morphine in opium, 15 c.c. of ether being used to rinse the contents of the bottle and 10 c.c. to wash the filter paper. For titrations 0·3 grm. of the crystals used and to the weight determined by titration 0·1 grm. per 100 c.c. of filtrate used are added as a correction for loss. 100 c.c. of the tincture should yield not less than 0·7 nor more than 0·8 grm. of anhydrous morphine.

Codeine (*Methylmorphine*) $C_{18}H_{21}O_3N$ exists in small quantity in opium.

Preparation. The mixed hydrochlorides of morphine and codeine, having been separated from opium by Gregory's method (*see preparation of morphine*), and the morphine precipitated by ammonia, the alkaline filtrate, which contains codeine hydrochloride, is evaporated to a small volume and precipitated by potash. The codeine is purified by crystallisation from ether or from water. Codeine may be prepared from morphine by heating it with alcoholic soda and methyl iodide (Grimaux, Ann. Chim. Phys. 1882, [v.] 27, 273; Hesse, Annalen, 1884, 222, 210), or by the action of potassium methyl sulphate on morphine dissolved in methyl alcohol.

Properties. Large rhombic crystals from water with $1H_2O$, which melt in boiling water; small anhydrous crystals from ether, m.p. 155°. Lævorotatory $[\alpha]_D - 137{\cdot}75°$ in alcohol. Slightly soluble in cold water, more soluble in hot water, alcohol, ether, or benzene; sparingly soluble in light petroleum. The aqueous solution is strongly alkaline. Codeine is a monacidic base; the principal salts are crystalline and soluble in water. In physiological action codeine and its salts resemble morphine, but are less poisonous.

Reactions and constitution. Codeine is distinguished from morphine by not giving the colour reaction with ferric chloride, and by producing with nitric acid a yellow, and not a red, colour. Concentrated sulphuric acid does not colour codeine except after prolonged standing, but if a trace of nitric acid or ferric salt is added to the mixture it becomes blue. For an account of the qualitative reactions of codeine, *see* Marmé, Zeitsch. anal. Chem. 1885, 24, 643. The decomposition products of codeine are, for the most part, analogous to those of morphine (p. 657), of which it is the methyl derivative. The methyl group replaces an atom of hydrogen in the phenolic hydroxyl group of morphine (for formula, *see* p. 659).

Estimation. The following process has been devised by Andrews (Analyst, 1911, 36, 489). Dry opium (12 grms.) is exhausted by successive portions of cold water, the filtrate made up to 100 c.c., and 20 c.c. of 20 p.c. lead acetate solution added, to remove colouring matter and some narcotine. The mixture is kept overnight, then passed through a filter paper in a Buchner funnel, and from 100 c.c. of the filtrate (10 grms. of opium) the excess of lead is removed by hydrogen sulphide, and this in turn removed by a current of air. The washings from the lead sulphide precipitate are collected separately, evaporated to a small bulk, and added to the main filtrate, which should then not exceed 130 c.c. To this 20 c.c. of a 20 p.c. solution of sodium salicylate are added, and the flask containing the mixture corked and shaken. A resinous precipitate separates leaving a nearly clear liquor, which is passed through a small pleated filter, into a beaker containing a few crystals of thebaine salicylate, to facilitate the separation of this salt from the filtrate, which is well stirred to assist this operation. After standing over-night the liquid is again passed through the same pleated filter and the treatment repeated until no further deposition of solid matter takes place. The final filtrate and washings, concentrated to about 10–15 c.c. on a water-bath, are transferred while still warm to a glass separator (No. 1), the washings of the dish being placed in a second separator (No. 2). The contents of No. 1 are washed with three successive portions of ether, each portion being in turn also used to wash the contents of No. 2. The latter are finally added to separator No. 1, and 10 c.c. of a 20 p.c. solution of caustic soda added, to keep the morphine dissolved. This strongly alkaline liquid is extracted four times succession with rather more than its own volume of ether, each portion of ether, as separated, being washed with 20–30 c.c. of water and finally run into a dry flask containing anhydrous sodium sulphate to dry it. The dry ethereal solution of codeine is distilled in a flask down to a few c.c., which are allowed to evaporate spontaneously, when, as a rule, the codeine separates in well-defined crystals, and after drying can be weighed, the weight being checked by dissolving in excess of N/10 acid and titrating back with N/10 sodium hydroxide, using litmus or methyl-orange as indicator.

Thebaine $C_{19}H_{21}O_3N$ occurs in small quantity (up to 1 p.c.) in opium, and remains in the mother liquor after the separation of morphine and codeine hydrochlorides (p. 656). It is precipitated from this along with narcotine and papaverine by addition of ammonia. The precipitate is dried and dissolved in boiling alcohol. On cooling narcotine and papaverine crystallise out. The filtrate is evaporated to dryness, the residue dissolved in acetic acid, and the solution decolorised with lead acetate. From the filtrate, after removal of excess of lead by hydrogen sulphide, thebaine is precipitated by adding ammonia.

Properties and reactions. Leafy or prismatic crystals, m.p. 193°. Lævorotatory. Nearly insoluble in cold water, slightly soluble in ether, very soluble in alcohol, chloroform, or benzene. Slightly soluble in aqueous alkalis. Thebaine is a monacidic base; the principal salts are crystalline and soluble in water. The alkaloid and its salts are poisonous and exercise a tetanising action, but are less powerful than strychnine and its salts. Thebaine is coloured bright red by concentrated sulphuric acid. It is converted into thebenine when warmed with dilute acids, and is attacked by concentrated hydrochloric acid, with the formation of morphothebaine, isomeric with thebenine $C_{18}H_{19}O_3N$.

CONSTITUTION. Thebaine is related somewhat closely to morphine and its methyl ether, codeine, as inspection of slightly extended formulæ for the three alkaloids shows—

$$\left.\begin{matrix}\mathrm{HO}\\\mathrm{HO}\end{matrix}\right>C_{16}H_{14}O\cdot NMe \qquad \left.\begin{matrix}\mathrm{MeO}\\\mathrm{HO}\end{matrix}\right>C_{16}H_{14}O\cdot NMe$$

Morphine. Codeine.

$$\left.\begin{matrix}\mathrm{MeO}\\\mathrm{MeO}\end{matrix}\right>C_{16}H_{12}O\cdot NMe$$

Thebaine.

When codeine is oxidised by chromic acid the alcoholic hydroxyl group is converted into a carbonyl group with the formation of codeinone, thus—

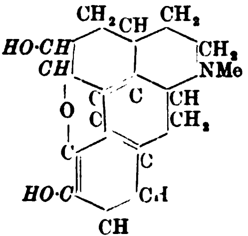
$$\left.\begin{matrix}\mathrm{MeO}\\\mathrm{HO}\end{matrix}\right>C_{16}H_{14}O\cdot NMe \rightarrow \left.\begin{matrix}\mathrm{MeO}\\\mathrm{O}\end{matrix}\right>C_{16}H_{13}O\cdot NMe$$

Codeine. Codeinone.

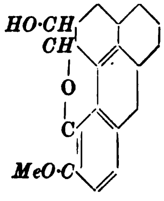
On treatment with dilute acids both thebaine (Howard and Roser, Ber. 1886, 19, 1596; and Freund, *ibid.* 1899, 32, 168) and codeinone (Knorr, *ibid.* 1903, 36, 3074) yield thebenine, whilst with strong acids they furnish the isomeric morphothebaine (*l.c.*). Further, hot acetic anhydride decomposes thebaine (Freund, *ibid.* 1897, 30, 1357) and codeinone (Knorr, *l.c.*) in the following ways (*cf.* Pschorr, Seydel and Stöhrer, *ibid.* 1902, 35, 4400)—

Codeinone → 6-Methoxy-3 : 4-dihydroxyphenanthrene }
Thebaine → 3 : 6 - Dimethoxy - 4-hydroxyphenanthrene } + hydroxyethylmethylamine

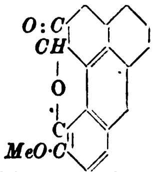
Thebaine must therefore be the methyl ether of an enolic form of codeinone. Accepting Pschorr's formulation of morphine, the three alkaloids, codeine, codeinone, and thebaine, will be represented by the following formulæ in which the variable groups only are shown in the last three (Ber. 1902, 35, 4382; 1905, 38, 3160; 1907, 40, 1984; *cf.* Knorr and others, *ibid.* 1907, 40, 3341, 4891, Wieland and Kappelmeier, Ann. 1911, 382, 306; Freund. Ber. 1905, 38, 3238; 1910, 43, 2128).



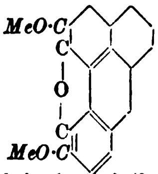
Morphine (Pschorr).



Codeine.



Codeinone (keto form).



Thebaine (methyl ether of *enol*codeinone).

Narcotine Group (Narcotine, Gnoscopine, Hydrocotarnine, Narceine).

Narcotine $C_{22}H_{23}O_7N$ usually occurs to the extent of about 5–6 p.c. in Asia Minor opium, but in larger quantity in Indian and Persian opiums. Unlike most alkaloids, narcotine appears, as a rule, to exist in the plant in the free state, and not as a salt.

Preparation. If the opium is extracted with water in order to isolate the morphine, &c., the greater part of the narcotine remains undissolved, since this alkaloid is nearly insoluble in water. By exhausting the residue with dilute hydrochloric acid, the narcotine is removed as hydrochloride, and from the solution of this salt the base may be precipitated by sodium bicarbonate, and crystallised from alcohol. Or the narcotine may be extracted from the opium by boiling it with ether; *see* also Hesse, Annalen, Suppl. 8, 284.

Estimation. Narcotine is most readily estimated in opium by drying the drug at 100° and then extracting a weighed quantity with hot ether. From the ether solution the alkaloid may be extracted by repeated agitation with dilute sulphuric acid, and may be obtained clean by adding alkali and re-extracting with ether.

Properties. Prismatic crystals, m.p. 174°–175°. Almost insoluble in water (1 in 25,000 at 15°, 1·1 in 7000 at 100°); soluble in alcohol (1 in 100 at 15°, 1 in 20 at b.p.); ether (1 in 166 at 16°); and in benzene (1 in 22 at 15°); very soluble in chloroform (1 in 2·69 at 15°); slightly soluble in amyl alcohol or light petroleum, dissolves in lime or baryta water, and slightly in aqueous ammonia. Lævorotatory, $[a]_D = -185°$ in alcohol (Hesse, Annalen, 1875, 176, 192), $-199·9°$ in chloroform (Perkin and Robinson, Chem. Soc. Proc. 1910, 26, 131). The solution in dilute acids is dextrorotatory. Narcotine is a feeble monacidic tertiary base; its aqueous solution is neutral to litmus. The principal salts crystallise with difficulty; their aqueous solutions are acid, and are decomposed, with separation of narcotine when evaporated. The free alkaloid may even be extracted from the aqueous solution of some narcotine salts by agitating with ether or chloroform. In larger doses than are necessary in the cases of morphine and codeine, narcotine and its salts exert a narcotic action.

Reactions and constitution. Concentrated sulphuric acid dissolves narcotine, and the solution soon becomes yellow; on warming a rapid transition of different colours is observed, the mixture becoming orange-red, blue, and finally purple. Nitric acid dissolves the alkaloid with a yellow colour.

When heated with hydriodic acid narcotine furnishes three molecular proportions of methyl iodide and *nornarcotine* $C_{19}H_{17}O_7N$ or

$$C_{19}H_{14}(OH)_3O_4N.$$

The less energetic action of hydriodic acid produces one molecular proportion of methyl iodide, and *dimethylnornarcotine*

$$C_{19}H_{14}(OCH_3)_2(OH)O_4N,$$

or two molecular proportions of methyl iodide and *methylnornarcotine* $C_{19}H_{14}(OCH_3)(OH)_2O_4N$.

When heated with water in a closed tube at 100°, or by prolonged ebullition with water, the alkaloid is resolved into *opianic acid*

$$C_6H_2(OMe : OMe : COOH : CHO = 1 : 2 : 3 : 4)$$

and *hydrocotarnine*

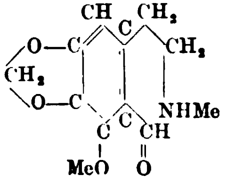
$$(C_{22}H_{23}O_7N + H_2O = C_{10}H_{10}O_5 + C_{12}H_{15}O_3N)$$

from which cotarnine $C_{12}H_{15}O_4N$ results by oxidation (Beckett and Wright, Chem. Soc. Trans. 1875, 28, 583). Cotarnine is largely employed in the form of its chloride (stypticin) as an internal styptic (*cf. Hydrastinine*, p. 654).

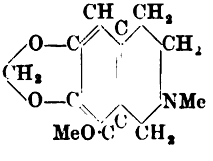
Nascent hydrogen converts narcotine into *meconin* and *hydrocotarnine* $C_{12}H_{15}O_3N$, and on oxidation *cotarnine* and *opianic acid* (*see* above) are formed, the latter by further oxidation becoming *hemipinic acid*.

$$C_6H_2(OMe : OMe : COOH : COOH = 1 : 2 : 3 : 4).$$

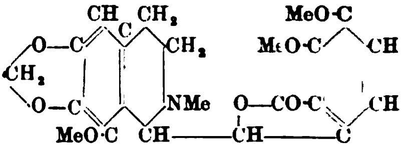
On 'exhaustive methylation' cotarnine yields *cotarnone* $C_{11}H_{10}O_4$, which on oxidation gives *cotarnic acid* $C_{10}H_8O_7$, and this with hydrochloric acid furnishes the methylmethylene ether of gallic acid. From these and other data Roser has assigned the following formulæ to cotarnine, hydrocotarnine, and narcotine (Annalen, 1888, 249, 156, 168; 1889, 254, 334, 351; 1893, 272, 221; *cf.* Freund and Becker, Ber. 1903, 36, 1521)—



Cotarnine.



Hydrocotarnine.



Narcotine.

The synthesis of narcotine has been effected by Perkin and Robinson by treating an alcoholic solution of cotarnine and meconin with potassium carbonate, or by simply boiling an alcoholic solution of these two substances (Chem. Soc. Proc. 1910, 26, 46; Chem. Soc. Trans. 1911, 99, 778; *cf.* Liebermann, Ber. 1896, 29, 184). Cotarnine had been prepared previously by Salway (Chem. Soc. Trans. 1910, 97, 1208) from myristicin. The substance actually produced in Perkin and Robinson's synthesis is the alkaloid *gnoscopine*, isolated from opium by T. and H. Smith (Pharm. J. 1878, [iii.] 9, 82; 1893, [iii.] 52, 794), and which Rabe had suggested (Ber. 1907, 40, 3280; 1910, 43, 800; Annalen. 1910, 377, 223) was *dl*-narcotine produced by racemisation of narcotine during its isolation from opium. Natural and synthetic gnoscopines were resolved by crystallising the *d*-camphorsulphonate into *d*- and *l*-narcotine, the latter identical with the natural alkaloid, by Perkin and Robinson (Chem. Soc. Proc. 1910, 26, 46, 131).

Narceine $C_{23}H_{27}O_8N,H_2O$ occurs in opium to the extent of 0·1 p.c., and is recovered from the mother liquors from which morphine and codeine hydrochlorides have crystallised out, after the removal from these of narcotine, thebaine, and papaverine (pp. 656, 659).

Properties. Crystallises from water or alcohol in prisms or slender needles with $3H_2O$, m.p. 170°, or 140°–145° ($1H_2O$) when dried at 100°. Sparingly soluble in cold water (1 in 1285 at 13°) or cold alcohol (1 in 945 of 80 p.c. alcohol), much more soluble in hot water or hot alcohol. Somewhat soluble in ammonia and alkalis. Optically inactive. Narceine has no marked physiological action. It is a monacidic base and forms well-crystallised salts with acids. It also behaves as a monocarboxylic acid and forms a series of salts with metals (potassium-narceine

$$C_{23}H_{26}O_8NK,$$

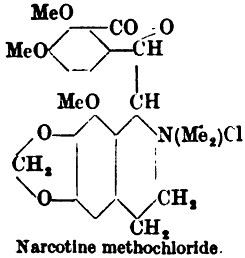
rosettes of needles), and yields esters with alcohols (narceine ethyl ester hydrochloride

$$C_{23}H_{26}(C_2H_5)O_8N,HCl$$

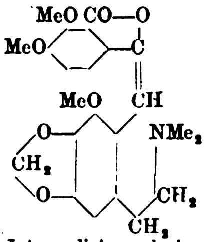
is crystalline, m.p. 206°–207°). Methyl iodide reacts with narceine to form narceine methyl ester methiodide $C_{23}H_{26}(CH_3)O_8N,CH_3I$, m.p. 193°–194°.

Reactions and constitution. Narceine gives with chlorine water, followed by ammonia solution, a blood-red coloration. Its constitution is established by the fact that it can be prepared by heating narcotinemethochloride with alkalis. According to Freund this change takes place as shown by the formulæ at top of next page.

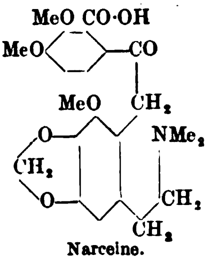
The chief papers relating to narceine are Pelletier, Annalen, 1832, 5, 163; Anderson, *ibid.* 1853, 86, 182; Hesse, *ibid.* 1875, 176, 189; Roser, *ibid.* 1888, 247, 169; Freund and collaborators, *ibid.* 1893, 277, 6; Ber. 1909, 42, 1084).



Narcotine methochloride.



Intermediate product.



Narceine.

Papaverine Group (*Papaverine*, *Laudanosine*, *Laudanine*, &c.).

Papaverine $C_{20}H_{21}O_4N$. This alkaloid separates with narcotine as described under thebaine (p. 659) and is separated from it by conversion into the acid oxalate, which is sparingly soluble in alcohol, that of narcotine being readily soluble.

Properties. Prismatic crystals, m.p. 147°. Very slightly soluble in hot or cold water; easily soluble in hot alcohol, chloroform, or benzene. Optically inactive. A monacidic base which forms crystalline salts. It is mildly soporific in action.

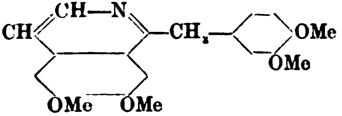
Reactions and constitution. Sulphuric acid dissolves papaverine in the cold without coloration. Commercial papaverine gives a violet coloration due to the presence of cryptopine (p. 650) (Pictet and Kramers, Ber. 1910, 43, 1329). With sulphuric and iodic acids it gives a purple coloration changing to green.

Nascent hydrogen converts papaverine into a dihydride (Pyman, Chem. Soc. Trans. 1909, 95, 1610). When heated with concentrated hydriodic acid it furnishes papaveroline $C_{16}H_{13}O_4N$, together with four molecular proportions of methyl iodide, from which it is inferred that four methoxyl groups are present.

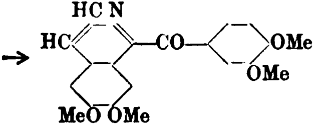
On oxidation with permanganate papaverine yields a large number of products, the principal being *veratric acid*, *metahemipinic* or *dimethoxy*-o-*phthalic acid* $C_6H_2(OCH_3)_2(CO_2H)_2$, *pyridine-αβγ-tricarboxylic acid*, and *papaveraldine*. According to Dobson and Perkin (Chem. Soc. Trans. 1911, 99, 135) papaveraldine (*see* below) is identical with *xanthaline*, an alkaloid isolated from opium by T. and H. Smith (Pharm. J. 1893, [iii.] 52, 793).

When fused with alkali papaverine affords *veratric acid*, together with *dimethoxy*-iso-*quinoline*.

From these and other results Goldschmiedt (Monatsh. 1883, 4, 704; 1885, 6, 372, 667, 956; 1886, 7, 488; 1887, 8, 510; 1888, 9, 42, 327, 349) has concluded that papaverine is tetramethoxybenzyl*iso*quinoline, and this constitution has been established by synthesis of the alkaloid (Pictet and Gams, Compt. rend. 1909, 149, 210).

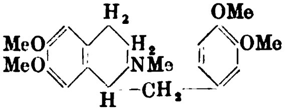


Papaverine.



Papaveraldine (xanthaline).

Laudanosine, $C_{21}H_{27}O_4N$. When papaverine methochloride is reduced with tin and hydrochloric acid it furnishes *dl-N*-methyltetrahydropapaverine, m.p. 115°, and this on crystallisation of the quinate, separates into the *d*- and *l*-bases, the former being identical with d-*laudanosine* which occurs in opium. It crystallises in needles, m.p. 89°, $[\alpha]_D + 103°$ in alcohol and contains four ·OMe groups. Laudanosine is more poisonous than papaverine, and resembles thebaine in physiological action; it exerts no narcotic effect (Pictet and Athanasescu, Ber. 1900, 33, 2346). *dl*-Laudanosine is also formed when *laudanine* $C_{20}H_{25}O_4N$, crystals, m.p. 166°, $[\alpha]_D = 0°$, an alkaloid occurring in opium, is methylated, so that it appears to be the methyl ether of laudanine (Hesse, Annalen, 1894, 282, 208; J. pr. Chem. 1902, [ii.] 65, 42). Syntheses of laudanosine have been effected by Pictet and Mdlle. Finkelstein (Compt. rend. 1909, 148, 925), and by Gadamer (Arch. Pharm. 1911, 249, 680; *cf.* Pschorr, Ber. 1904, 37, 1926), so that the constitution of the alkaloid is now clearly established—



Laudanosine.

Laudanine differs from laudanosine only in containing a hydroxyl group in place of a methoxyl (probably in the benzene ring). The alkaloid *laudanidine*, isomeric with laudanine, which also occurs in opium, is probably *l*-laudanine. It resembles laudanine in crystalline form and in its reactions, but melts at 177° and has $[\alpha]_D - 87{\cdot}8°$ in chloroform (Hesse, Annalen, 1894, 282, 208).

Muscarine $C_5H_{15}O_3N$ occurs in various poisonous fungi, especially in fly agaric (*Amanita muscaria*). Hygroscopic crystals. Tasteless. Its constitution is uncertain, but it is believed to be the hydrated aldehyde of choline (Berlinerblau, Ber. 1884, 17, 1139; E. Fischer, *ibid.* 1893, 26, 468; 1894, 27, 165; Nothnagel, *ibid.* 1893, 26, 801). Choline on oxidation furnishes a muscarine, which is not identical in physiological actions with the natural one. Muscarine somewhat resembles pilocarpine in physiological action, is antagonistic to atropine and highly toxic (*v.* PTOMAINES).

Myoctonine. *See* under *Aconitine and the aconite alkaloids* (p. 634).

Napelline. A name applied by Hubschmann to what was probably a mixture of amorphous alkaloids from *Aconitum Napellus* (Linn.). *See Aconite and the aconite alkaloids* (p. 630).

Narceine. *See* under *Morphine* (p. 660).

Narcissine $C_{16}H_{17}O_4N$, occurs in the bulbs of *Narcissus Pseudo-Narcissus* (Linn.) and *Buphane disticha*; crystals, m.p. 266°–267° $[a]_D^{10}$—95·8° in alcohol. Causes nausea and purgation (Ewins, Chem. Soc. Trans. 1910, 97, 2406; Tutin, *ibid.* 1911, 99, 1240).

Narcotine. *See* under *Morphine* (p. 659).

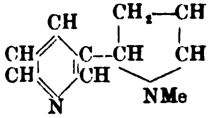
Nicotine $C_{10}H_{14}N_2$, a liquid, volatile alkaloid, occurring in tobacco (*Nicotiana Tabacum* [Linn.]) as malate and citrate, together with several other alkaloids of comparatively little importance, *e.g.* *nicoteine* $C_{10}H_{12}N_2$, b.p. 266°, liquid; *nicotimine* $C_{10}H_{14}N_2$, b.p. 250°–255°, liquid; *nicotelline* $C_{10}H_8N_2$, m.p. 148°, prismatic needles. Nicotine also occurs in *Duboisia Hopwoodii* (F. Muell.) (Rothera, Bio-Chem. J. 1910, 5, 193), from which it was isolated under the name 'piturine' (*see* Petit, Pharm. J. 1878–1879, [iii.] 9, 819). Tobacco contains, as a rule, from 1 to 8 p.c. of nicotine, but by far the greater proportion of commercial tobacco contains not more than 4 p.c. (*v.* TOBACCO).

Preparation. Nicotine and tobacco extract are now largely used as insecticides, and a considerable industry has sprung up in the last few years in the manufacture of these products. For these purposes tobacco leaf midribs and waste tobacco are largely used, as well as the liquors obtained in the manufacture of chewing tobacco. The tobacco is extracted with water usually in some form of continuous extraction apparatus, and this liquor, or that produced in making chewing tobacco, is concentrated to form tobacco extract. From the latter crude nicotine can be obtained by adding lime or soda solution and steam-distilling, the distillate being extracted with ether.

Estimation. The process generally employed for this purpose is that of Kissling (Zeitsch. anal. Chem. 1882, 21, 64; 1883, 22, 199), which has been modified in various ways. The following form of this process is stated to give good results: 20 grms. of powdered tobacco, dried at a temperature not exceeding 60°, is mixed with 10 c.c. of alcohol containing 0·6 grm. of sodium hydroxide and extracted with ether in a Soxhlet apparatus until exhausted (usually in 3 hours). The solvent is distilled off and the residue mixed with 50 c.c. of 0·4 p.c. soda solution and steam-distilled, and the distillate titrated with N-sulphuric acid in presence of rosolic acid. For extracts the same process may be used, alkali being added to the extract and the mixture steam-distilled. For recent work on the estimation of nicotine in tobacco and tobacco extracts, *see* Tóth, Rev. Intern. Fals. 1901, 14, 12; Chem. Zeit. 1911, 35, 146, 926; Bertrand and Javillier, Bull. Soc. chim. 1909, [iv.] 5, 241; Ann. Chim. anal. 1911, 16, 251; Schröder, Chem. Zeit. 1911, 35, 30, 382; *cf.* Kissling, *ibid.* 98, 200, and Leister, *ibid.* 239; Koenig, *ibid.* 1911, 35, 521; Surre, Ann. Falsif. 1911, 4, 331 (a process for estimating nicotine in presence of pyridine bases).

Properties. Pungent, colourless, hygroscopic liquid, which oxidises in air becoming brown and resinous, b.p. 247°. Distils unchanged in a current of hydrogen or steam, but suffers oxidation when distilled in air, sp.gr. 1·0110 at 20°. The density increases to 1·04 on addition of water up to 33 p.c. (*cf.* Hudson, Zeitsch. physikal. Chem. 1904, 47, 113). Lævorotatory $[a]_D = -163·85°$; salts dextrorotatory. The aqueous solution is strongly alkaline and precipitates solutions of many metallic salts. The salts crystallise with difficulty, but the picrate $B,2C_6H_2(NO_2)_3OH$ forms glancing yellow prisms, m.p. 218°, and is characteristic. Nicotine and its salts are precipitated even in dilute solutions by alkaloidal reagents. Nicotine treated with a drop of formaldehyde solution and then with a drop of nitric acid gives a rose-red coloration.

Reactions and constitution. Nicotine reacts with methyl iodide as a ditertiary base, and on oxidation furnishes β-pyridine derivatives, so that it must contain a pyridine nucleus, with a side chain or a second ring attached in the β-position. Pinner first suggested that this residual portion of the molecule consisted of a N-methylpyrrolidine ring (Ber. 1892, 25, 2816; 1893, 26, 292, 769), and this has received support from the synthesis of nicotine by Pictet and collaborators (*ibid.* 1895, 28, 1911; 1898, 31, 2018; 1900, 33, 2355; 1904, 37, 1225).



Nicotine (Pinner).

Oxyacanthine. *See* under *Berberine* (p. 640).

Palmatine. *See* under *Columbamine* (p. 648).

Palmatisine. *See* under *Aconitine* (p. 634).

Papaverine. *See* under *Morphine and the opium alkaloids* (p. 661).

Paucine $C_{27}H_{39}O_5N_5$, obtained from the seeds of *Pentaclethra macrophylla* (Benth.) sometimes imported from West Africa as an oil-seed ('Owala beans'). Yellowish leaflets with $6\frac{1}{2}H_2O$, m.p. 126°. Salts crystalline. Poisonous (Merck's Bericht, 1894, p. 11).

PELLETIERINE AND THE ALKALOIDS OF POMEGRANATE ROOT BARK.

Tanret isolated from the bark four alkaloids (Compt. rend. 1878, 86, 1270; 1879, 88, 716; 1880, 90, 696), to which a fifth, *iso*methylpelletierine was added by Piccinini (Gazz. chim. ital. 1899, 29, 311). The alkaloids known to occur in the bark are—

Pelletierine $C_8H_{15}ON$
*iso*Pelletierine $C_8H_{15}ON$
Methylpelletierine $C_9H_{17}ON$
*iso*Methylpelletierine $C_9H_{17}ON$
*pseudo*Pelletierine $C_9H_{15}ON$.

The bark has long been used as an anthelmintic, and Schroeder has observed that the first two alkaloids in the above list have a specific action on tape worms. None of the alkaloids are very active poisons, though in large doses the first two produce toxic effects.

Preparation (*see* Tanret, *l.c.*).

Estimation (*see* Ewers, Arch. Pharm. 1899, 237, 49, and German Pharmacopeia v.). According to Ewers (*l.c.*) pomegranate root bark contains 0·63–0·72 p.c. total alkaloids, of which 40–50 p.c. consists of the active alkaloids pelletierine and *iso*pelletierine; branch bark contains 0·52 p.c. total alkaloids. The quantity of alkaloids diminishes on long storage of the bark.

Pelletierine $C_8H_{15}ON$. Liquid, sp.gr. 0·9 at 0°. Darkens and resinifies in air, by

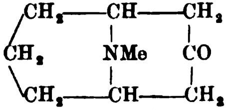
195°. Dextrorotatory $[\alpha]_D = +8°$. Soluble in water (1 in 23 at 15°); readily soluble in alcohol, ether, or chloroform. The aqueous solution is strongly alkaline. The salts are crystalline; the sulphate is lævorotatory.

***iso*Pelletierine** $C_8H_{15}ON$ closely resembles pelletierine, but is optically inactive.

Methylpelletierine $C_9H_{17}ON$, liquid, b.p. 215°; the hydrochloride is dextrorotatory and hygroscopic (Tanret, *l.c.*; and Bull. Soc. chim. 1879, [ii.] 32, 464, 466; 1881, [ii.] 36, 256).

***iso*Methylpelletierine** $C_9H_{17}ON$, liquid, b.p. 114°–117°/26 mm., strongly alkaline; the aurichloride, m.p. 115°–117°, forms orange-yellow rosettes. The alkaloid contains a : NMe and a : CO group (Piccinini, *l.c.*).

***pseudo*Pelletierine** $C_9H_{15}ON$ forms prismatic crystals from light petroleum, m.p. 48°, b.p. 246°. Easily soluble in ether, chloroform, or alcohol. Strong, optically inactive base, forming crystalline salts. The oxygen atom is present as carbonyl. Ciamician and Silber have shown (Ber. 1892, 25, 1601; 1893, 26, 156, 2740; 1894, 27, 2851; 1896, 29, 492) that *pseudo*pelletierine yields a series of derivatives which bring it into close relationship with tropine (p. 637). Piccinini has extended these observations (Gazz. chim. ital. 1899, 29, i. 408; ii. 115; 1901, 31, i. 561), and using Willstätter's formula for tropine (p. 637) as a basis, has assigned the following constitution to *pseudo*pelletierine (*cf.* Willstätter and Veraguth, Ber. 1905, 38, 1984)—



*pseudo*Pelletierine.

Pellotine. *See* under *Mezcaline* (p. 656).
Pelosine. *See Bebeerine* (p. 639).

Physostigmine and the Alkaloids of Calabar Bean.

Physostigmine (*Eserine*) $C_{15}H_{21}O_2N_3$, the chief alkaloid of Calabar bean (*Physostigma venenosum* [Balf.]). (*v.* Ordeal Bean, vol. iv. p. 21).

Preparation. The powdered beans are extracted with alcohol and the alcohol distilled off. The extract is mixed with excess of sodium carbonate and extracted repeatedly with ether; the ethereal solution is shaken with successive portions of dilute sulphuric acid (5 p.c.) until the aqueous liquid extract becomes just acid. It is then filtered and the physostigmine precipitated as salicylate. From the mother liquor a further portion may be obtained by repetition of the treatment. From the salicylate the alkaloid may be recovered by agitation with aqueous sodium carbonate in presence of ether and re-crystallising from benzene and light petroleum (Jobst and Hesse, Annalen, 1864, 129, 115; Vée, J. 1865, 456; Hesse, Annalen, 1867, 141, 82; Petit and Polonowsky, Bull. Soc. chim. 1893, [iii.] 9, 1008; Orloff, Chem. Zeit. 1897, 1214; Salway, Chem. Soc. Trans. 1911, 99, 2148).

Estimation of physostigmine. 20 grams of Calabar beans in No. 60 powder are macerated with 200 c.c. of ether and 10 c.c. of 10 p.c. sodium carbonate solution during 4 hours. 100 c.c. of ether are withdrawn and the alkaloids extracted by shaking with several portions of N/10 acid. The combined acid liquids are made alkaline with 10 p.c. sodium carbonate solution, and the alkaloid extracted by shaking at least ten times with ether using 20 c.c. ether each time. The combined ethereal solutions are shaken once with 5 c.c. of water, and the residue left on distilling off the solvent, dissolved in 5 c.c. N/10 acid, and titrated back with N/50 alkali, using iodo-eosin as indicator (Salway, Amer. J. Pharm. 1912, 84, 49).

Properties. The alkaloid is dimorphous and forms stout prisms, m.p. 86°–87°, or 105°–106°; lævorotatory $[\alpha]_D -75{\cdot}8°$ in chloroform (Salway, *l.c.*). Very slightly soluble in water, but readily soluble in alcohol, ether, chloroform, or benzene. Strongly alkaline. The sulphate $B_2{\cdot}H_2SO_4{,}xH_2O$, colourless needles, m.p. 140°, is very soluble in water, alcohol, or chloroform, less so in ether (1 in 200 at 25°); the salicylate $B{\cdot}C_7H_6O_3$ forms acicular crystals, m.p. 180–181°, and is soluble in water (1 in 72·5 at 25°), alcohol (1 in 12·7 at 25°), ether (1 in 175 at 25°), or chloroform (1 in 8·6 at 25°). Both these salts are used in medicine. The alkaloid forms no definite aurichloride or platinichloride; the picrate forms feathery yellow needles from dilute alcohol, m.p. 114°. The sulphate, on addition of excess of ammonia, when warmed at 100°, gives a play of colours red, reddish-yellow, green, blue (Petit, Compt. rend. 1871, 72, 569). A fragment of the alkaloid dissolved in a drop or two of fuming nitric acid, and evaporated to dryness at 100°, leaves a green residue. Causes contraction of the pupil of the eye—*i.e.* myotic—and when administered internally acts as a powerful poison (*cf.* Cushny, J. Physiol. 1910, 41, 233). Forms a methiodide B·MeI; only one of the three nitrogen atoms is basic (Petit and Polonowsky, *l.c.*). Is oxidised when exposed to air, especially in presence of alkali, forming first *eseroline* $C_{13}H_{18}ON_2$ by loss of carbon dioxide and methylamine, and eventually a red crystalline colouring matter *rubreserine*. When calcium chloride is added to its aqueous solution a fine red colouring matter is also produced. When alkalis act on eserine the alkaloid *calabarine* appears to be formed (*see* below).

Physovenine $C_{14}H_{18}O_3N_2$ occurs in the mother liquors from which eseramine has been crystallised (*see* below). Colourless prisms, m.p. 123°, from dilute alcohol or benzene and light petroleum; very soluble in alcohol, benzene, or chloroform, moderately so in ether, insoluble in water or light petroleum. Salts dissociated by water. Barium hydroxide decomposes it, forming barium carbonate and a red colouring matter. Physovenine appears to be an intermediate product in the formation of eseroline from physostigmine. Powerfully myotic (Salway, *l.c.*).

Eseramine $C_{16}H_{25}O_3N_4$ occurs in the ethereal liquors from which physostigmine has been extracted by dilute sulphuric acid (*see* above), and can be isolated by washing the residue with small quantities of ether and re-crystallising the matter insoluble in ether from alcohol; colourless needles, m.p. 245°; sparingly soluble in ether, chloroform, or benzene, readily so in hot alcohol (Ehrenberg, Verh. Ges. Deut. Naturf. Aertzte, 1893, ii. 102; and Salway, *l.c.*).

In addition to the foregoing the following alkaloids have been stated to occur in Calabar beans, but Salway (*l.c.*), was unable to confirm their presence.

Calabarine. Harnack and Wittkowski state (Arch. expt. Path. Pharm. 1876, 5, 401; 8, 125; 9, 434; 10, 301; 12, 101) that this alkaloid is formed by the action of alkalis on physostigmine, and that it also occurs in Calabar beans. The evidence for its existence is based mainly on evidence obtained from its physiological action, which is stated to be strychnine-like and antagonistic to that of physostigmine. It is probable that 'calabarine' is a mixture of decomposition products of physostigmine (*cf.* Ehrenberg, *l.c.*). *Eseridine* $C_{15}H_{23}O_3N_3$, crystalline (Böhringer and Söhne, Ph. Post. 1888, 21, 663; Eber, Pharm. Zeit. 1892, 37, 483). iso*Physostigmine* $C_{15}H_{21}O_2N_3$ (Ogui, Apoth. Zeit. 1904, 19, 891).

PILOCARPINE AND THE ALKALOIDS OF JABORANDI.

The jaborandi of commerce now consists of the leaves of *Pilocarpus microphyllus* (Stapf.), though the leaves of *P. Jaborandi*, *P. pennatifolius* (Lem.), *P. spicatus* (A. St. Hill), and *P. trachylophus* have also appeared in trade. The drug was examined by Hardy (Bull. Soc. chim. 1875, [ii.] 24, 497), Gerrard (Pharm. J. 1875, [iii.] 5, 865, 965; 1877, [iii.] 7, 225), Harnack and Meyer (Annalen, 1880, 204, 67), Jowett (Chem. Soc. Trans. 1900, 77, 474, 851; 1901, 79, 581, 1331), and Pyman (*ibid.* 1912, 101, 2260; *cf.* Leger and Roques, Compt. rend. 1912, 155, 1088; 1913, 156, 1687). The results of these researches show that *P. microphyllus* leaves contain pilocarpine, *iso*-pilocarpine (β-pilocarpine of Bruhl, Hjelt, and Aschan; pilocarpidine of Petit and Polonowsky (J. Pharm. Chim. 1897, [vi.] 5, 370, 430, 475; 1898, 6, 8), and pilosine, $C_{16}H_{18}O_3N_2$, plates, m.p. 187°. Harnack and Meyer's pilocarpidine (Chem. Zeit. 1885, 628) and jaborine (Annalen, 1880, 204, 67) may occur in *P. Jaborandi* leaves, which are no longer obtainable in commerce. Petit and Polonowsky have stated that *P. spicatus* leaves contain ψ-pilocarpine and ψ-jaborine (*l.c.*). Pilocarpine, *iso*pilocarpine, and pilocarpidine cause contraction of the pupil of the eye and act as sialogogues. Pilocarpine is most, and pilocarpidine least, active. In certain respects they are antagonistic to atropine (*v.* JABORANDI, vol. iii. p. 184).

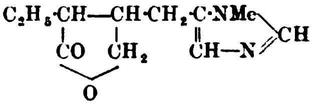
Preparation. The finely-powdered leaves are extracted with alcohol containing hydrochloric acid. The solvent is distilled off, the aqueous residue filtered, neutralised with ammonia and evaporated to a low bulk. Excess of ammonia is then added and the alkaloids extracted with chloroform. The chloroform is distilled off, the residue dissolved in as little water as possible and neutralised with dilute nitric acid. The crystalline nitrates which form are separated into pilocarpine nitrate and *iso*pilocarpine nitrate, by re-crystallisation from alcohol until each is of constant melting-point.

Estimation. A weighed quantity of the finely-powdered drug is extracted in a Soxhlet apparatus with alcohol containing 1 p.c. of ammonia. The alcohol is distilled off and the residue dissolved in water, made alkaline with ammonia if necessary, and extracted with chloroform. The chloroform solution is separated, the solvent distilled off, and the residue dried at 100° and weighed. It represents the total alkaloids. Jowett (Pharm. J. July 29, 1899) has proposed a method for the approximate estimation of pilocarpine in this residue by conversion into the crystalline nitrate and observation of the optical rotation of the product.

Pilocarpine $C_{11}H_{16}O_2N_2$ is a colourless oil, soluble in water, alcohol, or chloroform, b.p. 260° under 5 m.m. pressure, being partially converted into *iso*pilocarpine (*see* below) in the process. Dextrorotatory, $[\alpha]_D + 100{\cdot}5°$; the rotation is reduced by the addition of alkali. The salts crystallise well; the nitrate $B.HNO_3$ forms well-defined prisms, m.p. 178°, the aurichloride $B{\cdot}HAuCl_4$, lemon-yellow needles, m.p. 117°–130° (dry), and the picrate, characteristic long needles, m.p. 147°.

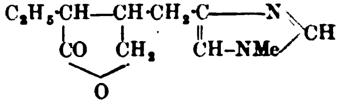
***iso*Pilocarpine** $C_{11}H_{16}O_2N_2$. When pilocarpine is heated alone or with alcoholic soda it is changed into *iso*pilocarpine, which also occurs in *P. microphyllus* and *P. Jaborandi* leaves, and according to Jowett (Chem. Soc. Trans. 1900, 77, 473), is frequently found in commercial pilocarpine nitrate. It is an oil, b.p. 261°/10 mm., $[\alpha]_D = +42{\cdot}8°$ in alcohol. The nitrate $B{\cdot}HNO_3$, m.p. 159°, crystallises in prisms, and is less soluble in alcohol than pilocarpine nitrate (Jowett, *l.c.*). The aurichloride, m.p. 158°–159°, forms lemon-yellow needles.

Reactions and constitution. On solution in alkalis both alkaloids form unstable sodium salts, viz. sodium pilocarpate and sodium *iso*pilocarpate, from which salts of other metals may be prepared. On oxidation with permanganate *iso*pilocarpine produces homopilopic acid $C_8H_{12}O_4$, and pilopic acid $C_7H_{10}O_4$. The former on fusion with potash yields α-ethyltricarballylic acid, and the second, on similar treatment, gives *n*-butyric acid. By distillation with soda-lime *iso*pilocarpine yields 1 : 3- (or 5-) dimethylglyoxaline (Jowett, Chem. Soc. Trans. 1900, 77, 474, 851; 1901, 79, 581, 1331; 1903, 83, 440; *cf.* Pinner and collaborators, Ber. 1900, 33, 1424, 2357; 1901, 34, 727; 1902, 35, 2241). One of the two following formulæ is regarded as representing *iso*pilocarpine—



I.

or



II. *iso*-Pilocarpine (Jowett).

the balance of evidence being in favour of I. (Jowett, Chem. Soc. Trans. 1903, 83, 438; 1905, 87, 794; and Pyman, *ibid.* 1910, 97, 1814; *cf.* Pinner and Schwarz, Ber. 1902, 35, 2441). Pilocarpine is probably a stereoisomeride of *iso*pilocarpine (Jowett, *loc. cit.*).

Pilocarpidine $C_{10}H_{14}O_2N_2$ occurs in *Pilocarpus Jaborandi* leaves, but not in those of *P. microphyllus*, and consequently is not obtainable from the jaborandi leaves of present-day commerce. The alkaloid is liquid, but yields crystalline salts; the hydrochloride has $[\alpha]_D +72°$; the nitrate, m.p. 137°, $[\alpha]_D +73{\cdot}2°$, is much more soluble in alcohol than pilocarpine and *iso*pilocarpine nitrates; the aurichloride, m.p. 124°–125°, is soluble in water. As in the case of pilocarpine, the optical rotation of pilocarpidine is reduced by the addition of alkali (Harnack and Meyer, Chem. Zeit. 1885, 628; Merck, Arch. Pharm. 1898, 236, 141; Jowett, Chem. Soc. Trans. 1900, 77, 474). The name pilocarpidine was erroneously applied by Petit and Polonowsky to *iso*pilocarpine (p. 664).

Jaborine. This amorphous alkaloid may occur in *P. Jaborandi* leaves (Harnack and Meyer, Annalen, 1880, 204, 67). According to Jowett (*l.c.*) commercial jaborine is a mixture of *iso*pilocarpine, pilocarpidine, and possibly pilocarpine, with colouring matter.

Pilosine. *See* under *Pilocarpine* (p. 664).

Piperine $C_{17}H_{19}O_3N$, the alkaloid contained in the fruits of *Piper nigrum* (Linn.), as well as in other plants belonging to the natural order *Piperaceæ, e.g. Piper longum* (Linn.), *P. Clusii* (C. DC.), *P. methysticum* (Forst.), &c. Commercial black and white peppers contain from 5 to 9 p.c. of this alkaloid (*v.* PEPPER, vol. iv. pp. 108, 111.

Preparation. Piperine may be extracted from finely-powdered pepper, preferably white pepper, by means of alcohol. The alcohol is distilled from the solution, and the alkaloid precipitated from the remaining aqueous residue by adding excess of potash, so that the greater part of the resin is dissolved. The base is purified by crystallisation from alcohol.

Another plan is to mix the powdered pepper with milk of lime and boil the mixture for about 15 mins.; it is then evaporated to dryness on the water-bath. The free piperine is extracted from the dry mass by means of boiling ether and crystallised from alcohol (Cazeneuve and Caillot, Bull. Soc. chim. 1877, [ii.] 27, 290). This process is also employed for the estimation of piperine in pepper.

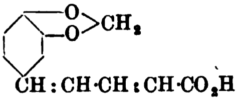
Properties. Monoclinic crystals, m.p. 128°–129°. Slightly soluble in water, more soluble in ether, alcohol, benzene, or chloroform. Optically inactive. An alcoholic solution has a pepper-like flavour. Piperine is a weak base. It is not alkaline, and may be extracted from solutions in dilute acids by indifferent solvents, such as ether. The principal salts are formed by combination with acids in the absence of much water. The platinichloride and mercurichloride are crystalline and insoluble in water; the triiodide $B_2{\cdot}HI,I_2$, formed by adding iodine in potassium iodide to a solution of piperine in alcohol containing hydrochloric acid, forms steel-blue needles.

Reactions and constitution. Piperine dissolves in strong sulphuric acid, forming a dark-red solution. Nitric acid converts the alkaloid into a resinous mass, which dissolves in potash, producing a dark-red solution.

When piperine is heated with aqueous alkalis it is hydrolysed into piperidine and piperic acid

$$C_{17}H_{19}O_3N+H_2O=C_5H_{11}N+C_{12}H_{10}O_4.$$

Piperidine is hexahydropyridine, whilst piperic acid is a derivative of protocatechuic acid having the following constitution—



Piperic acid.

Piperine has been prepared by the action of piperyl chloride on piperidine (Rugheimer, Ber. 1882, 15, 1390), and Ladenburg and Scholz have prepared piperic acid from protocatechuic aldehyde (*ibid.* 1894, 27, 2958). Piperine is therefore piperylpiperidine.

Piperovatine $C_{16}H_{21}O_2N$ occurs in *Piper ovatum* (Vahl.). Forms colourless needles, m.p. 123°, from alcohol by addition of ether. Optically inactive and feebly basic. Heated with water at 160° it gives a volatile base, probably a pyridine derivative, an acid and a substance having an odour of anisole. It is a temporary depressant of motor and sensory nerves and sensory nerve terminations, producing some local anæsthesia. It behaves as a heart poison and stimulates the spinal cord in frogs, causing tetanic spasms somewhat resembling those induced by strychnine (Dunstan (with Garnett), Chem. Soc. Trans. 1895, 67, 94; (with Carr), Chem. Soc. Proc. 1895, 177). It closely resembles *pellitorine* (pyrethrine), the alkaloid of pyrethrum root (*Anacyclus Pyrethrum* [DC.]) (Dunstan and Garnett, *l.c.* 101; *cf.* Buchheim, Arch. expt. Path. Pharm. 1876, 5, 458).

Pituribe, from the Australian plant 'pituri' (*Duboisia Hopwoodii* [F. Muell.]), is probably identical with nicotine (p. 662) (*cf.* Langley and Dickenson, J. Physiol. 1884, 11, 265; Rothera, Bio-Chem. J. 1910, 5, 193).

Protopine $C_{20}H_{19}O_5N$ (*Fumarine, Macleyine*) is widely distributed in plants of the N. O. *Papaveraceæ* and *Fumariaceæ, e.g.* in *Chelidonium majus* (Linn.) (Schmidt and Selle, Arch. Pharm. 1890, 228, 441), *Sanguinaria canadensis* (Linn.) (König and Tietz, *ibid.* 1893, 231, 145, 161), *Bocconia cordata* (Willd.) (Eykman, Rec. trav. chim. 1884, 3, 182), opium (Hesse, Annalen, 1872, S. 8, 318), *Adlumia cirrhosa* (Rafin.), *Glaucium flavum* (Crantz.), *Corydalis* spp., *Dicentra* spp., &c. (*cf.* Schmidt, Arch. Pharm. 1901, 239, 395; 1911, 249, 224; Fischer and Soell, Ph. Ar. 1902, 5, 121; Heyl, Arch. Pharm. 1903, 241, 313; Asahina, *ibid.* 1909, 247, 201; Danckwortt, *ibid.* 1912, 250, 590). Monoclinic crystals, m.p. 207°. Tertiary base. The salts are crystalline; the aurichloride $B{\cdot}HAuCl_4$, amorphous, melts at 182°. Protopine gives with sulphuric acid a blue-violet coloration, changing to green.

Pseudojervine. *See* under *Cevadine* (p. 644).

Psychotrine. *See* under *Emetine* (p. 652).

QUININE AND THE CINCHONA ALKALOIDS.

The barks of the different species of cinchona (*C. officinalis* (Linn.), *C. succirubra* (Pav.) *C. Ledgeriana* (Moens.), *C. Calisaya* (Wedd.), &c.) contain a large number of crystalline and amorphous alkaloids. At the present time most of the cinchona bark of commerce is derived from *Cinchona Ledgeriana* (a cultivated variety), or from hybrids, produced by selection, according to the richness of their barks in quinine, although a certain amount of *C. succirubra* bark is still marketed for galenical use. Statements as to the amount and nature of the alkaloids in barks of particular species have therefore little but historical or academic interest. These alkaloids exist in the bark chiefly as salts of quinic and cinchotannic acids. Closely related to the cinchona alkaloids proper are those derived from *Remijia pedunculata*, of which the most important is cuprëine. The following are the names and formulæ of the principal alkaloids—

Quinine $C_{20}H_{24}O_2N_2$
Quinidine $C_{20}H_{24}O_2N_2$
Hydroquinine $C_{20}H_{26}O_2N_2$
Hydroquinidine $C_{20}H_{26}O_2N_2$
Cinchonine $C_{19}H_{22}ON_2$
Cinchonidine $C_{19}H_{22}ON_2$
Hydrocinchonine (cinchotine) $C_{19}H_{24}ON_2$
Hydrocinchonidine (cinchonamine) $C_{19}H_{24}ON_2$
Quinamine $C_{19}H_{24}O_2N_2$
Conquinamine $C_{19}H_{24}O_2N_2$
Cuprëine $C_{19}H_{22}O_2N_2$

Quinine $C_{20}H_{24}O_2N_2$, the principal crystalline alkaloid contained in the bark (not in the wood) of many species of *Cinchona*. The amount of quinine contained in the different species varies considerably.

C. Ledgeriana (Moens.) bark is said sometimes to contain as much as 11 p.c. of quinine, whilst *C. officinalis* (Linn.), *C. Calisaya* (Wedd.), and *C. succirubra* (Pav.) usually contain from 2 to 5 p.c. On the average, Java cinchona bark of present-day commerce yields from 5 to 7 p.c. of quinine sulphate. The alkaloids which commonly accompany the quinine in these barks are hydroquinine cinchonidine, cinchonine, and quinidine, but the kind and quantity of the accompanying alkaloids vary in the different species.

Preparation. The total alkaloids are first extracted from the bark. Water dissolves for the most part only the alkaloidal quinates, and not the cinchotannates. The cinchotannates may be dissolved by a dilute acid (sulphuric or hydrochloric acid), or they (as well as the quinates) may be decomposed, and the alkaloids liberated by mixing the bark with an aqueous alkali (lime and water). The various processes proposed for the extraction of the total alkaloid from cinchona bark involve the decomposition of the natural salts in one or other of these two ways. Extraction with dilute hydrochloric acid, which was at first largely resorted to, has been almost entirely abandoned, since much colouring matter was dissolved as well as alkaloid, and its complete removal complicated the subsequent operations. On the large scale the finely-powdered bark is mixed with about one-third of its weight of slaked lime and made into a paste with water. The mixture is thoroughly dried at 100°, powdered, and exhausted in an extraction apparatus with boiling petroleum (Landrin, Compt. rend. 1889, 108, 750), alcohol, or amyl alcohol. On the small scale, chloroform, ether, or a mixture of three volumes of benzene with one of amyl alcohol may be employed. The alkaloids are removed from the solvent by agitating it (or, in the case of alcohol, the evaporated residue is similarly treated) with dilute hydrochloric acid, and the alkaloids are precipitated from the clear acid solution by a slight excess of soda or ammonia.

The alkaloids thus obtained from an ordinary commercial specimen of cinchona bark will, as a rule, be chiefly composed of quinine, hydroquinine, cinchonidine, cinchonine, and a little quinidine.

A nearly complete separation of the quinine may be effected by taking advantage of the smaller solubility of quinine sulphate in cold water. The total alkaloid is dissolved in a slight excess of very dilute sulphuric acid, and almost, but not quite, exactly neutralised with dilute soda or ammonia. The solution is heated to 100° and diluted with hot water, so that for each gram of total alkaloid taken there will be about 70 c.c. of solution. On cooling this solution to 15° quinine sulphate will crystallise, whilst nearly the whole of the other alkaloidal sulphates will remain dissolved. The salt thus obtained is recrystallised several times from boiling water. Great care must be taken in the first instance not to leave the liquid more than just perceptibly acid, or the quinine sulphate will be converted into the exceedingly soluble acid sulphate.

The quinine may also be separated, but less satisfactorily, by extracting the total alkaloid with ether, in which the other alkaloids, especially cinchonine, are much less soluble. For the preparation of small quantities of pure quinine the decomposition of herepathite (*see* below) by hydrogen sulphide (de Vrij and Alluard, J. 1864, 445) may be resorted to.

Properties. Amorphous and anhydrous when precipitated by alkalis from solutions of its salts, but crystallises with $3H_2O$ from a solution in dilute alcohol or aqueous ammonia. Crystalline mono- and di-hydrates have also been described, as well as an amorphous hydrate containing $9H_2O$. These hydrates lose the whole of their water by prolonged exposure over sulphuric acid, or at 100°, and more rapidly at 110°–120°. The ordinary trihydrate melts at 57°, and when warmed in dilute alcohol dissolves and deposits long, colourless needles of anhydrous quinine, m.p. 176° (Hesse, Annalen, 1890, 258, 135); 172·8° (corr.) (Lenz, Zeitsch. anal. Chem. 1888, 27, 549). Quinine is very slightly soluble in cold water (1 in 1960 at 15°), but is rather more soluble in hot water, rather less soluble in water in presence of alkalis or ammonia (except when freshly precipitated; it is readily soluble in alcohol, ether, or chloroform. It dissolves in hot benzene and separates on cooling in crystals containing 1 mol. of the solvent.

The aqueous solution is bitter and alkaline to litmus. The following quantities of quinine trihydrate are dissolved by 100 parts of the respective solvents at 15°; absolute alcohol, 88·2 parts; chloroform, 51·9 parts; ether, 4·42 parts. Also soluble in carbon disulphide, benzene, amyl alcohol, or light petroleum. Quinine shows lævorotation varying in amount with the concentration and the solvent; for the anhydrous alkaloid $[\alpha]_D^{15} = -158°$. For determination of the rotatory power in alcohol and ether *see* Hesse, Annalen, 1875, 176, 285; 1876, 182, 128; Oudemans, *ibid.* 1876, 182, 44.

Quinine readily dissolves in dilute acids forming salts. The acid solutions of the salt show a magnificent blue fluorescence if the acid used contains oxygen (*e.g.* sulphuric acid), but not if the acid contains no oxygen (*e.g.* hydrochloric acid). In the formation of salts quinine behaves as a diacidic base, unlike most of the vegetable alkaloids, which are monacidic. The salts ordinarily met with, however, contain 1 mol. prop. of a monobasic acid to 1 of quinine, or 1 mol. prop. of a dibasic acid to 2 of quinine, &c. Nearly all the quinine salts crystallise, and are readily soluble in water or alcohol. The hydrochloride $B{\cdot}HCl,2H_2O$, prepared by neutralising the alkaloid with dilute hydrochloric acid, crystallises in long, silky needles, soluble in water, alcohol, or chloroform. Its solutions are lævorotatory. The dihydrochloride $B{\cdot}2HCl$ is produced when dry hydrochloric acid gas combines with quinine, or when the disulphate is decomposed in solution by barium chloride. On evaporation of its solution it is obtained in hard needles. The normal sulphate or diquinine sulphate $B_2{\cdot}H_2SO_4,8H_2O$, sometimes called 'bisulphate,' is the ordinary commercial sulphate of quinine. It is prepared by exactly neutralising warm dilute sulphuric acid with the alkaloid. When the crystals are exposed to air they effloresce and gradually lose $6H_2O$. The salt as usually met with contains about $7\frac{1}{2}H_2O$. Quinine sulphate is slightly soluble in water (1 in 740 at 15°), and differs in this respect from the normal sulphates of the other principal cinchona alkaloids, all of which are more soluble. In boiling water quinine sulphate is far more soluble (1 in 30), and may readily be obtained in crystals by cooling the solution. The aqueous solution is very bitter and slightly fluorescent. Alcohol dissolves the sulphate much more easily than water (1 in 65 at 15°; 1 in 6 at b.p.). The salt is slightly soluble in chloroform (1 in 1000) and almost insoluble in ether. Dilute acids dissolve large quantities of quinine sulphate; sulphuric acid converts it into the very soluble acid sulphate $B_2(H_2SO_4)_2$ or $B{\cdot}H_2SO_4$.

Quinine sulphate, like the alkaloid, is lævorotatory. In alcohol at 15°, $[\alpha]_D = -166{\cdot}36°$; for the anhydrous sulphate in water $[\alpha]_D = -233{\cdot}75°$ (Hesse).

The salt of commerce is liable to be impure from the presence of the sulphates of other cinchona alkaloids. It may be purified by recrystallisation from water several times, or, better, by dissolving 1 part of the commercial salt in about 30 parts of hot water rendered just acid with sulphuric acid. The crystals which separate on cooling are washed with cold water and dried in the air (Hesse, Annalen, 1880, 205, 218). For methods of estimating the amount of pure salt in the commercial sulphate, *see* ***Estimation of quinine*** (p. 669).

The acid sulphate or monoquinine sulphate $B{\cdot}H_2SO_4,7H_2O$ is produced when the normal sulphate is dissolved in dilute sulphuric acid (Hesse, *ibid.* 1873, 166, 221; 1875, 176, 214). The rhombic crystals effloresce in air and lose their water at 100°. The salt is very soluble in water (1 in 11 at 13°; 1 in 8 at 22°); less soluble in alcohol. The aqueous solution is extremely bitter and exhibits an intense blue fluorescence, which is perceptible in very dilute solutions. The acid sulphates of cinchonidine and cinchonine do not produce this effect, but it is observed with the acid sulphate of quinidine. By dissolving the acid sulphate in sulphuric acid the "tetrasulphate" containing an additional proportion of sulphuric acid $B{\cdot}2H_2SO_4,7H_2O$ may be obtained (Hesse, Annalen, 1873, 166, 222).

In consequence of its marked antipyretic and tonic action quinine is a valuable therapeutic agent. A large proportion of the quinine taken internally is excreted unchanged in the urine.

Reactions. The most striking qualitative reaction of quinine is that known as the thalleioquin (*thallos*, a young twig), colour reaction. It is observed when weak chlorine-water or bromine-water is gradually added to an acidified solution of quinine sulphate, until a permanent, faint yellow coloration is perceptible; excess of the halogen must be avoided. Ammonia solution is at once added to this liquid, drop by drop, when a dark-green coloration or precipitate makes its appearance. If the green liquid is acidified its colour changes to red. This reaction, which may be obtained with dilute solutions, is also given by some other alkaloids of this group, notably by quinidine, but cinchonine and cinchonidine do not exhibit it. Ammonia precipitates the alkaloid from solutions of its salts, the precipitate being soluble in excess; quinidine and cinchonidine are less soluble in solution of ammonia; cinchonine almost insoluble. Potash and soda also precipitate salts of quinine, but the alkaloid is only slightly dissolved by excess of these alkalis. The precipitated quinine is readily soluble in ether, quinidine is less soluble, cinchonidine still less soluble, whilst cinchonine is nearly insoluble.

When an alcoholic solution of quinine sulphate, acidified with dilute sulphuric acid, is mixed with an alcoholic solution of iodine, a reddish precipitate is thrown down, which dissolves when the liquid is heated, and on cooling separates in iridescent crystals, which are green by reflected light, and red by transmitted light. This substance is an iodosulphate of quinine or periodide of quinine sulphate $[B_4(H_2SO_4)_3(HI)_2I_4,6H_2O]$, and has been called 'herepathite,' after its discoverer Herepath. Similar compounds may be formed from the sulphates of other cinchona alkaloids; and, since they are more soluble than the quinine compound, De Vrij has proposed a method of estimating quinine in which the herepathite is collected and weighed, when it will represent 55·055 p.c. of its weight of quinine (J. Pharm. Chim. 1875–1876, [iii.] 6, 461).

Moderately concentrated solutions of quinine salts are precipitated by ammonium oxalate, the crystalline quinine oxalate $(B_2{\cdot}H_2C_2O_4,6H_2O)$ being sparingly soluble.

Sodium tartrate, or Rochelle salt (potassium sodium tartrate), in aqueous solution precipitates moderately concentrated solutions of quinine salts. The quinine tartrate $B_2{\cdot}H_2C_4H_4O_6,H_2O$ is much less soluble than the quinidine and cinchonine tartrates, but is rather more soluble than cinchonidine tartrate. These facts are utilised in the separation and estimation of quinine and cinchonidine.

Quinine is remarkable in forming a large number of compounds, many of which are crystalline, with different organic bodies, hydrocarbons of the benzene series, phenols, aldehydes, carbamides, &c.

Detection. Quinine may be detected by means of the properties and reactions described above; the fluorescence of solutions of the acid sulphate, the solubility of the alkaloid in ether, and the thalleioquin reaction being especially useful.

Assay of cinchona bark. For the assay of cinchona bark a large number of processes have been devised. For bark used for the manufacture of galenical preparations the determination of the total alkaloids is generally sufficient, but in the British Pharmacopœia a certain proportion of quinine and cinchonidine taken together is specified, and in that of the United States a certain proportion of ether-soluble alkaloids (quinine, cinchonidine, and quinidine) is prescribed.

The British Pharmacopœia, 1898, gives the following method: 20 grms. of the bark (*C. succirubra*) in No. 60 powder are mixed with 6 grms. of slaked lime and the whole moistened with 20 c.c. of water and allowed to stand for 2 hours. This is transferred to a flask provided with a reflux condenser and boiled with 130 c.c. of benzolated amylic alcohol (benzene 3 vols., amyl alcohol 1 vol.) during 30 mins. The liquid is filtered off and the treatment repeated twice, the mixture of bark and lime being finally transferred to the filter and washed with the solvent until exhausted. The total filtrate, still warm, is placed in a separator and shaken with 2 c.c. of dilute hydrochloric acid (sp.gr. 1·052), diluted with 12 c.c. of water, the acid liquor withdrawn, and the extraction continued with water acidified with hydrochloric acid until all the alkaloids have been extracted. The total acid liquid is then just neutralised with ammonia and evaporated to 16 c.c. To this 1·5 grm. of sodium potassium tartrate, dissolved in 3·0 grms. of water, are added and the mixture stirred well and set aside for 1 hour. The precipitated quinine and cinchonidine tartrates are then collected on a tared filter, washed, dried, and weighed. The precipitate contains $\frac{8}{10}$ of its weight of alkaloids, and this multiplied by 5 gives the percentage of quinine and cinchonidine in the bark. To the mother liquor and washings ammonia solution is added in slight excess and the precipitate collected, washed, dried, and weighed. This weight multiplied by 5 gives the percentage of 'other alkaloids' in the bark, and the sum of the two gives the percentage of total alkaloids. The bark should contain 5–6 p.c. of total alkaloids, of which at least half should be quinine and cinchonidine.

The U.S. Pharmacopœia (8th revision) process is as follows: 15 grms. of bark (*C. Ledgeriana*, *C. Calisaya* or *C. officinalis* or hybrids of these) in No. 80 powder is shaken with 250 c.c. of ether (sp.gr. 0·720 at 25°) and 50 c.c. of chloroform and set aside for 10 mins. in a stoppered flask or bottle. 10 c.c. of ammonia solution (sp.gr. 0·958 at 25°) are then added and the mixture shaken frequently during 5 hours. 15 c.c. of water are then added and the mixture shaken to cause the powder to settle easily. 200 c.c. of the clear supernatant liquid (10 grms. of bark) are then decanted into a separator, 15 c.c. of N-sulphuric acid added, and the whole shaken vigorously. The aqueous layer is withdrawn, and the extraction continued with (*a*) 5 c.c. of N-acid and 5 c.c. of water, and (*b*) 5 c.c. of water. The combined acid liquors are filtered into a measuring cylinder and the filter paper washed with enough water to make the contents of the cylinder measure 50 c.c. Of this 25 c.c. are placed in a separator and 25 c.c. of a mixture of chloroform (3 vols.) and ether (1 vol.), followed by 5 c.c. of ammonia solution added and the whole shaken. The chloroform-ether solution (lower layer) is withdrawn and the extraction continued with (*a*) 20 c.c. of the chloroform-ether mixture, and (*b*) 10 c.c. of chloroform. The mixed chloroform-ether extracts are run into a tared flask, the solvent distilled off, the residue re-dissolved in 3 c.c. of ether, the solvent evaporated and the residue dried at 110° and weighed. The weight multiplied by 20 gives the percentage of total alkaloids, which should not be less than 5 p.c.

The second 25 c.c. of solution is mixed in a separator with 25 c.c. of ether and 5 c.c. of ammonia solution. The whole is cooled below 20° if necessary, and shaken moderately during 2 mins., and then set aside during 10 mins. at 15°. The lower aqueous layer is rejected and the ethereal solution transferred to a tared beaker. The separator is rinsed out with 5 c.c. of ether and this added to the beaker. The solvent is evaporated and the residue dried at 110° and weighed. This weight multiplied by 20 gives the percentage of ether-soluble alkaloids (quinine, quinidine, and cinchonidine), which should be at least 4 p.c.

The German Pharmacopœia (1910 ed.) prescribes a method on the same lines as that of the United States, but the total alkaloids only are determined, and this is done by titration, using hæmatoxylin as indicator.

Estimation of quinine in cinchona bark. Most of the cinchona bark which comes into commerce is used for the manufacture of quinine sulphate, and consequently the estimation of quinine in such bark is of the first importance. The methods used are very varied, and recently an association of cinchona planters in Java has offered a prize for a method, which will give accurate results, and can be recommended for general adoption.

The chief methods which have been proposed for the separation and estimation of quinine in the total alkaloids, depend upon the smaller solubility of the quinine sulphate in water, and since the usual object is to ascertain the yield of quinine sulphate obtainable from the bark, it is probable that such methods are best for this purpose.

A quantity (1–5 grms.) of the total alkaloid (isolated as described above) is weighed in a beaker, a small quantity of warm water is added, and the mixture titrated with decinormal sulphuric acid until it is just acid to litmus. The solution is heated for about 15 mins. on the water-bath, and at the end of this time should still be feebly acid. The warm liquid is now titrated to exact neutrality with decinormal soda solution. The number of c.c. of soda solution required deducted from the number of c.c. of acid used, gives the number of c.c. of acid neutralised by the total alkaloid, and this number multiplied by 0·03 ought to give a close approximation to the amount in grams of total alkaloid originally taken.

The amount of total alkaloid having been thus verified by titration, the neutralised liquid is diluted with water until its weight is 70 times that of the total alkaloid, and then heated to about 90° for 5 mins. It is now cooled to 15°, and kept at this temperature for half an hour. If crystals have not separated there is not more than 8 p.c. of quinine in the total alkaloid. As a rule, crystals will be deposited, and these must be collected on a small weighed filter and washed with sufficient cold water (15°) to make the total weight of filtrate equal to 90 times that of the total alkaloid present. The crystals are dried at 100° and weighed as anhydrous quinine sulphate. To this weight must be added 0·12 p.c. of the weight of the filtrate and washings, in order to compensate for the loss of the sulphate through its solubility in water at 15°.

Estimation of quinine and impurities in commercial quinine sulphate. Commercial quinine sulphate is rarely, if ever, quite pure. That intended for medicinal use should not afford any appreciable reaction for cinchonine, quinidine, cupreine, or amorphous alkaloid, and should not yield more than 3 p.c. of crystals of cinchonidine (B. P. 1898). The principal impurities are cinchonidine and hydroquinine sulphates, but there may also be present quinidine and cinchonine sulphates, whilst if the alkaloid has been derived from cuprea bark, sulphate of cupreine may be found.

The various methods of examining commercial quinine sulphate for the sulphates of other cinchona alkaloids depend either on the greater solubility of the quinine in a definite volume of aqueous ammonia (Kerner's test), or in a definite volume of ether (the so-called 'Liebig's test'), or on a combination of these two facts (Hesse's test).

The German Pharmacopœia (1910) gives the following directions for the application of Kerner's test. Two grms. of the quinine sulphate dried completely at 40°–50°, are mixed with 20 c.c. of water, and the mixture kept with occasional agitation for 30 mins. at 60°–65°; the mixture is then kept at 15° during 2 hours, poured through linen, and finally filtered through filter paper; 5 c.c. of the clear solution are placed in a test-tube, and 4 c.c. of aqueous ammonia (rel. dens. 0·959) added. The precipitate formed should dissolve completely on shaking.

The French Codex (1909) directs that 1 grm. of the hydrated salt should be dissolved by boiling with 30 c.c. of water, after which the liquid must be cooled to 15°, and kept at this temperature with agitation for 30 mins. 5 c.c. is specified as the quantity of ammonia solution required to re-dissolve the precipitate. The U.S. Pharmacopœia method (8th revision) is essentially the same as that of the German Pharmacopœia, but 7 c.c. of ammonia solution is added all at once, and under these conditions the sulphate is required to give a clear solution. Tutin (Pharm. J. 1909, [iv.] 29, 600) has critically examined these methods, and recommends a modified form of the French Codex method, which, however, is only applicable to quinine sulphate: he suggests 6 c.c. of ammonia solution as ensuring a reasonable degree of purity in the salt.

A modification of this method is adopted in the British Pharmacopœia (1898) for the detection of cinchonidine and cinchonine. 4 grms. of the quinine sulphate are dissolved in 120 c.c. of boiling water; the solution is cooled slowly to 50° with frequent stirring, and filtered from the quinine sulphate, which has crystallised. The filtrate is concentrated by evaporation to 10 c.c. or less and placed in a stoppered flask, and when cold 10 c.c. of ether (better, purified ether, Tutin, *l.c.*), and 5 c.c. of ammonia (sp.gr. 0·959) are added. The flask is set aside in a cool place for 24 hours and the separated crystals of cinchonidine with cinchonine and a little quinine are collected, washed with a little ether, dried and weighed. They should not amount to more than 0·12 grm. According to Tutin (*l.c.*) 3 p.c. of cinchonidine may be detected by this method if purified ether is used. Quinidine, if present, would not be separated in the foregoing test, and therefore the British Pharmacopœia includes the following method, which is based on the fact that quinidine sulphate is more soluble in water than quinine sulphate, and that of the two hydriodides the quinidine hydriodide is less soluble in water. 1 grm. of the quinine sulphate is dissolved in 30 c.c. of boiling water and the solution cooled and filtered. To the filtrate, a solution of potassium iodide (20 grms. in 200 c.c.) is added and a little alcohol to prevent precipitation of amorphous hydriodides. The precipitated quinidine hydriodide is collected, washed with a little water, dried, and weighed. Its weight is approximately equivalent to that of the crystallised quinidine sulphate. None or only traces should be found.

The *cupreine sulphate* (*see Cupreine*) may be found and estimated by taking advantage of the slight solubility of cupreine in ether. The cupreine sulphate, being but sparingly soluble in cold water, will be mixed with the recrystallised quinine sulphate which was removed in testing for cinchonidine and cinchonine (*v. supra*). The quinine and cupreine sulphates are mixed with 25 c.c. of ether and 6 c.c. of aqueous ammonia (10 p.c.). After shaking the mixture the ethereal solution is removed and added to the ethereal liquid obtained in the test for cinchonidine and cinchonine, out of which these alkaloids had crystallised. The ethereal solutions are now agitated with about 6 c.c. of aqueous soda (10 p.c.), which dissolves the cupreine. The ether is removed, the alkaline solution washed with more ether, and finally heated to 100°. The hot liquid is exactly neutralised with dilute sulphuric acid, and when the solution is cold the cupreine sulphate which has crystallised out is collected, dried, and weighed. None or only traces should be obtained.

For cinchonine and amorphous alkaloids the B. P. 1898, prescribes the following test: 1 grm. of the quinine sulphate is dissolved in 30 c.c. of boiling water and 1 grm. of sodium potassium tartrate added. The mixture is cooled with frequent stirring and filtered. The filtrate after evaporation to a small bulk should give little or no precipitate with solution of ammonia.

For the estimation of hydroquinine Howard (Pharm. J. 1896, [iv.] 3, 505) recommends dissolving the ether-soluble alkaloids obtained in the B. P. test for cinchonidine and cinchonine (*v. supra*) in dilute sulphuric acid, adding to this solution 4 p.c. permanganate solution so long as the latter is rapidly decolorised. The manganese dioxide is filtered off, the filtrate made alkaline with ammonia solution and shaken out with ether. The residue left on evaporating the ether is dissolved in dilute sulphuric acid, then just neutralised with ammonia and the crystals, which separate, dried and weighed.

For a comparison of the various methods of examining commercial quinine sulphate, *see* Lenz, Zeitsch. anal. Chem. 1888, 27, 549.

Quinidine or **Conquinine** $C_{20}H_{24}O_2N_2$. This isomeride of quinine is contained in small quantity in most of the ordinary cinchona barks, especially in *C. pitayensis* (Wedd.) and *Cinchona Calisaya*, which sometimes contain as much as 3 p.c. (Hesse, Annalen, 1874, 174, 338). It is most conveniently procured from the amorphous mixture of cinchona alkaloids commercially known as 'quinoidine.' The powdered 'quinoidine' is extracted with ether, and the ethereal solution shaken with dilute sulphuric acid. The neutralised aqueous liquid is precipitated with a strong solution of Rochelle salt, and the concentrated filtrate, decolorised if necessary with charcoal, precipitated with a strong solution of potassium iodide. The impure quinidine hydriodide is washed and dissolved, and the alkaloid precipitated from the solution with ammonia. The precipitated alkaloid is now dissolved in dilute acetic acid, and, if necessary, again decolorised with charcoal. The alkaloid is then reprecipitated with ammonia and crystallised from boiling alcohol (Hesse, Annalen, 1868, 146, 357; 1873, 166, 232).

Properties. Large prismatic crystals containing $2\frac{1}{2}H_2O$, which lose $\frac{1}{2}H_2O$ on exposure to air, or on recrystallising from ether, and $1H_2O$ on crystallising from boiling water (Hesse, Ber. 1877, 10, 2154).

The anhydrous alkaloid melts at 171·5° (corr.) (Lenz, Zeitsch. anal. Chem. 1888, 27, 571). Dextrorotatory $[\alpha]_D = +274{\cdot}7°$ in alcohol, 1 vol. and chloroform 2 vols. (Lenz), +243·5° (Rabe). Very slightly soluble in water (1 in 2000 at 15°; 1 in 750 at 100°), more soluble in alcohol (1 in 26 at 20°), and in ether (1 in 22 at 20°); also dissolved by amyl alcohol, benzene, or chloroform, but not appreciably by light petroleum. Dilute acids dissolve the alkaloid abundantly and, like quinine, the solutions, if acid with sulphuric acid or other oxygenated acid, exhibit a blue fluorescence. Like quinine, quinidine is a diacidic base, but only its normal salts are usually met with. The normal sulphate $B_2{\cdot}H_2SO_4,2H_2O$ is more soluble in cold water than the quinine salt (1 in 100 at 15°), and also in chloroform (1 in 20 at 15°). The acid sulphate $B{\cdot}H_2SO_4$ is very soluble in water, and its solution is highly fluorescent. The hydriodide $B{\cdot}HI$ is an important salt, since it is much less soluble in water (1 in 1250 at 15°) than the hydriodides of the other cinchona alkaloids, and is therefore employed in isolating and in estimating quinidine. It is precipitated at once, or from dilute solutions after standing and stirring, as a crystalline powder when potassium iodide is added to a neutral or slightly acid solution of a quinidine salt. In presence of much acid the soluble dihydriodide $B{\cdot}(HI)_2$ is produced.

Quinidine and its salts have a very bitter taste, and exert a physiological and therapeutic action very like that of quinine.

Reactions. The chief reactions of quinidine resemble those of quinine. It affords the thalleioquin colour reaction (p. 667); its derivatives and decomposition products are identical with those of quinine, of which it is a stereoisomeride, the carbon atom concerned being that numbered 3 in the general formula (p. 673) (Rabe, Annalen, 1910, 373, 85).

Detection and estimation. Quinidine may be detected by the fluorescence of acid solutions of its salts, by its affording the thalleioquin reaction, by solutions of its salts not being precipitated by solution of Rochelle salt (distinction from quinine and cinchonidine), and by the formation of the insoluble hydriodide, &c., and by other properties described above. For the estimation of the alkaloid in cinchona bark advantage may be taken of the solubility of the normal sulphate in chloroform or cold water, the solubility of quinidine tartrate, and the formation of the hydriodide, which is collected and weighed. The quinine and cinchonidine, having been removed from the total alkaloids as tartrates (*see Estimation of quinine*, pp. 668–9), the filtrate, somewhat concentrated, is precipitated with a saturated solution of potassium iodide. After standing for an hour the quinidine hydriodide is collected, washed with a little cold water, dried, and weighed.

For the estimation of quinidine in commercial sulphate of quinine, *see* under *Estimation of Quinine* (p. 669).

Cinchonine $C_{19}H_{22}ON_2$ is an alkaloid commonly occurring in cinchona bark to the extent of about 0·2–2 p.c. It may be readily prepared from the mother liquor remaining from the preparation of quinine (p. 666). This solution, which contains cinchonine sulphate, is precipitated with soda, and the precipitate crystallised from its solution in alcohol. The alkaloid thus obtained is purified by converting it into the normal sulphate, which is repeatedly crystallised from water (Hesse, Annalen, 1862, 122, 226); or the precipitate produced by the soda may be dried and digested with cold ether in which cinchonine is very slightly soluble. The residue is crystallised from alcohol.

Properties. Anhydrous, monoclinic prisms (from alcohol), or amorphous when precipitated, m.p. 264° (*cf.* Lenz, Zeitsch. anal. Chem. 1888, 27, 572; Hesse, Annalen, 1880, 205, 211). At a higher temperature it sublimes with some decomposition. Almost insoluble in water (1 in 3670 at 20°), slightly soluble in ether (rel. dens. 0·730, 1 in 371 at 10°) or benzene, more soluble in alcohol (rel. dens. 0·852, 1 in 126 at 20°), or chloroform (1 in 356 at 17°), but most readily in a mixture of chloroform and alcohol which dissolves more than either liquid alone. Soluble in amyl alcohol, nearly insoluble in aqueous ammonia, in light petroleum, or absolute alcohol. Readily soluble in dilute acids, but the solutions are not fluorescent. Dextrorotatory, $[\alpha]_D^{17°} = +223{\cdot}3°$ (Oudemans, Annalen, 1876, 182, 44; *cf.* Rabe, *ibid.* 1910, 373, 85).

Cinchonine is a diacidic base, and the ordinary salts correspond in composition with those of quinine. The normal sulphate $B_2{\cdot}H_2SO_4,2H_2O$ is soluble in water (1 in 70 at 15°; 1 in 14 at 100°); soluble also in alcohol (1 in 6 at 15°) or chloroform (1 in [illegible]0 at 15°). The acid sulphate $B{\cdot}H_2SO_4,4H_2O$ is soluble in water, but, unlike the correspond-quinine and quinidine salts, its aqueous solutions are not fluorescent, although commercial specimens of the sulphate, when dissolved in dilute sulphuric acid, are usually slightly fluorescent owing to the presence of quinine or quinidine. The salts of cinchonine are very bitter, and appear to exert the same physiological and therapeutic action as quinine, although much less powerfully.

Like quinine, cinchonine combines with phenols and certain other organic compounds.

Reactions. The reactions of cinchonine are similar to those of quinine. It does not, however, afford the thalleioquin colour reaction (p. 670).

In its combinations with methyl iodide, cinchonine, like quinine, acts as a tertiary diamine.

A large number of isomerides of cinchonine, produced by the action of sulphuric acid or other agents on the alkaloid, are known.

Detection and estimation. Cinchonine is readily distinguished from quinine and quinidine by not giving the thalleioquin reaction, as well as by other properties described above. From cinchonidine, which it resembles in not giving the colour reaction, it may be distinguished by its dextrorotation, its slight solubility in aqueous ammonia or ether, and also by the solubility of its normal sulphate in chloroform. The amount of cinchonine contained in the total alkaloids of cinchona bark may be estimated in the filtrate and washings from which the quinidine has been separated as hydriodide (*see* p. 670), by precipitating it with soda, and digesting the dried precipitate with a small quantity of ether in order to dissolve the amorphous alkaloid. The residue is dried and weighed as cinchonine.

For the detection and estimation of cinchonine n commercial sulphate of quinine, *see* under *Estimation of Quinine* (pp. 668–9).

Cinchonidine $C_{19}H_{22}ON_2$, an isomeride of cinchonine, found in most varieties of cinchona bark to the extent of from 0·5 to 5 p.c. Cinchonidine sulphate has been used in medicine as a substitute for quinine.

Preparation. The total alkaloids having been extracted from the cinchona bark (*see* under *Quinine*, p. 666), and the crystallised quinine sulphate separated, the aqueous solution (containing cinchonidine, cinchonine, and quinidine sulphates) is precipitated with ammonia in slight excess, and the precipitate repeatedly extracted with cold ether. The ethereal solution (containing cinchonidine and quinidine) is shaken with dilute hydrochloric acid, when the alkaloidal hydrochlorides pass into the aqueous liquid, which is neutralised, and the cinchonidine precipitated as tartrate by the addition of solution of Rochelle salt. The precipitate is dissolved in hydrochloric acid and precipitated with ammonia in slight excess. The alkaloid thus obtained is crystallised from its solution in boiling alcohol, then converted into the normal sulphate, which is crystallised from water. The crystallised salt is dissolved in 25 parts of boiling water, and the solution cooled to 35°, when any crystals which may have separated are removed and twice recrystallised. By precipitating a solution of this salt with ammonia and crystallising the precipitate from alcohol, pure cinchonidine is obtained (Hesse, Annalen, 1865, 135, 333; 1880, 205, 196).

The commercial sulphate of cinchonidine may be purified by this process. It generally contains small quantities of the sulphates of other cinchona alkaloids, especially quinine and homocinchonidine, an isomeride of cinchonidine which occurs with it in cinchona barks (Hesse, *ibid.* 1880, 205, 203).

Properties. Anhydrous prismatic crystals, which melt at 207·2° (corr.) (Lenz, Zeitsch. anal. Chem. 1888, 27, 564), 200°–201° (Hesse, Ber. 1881, 14, 1888). Slightly soluble in cold water. Soluble in alcohol (1 in 16·3 at 13°), or ether (1 in 188 at 15°). Readily soluble in chloroform or amyl alcohol. Slightly soluble in aqueous ammonia. Very soluble in dilute acids. Lævorotatory, $[\alpha]_D = -107{\cdot}48°$ in alcohol (Hesse, Annalen, 1875, 176, 219; 1876, 181, 137; *cf.* Skraup, *ibid.* 1879, 199, 365).

Cinchonidine is a diacidic base, but is monacidic in the salts usually met with. The normal sulphate $B_2{\cdot}H_2SO_4,6H_2O$ is used in medicine. It is readily soluble in hot water, but only sparingly in cold (1 in 97·5 at 12°; 1 in 67 at 22°). The acid sulphate $B{\cdot}H_2SO_4,5H_2O$ is very soluble in water. Its solutions are not fluorescent.

Cinchonidine and its salts are very bitter. Their therapeutic action is similar to, but weaker than, that of quinine. The administration of large doses of cinchonine or cinchonidine, but especially the latter, is said to be attended with danger.

Reactions. The principal reactions of cinchonidine resemble those of its stereoisomeride cinchonine. By the action of phosphorus pentachloride the chloro derivative $C_{19}H_{21}N_2Cl$, isomeric with the corresponding cinchonine derivative, is obtained. Although this 'chloride' is isomeric, and not identical with that of cinchonine, it furnishes the same cinchenine (p. 672) when acted on by potash.

The products of the oxidation of cinchonidine by nitric acid and chromic acid are the same as those afforded by cinchonine.

Detection and estimation. Cinchonidine is readily distinguished from quinine and quinidine by not affording the thalleioquin reaction, and in its acid salts not being fluorescent. It differs from cinchonine in its greater solubility in ether, as well as by the slight solubility of its tartrate, &c. It may be identified by the properties described above. Cinchonidine may be estimated in the total alkaloids from cinchona bark by precipitating the liquid from which the quinine has been removed by crystallisation as sulphate, with a strong solution of Rochelle salt, when the cinchonidine tartrate is precipitated. After standing some time the precipitate is collected, dried, and the anhydrous tartrate weighed. Another method consists in determining the amount of quinine in a portion of the total alkaloids, by crystallisation as sulphate, and in a second portion of the total alkaloids, precipitating the quinine and the cinchonidine as tartrates (*see Estimation of quinine*, pp. 668 9). The amount of quinine sulphate already found is then calculated into tartrate, and this quantity is deducted from the weight of the mixed tartrates; the remainder is the amount of cinchonidine tartrate.

It has also been proposed to separate quinine and cinchonidine (liberated from the tartrates) by dissolving out the quinine with ether, but the method does not afford accurate results, since the solubility of cinchonidine in ether is increased by the presence of quinine, owing apparently to the formation of a compound of the two alkaloids.

For other information respecting the estimation of cinchonidine in commercial sulphate of quinine, *see* under *Estimation of Quinine.*

Constitution of quinine, quinidine, cinchonine, and cinchonidine. Comparison of the linear formulæ of these four alkaloids shows that they form two pairs of isomerides, of which the second two differ from the first two by containing $-OCH_2$ less, indicating that quinine and quinidine are methoxyl derivatives of cinchonine, cinchonidine, or one of their isomerides. The single oxygen atom in cinchonine and cinchonidine is present as hydroxyl, whilst quinine and quinidine contain their two oxygen atoms in the form of hydroxyl- and methoxyl- in both cases. Since the four alkaloids have a common nucleus it is convenient to discuss their constitutions together. A great deal of work has been expended on the chemistry of these alkaloids by Skraup, Koenigs, von Miller, and Rabe. The most fruitful lines of work have been (1) investigation of the products of hydrolysis of their 'chlorides,' and (2) a study of the oxidation products of the alkaloids.

Hydrolysis of the Chlorides. When quinine or cinchonine is treated in chloroform solution with phosphorus pentachloride, the hydroxyl group in each case is replaced by a chlorine atom with the formation of quinine chloride $C_{20}H_{23}ON_2Cl$ and cinchonine chloride $C_{19}H_{21}N_2Cl$ respectively. These chlorides, on treatment with alcoholic potash, each lose 1 mol. of hydrogen chloride forming quinenine

$$C_{20}H_{22}ON_2$$

and cinchenine $C_{19}H_{20}N_2$ respectively, and these two products are hydrolysed by phosphoric acid in the following manner:—

Quinenine gives *p*-methoxylepidine and meroquinenine.

Cinchenine gives lepidine and meroquinenine.

Oxidation by Permanganate. Quinine yields quininic acid, cincholoiponic acid, and loiponic acid.

Cinchonine yields cinchoninic acid, cincholoiponic acid, and loiponic acid.

Loiponic acid is a product of the oxidation of cincholoiponic acid, and may therefore be neglected for the present purpose.

Quininic acid $C_{11}H_9O_3N$ is 6-methoxy-4-carboxyquinoline.

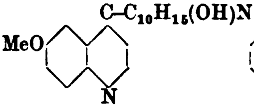
Cinchoninic acid $C_{10}H_7O_2N$ is 4-carboxyquinoline.

Methoxylepidine $C_{11}H_{11}ON$ is 6-methoxy-4-methylquinoline.

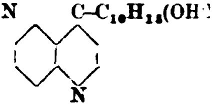
Lepidine $C_{10}H_9N$ is 4-methylquinoline.

The occurrence of these four substances in the oxidation and hydrolytic products clearly establishes the existence in quinine of a methoxymethylquinoline nucleus and in cinchonine of a methylquinoline nucleus.

The remaining portion of the molecule mu be identical both in quinine and cinchonin since it furnishes the same products on oxidat (cinchloiponic and loiponic acids) and on hydr lysis (meroquinenine). This residual portion the molecule has been the subject of mar investigations. It is conveniently spoken of the 'second half,' and is represented by th linear portion of the following formulæ—

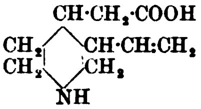


Quinine.

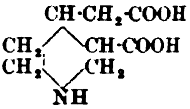


Cinchonine.

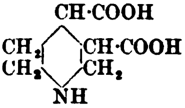
Meroquinenine $C_9H_{15}O_2N$, produced by th hydrolysis both of quinenine and cinchenine, also formed as an intermediate product in th oxidation of quinine and cinchonine. further oxidation it yields *cincholoiponic ac* $C_8H_{13}O_4N$, which also occurs in the oxidati products of the two parent alkaloids, and th in turn on oxidation yields *loiponic acid* $C_7H_{10}O_4$ which is hexahydropyridine-3 : 4-dicarboxyl acid. These three products are, therefor probably related as follows—



Meroquinenine.



Cincholoiponic acid.



Loiponic acid.

The nature of these oxidation products the 'second half,' shows that the latter mus include a heterocyclic ring containing nitrogen This second heterocyclic ring cannot, howeve consist of a reduced pyridine ring with si chains, since quinine and cinchonine are bo ditertiary bases. Further, when cinchenin (*see* above) is heated with hydrobromic acid 180° it loses a molecule of ammonia and form apocinchenine in which the quinoline nucleu still intact, although the 'second half' has bee converted into a benzenoid derivative. Apoc chenine is, in fact, a quinolyldiethylphe

$$C_9H_6N : C_6H_2Et_2OH[Et : Et : OH=4 : 5 : 6$$

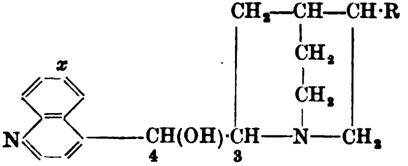
These and other reactions recall those of trop which has a dicylic nucleus with a nitroge atom, common to the two rings and all recent formulæ assigned to cinchonine quinine have represented the 'second half' the molecule by such a structure (*see* von Mil and Rohde, Ber. 1894, 27, 1187, 1279; 189 1056; 1900, 33, 3214; Königs, J. pr. Che 1900, [ii.] 61, 1; Annalen, 1906, 347, 143; Rab *ibid.* 1906, 350, 180; Ber. 1908, 41, 62; 1909, 364, 330; 1909, 365, 353, 366; 1910, 85). In determining the exact form of 'second half' the most important final fac have been as follows:—

1. When cinchonine is heated with ac acid it is converted into *cinchotoxine* (cinc cine), which is isomeric with cinchonine, behaves as a secondary base and con

carbonyl group. Cinchotoxine no longer possesses the characteristic physiological action of cinchonine, but is highly toxic. Quinine under similar conditions yields *quinotoxine*.

2. On careful oxidation with chromic acid in presence of acetic or sulphuric acid, cinchonine $C_{19}H_{22}ON_2$ furnishes a new base *cinchoninone* $C_{19}H_{20}ON_2$, which contains a carbonyl group, and on treatment with nitrous acid yields *cinchoninic* acid (p. 672), and an oxime which on hydrolysis yields *meroquinenine* (p. 672) and hydroxylamine. Cinchonidine also yields cinchoninone, whilst quinine and quinidine yield the same quininone (methoxycinchoninone) (Rabe, Ber. 1907, 40, 3655; 1908, 41, 62; Annalen, 1909, 365, 353; 1910, 373, 85; 1911, 382, 365).

On the basis of all these results Rabe has put forward the following general formula for this group of alkaloids—



The numbered carbon atoms are asymmetric.

In cinchonine, cinchonidine, quinine, and quinidine R=—CH : CH_2.

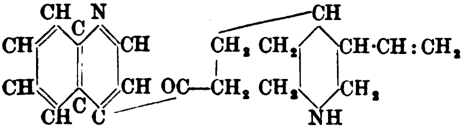
In hydrocinchonine, hydrocinchonidine, hydroquinine and hydroquinidine R=—$CH_2\cdot CH_3$ (*see* p. 674).

In cinchonine, cinchonidine, hydrocinchonine, and hydrocinchonidine *x*=H.

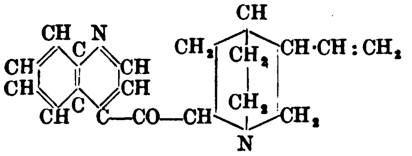
In quinine and quinidine and their hydrobases *x*=OMe.

In cupreine *x*=OH.

The following formulæ represent cinchotoxine and cinchoninone :—



Cinchotoxine (Rabe).



Cinchoninone (Rabe).

Miscellaneous cinchona alkaloids.

Cinchonamine $C_{19}H_{24}ON_2$ is contained in *Remijia Purdieana* (Wedd.). Crystals, m.p. 184°–185°. The salts are crystalline. The nitrate is remarkable in being nearly insoluble in dilute nitric acid (Arnaud, Bull. Soc. chim. 1884, [ii.] 41, 590; Hesse, Annalen, 1884, 225, 218).

Conquinamine $C_{19}H_{24}O_2N_2$. An isomeride of quinamine (p. 674), with which it occurs in several species of cinchona bark, especially in *C. succirubra* (Par.) (Hesse, Annalen, 1881, 209, 62; Oudemans, *ibid.* 1881, 209, 38).

Properties. Crystals, m.p. 121°. Very slightly soluble in water. Soluble in alcohol, chloroform, or ether. Dextrorotatory. The salts are crystalline and soluble in water.

Cupreine $C_{19}H_{22}O_2N_2$ is contained, with quinine, &c., in the bark of *Remijia pedunculata* (Flueck.), a plant closely related to, although distinct from, the cinchonas (Paul and Cownley, Pharm. J. 1884, [iii.] 15, 221, 401; Hesse, Annalen, 1885, 230, 57).

Preparation. The total alkaloids of cuprea bark are dissolved in dilute sulphuric acid, the solution is exactly neutralised, when the sulphates of cupreine and quinine crystallise out. These salts are dissolved in dilute sulphuric acid, and precipitated with excess of soda, which dissolves the cupreine and some of the quinine. On shaking the mixture with ether the quinine is dissolved by it, whilst the alkaline solution contains the cupreine. The aqueous liquid is now neutralised with dilute sulphuric acid when the cupreine sulphate crystallises out. The base is obtained by precipitating a solution of the recrystallised sulphate with ammonia. The precipitated alkaloid is crystallised from its solution in boiling ether and dried. It is then washed with chloroform and finally crystallised from alcohol (Hesse, *l.c.*).

Properties. Prisms with $2H_2O$, which lose their water at 120°, and then melt at 198°. Slightly soluble in ether or chloroform, more soluble in alcohol. Soluble in aqueous soda or potash; less soluble in aqueous ammonia; lævorotatory $[\alpha]_D = -175{\cdot}5°$ in dry alcohol. Ferric chloride produces a dark-green colour, and ammonia, after the addition of chlorine water, produces the green coloration known as the thalleioquin reaction (*see* p. 667).

Cupreine possesses both acid and basic properties. As a base it is diacidic. The neutral salts are crystalline solids; the acid salts are colourless, and their solutions are not fluorescent. Cupreine dissolves in aqueous alkalis and unites with bases to form definite compounds. One of these is of special interest, viz. that produced by the combination of cupreine with quinine, which may be effected by dissolving equimolecular proportions of quinine and cupreine in dilute sulphuric acid, precipitating with ammonia, and crystallising from ether. This compound

$$(C_{19}H_{22}O_2N_2\cdot C_{20}H_{22}O_2N_2,4H_2O)$$

was first obtained from the total alkaloids of cuprea bark, and was thought to be a single alkaloid 'homoquinine.' The substance melts at 177°, is lævorotatory, and dissolves with difficulty in ether, but readily in alcohol. It behaves as a single diacidic base and forms well-crystallised salts; the normal sulphate is fluorescent in acid solution. The compound may be resolved into its constituents by precipitating the sulphate with excess of soda, and extracting with ether, which dissolves some of the quinine. By repeating the process a number of times the two alkaloids may be more or less completely separated (Howard and Hodgkin, Chem. Soc. Trans. 1882, 41, 66; Hesse, Annalen, 1884, 225, 98; 1884, 226, 242; 1885, 230, 72; Paul and Cownley, *l.c.*).

For the methods of detecting cupreine in commercial quinine sulphate, *see Quinine* (p. 669). On methylation cupreine furnishes quinine, which is its methyl ether (for formula, *see* p. 673).

Hydrocinchonidine $C_{19}H_{24}ON_2$, also known as cinchamidine, obtained by Forst and Böhringer as a residue in the oxidation of commercial cinchonidine sulphate by permanganate (Ber. 1881, 14, 1270; 1882, 15, 520; Hesse, *ibid.* 1881, 14, 1683; Annalen, 1882, 214, 1). Hexagonal leaflets from dilute alcohol, m.p. 229°–230°, difficultly soluble in ether, attacked with difficulty by permanganate. For formula, *see* p. 673.

Hydrocinchonine $C_{19}H_{24}ON_2$, also known as 'cinchotine,' ψ-cinchonine, and cinchonifine, occurs in commercial cinchonine sulphate, from which it may be isolated by adding potassium iodide to a solution of the hydrochlorides when hydrocinchonine hydriodide is precipitated, or it may be obtained through the platinichloride, which is more soluble than that of cinchonine. Prisms, anhydrous, m.p. 277·3° (265°–267°, Forst and Böhringer, Ber. 1881, 14, 436; and von Arlt, Monatsh. 1899, 20, 425), $[\alpha]_D = +204{\cdot}5°$ ($+229{\cdot}6°$ Jungfleish and Léger, Compt. rend. 1901, 132, 410, 828) in alcohol. The salts crystallise well. The alkaloid is closely related to cinchonine in constitution (p. 673) (Hesse, Annalen, 1873, 166, 256; 1879, 197, 362; Königs and Horlein, Ber. 1894, 27, 2292; von Miller and Rohde, Ber. 1895, 28, 1063, 1075).

Hydroquinidine $C_{20}H_{26}O_2N_2$ occurs in the mother liquors from which quinidine sulphate has been crystallised and can be separated from quinidine by oxidising the latter with permanganate. Crystals with $2\frac{1}{2}H_2O$, m.p. 167°; readily soluble in alcohol, sparingly in ether. The sulphate $B,H_2SO_4,12H_2O$ fluoresces blue in dilute sulphuric acid and gives the thalleioquin reaction (p. 667). Like hydroquinine, hydroquinidine is not readily oxidised by permanganate (Forst and Böhringer, Ber. 1881, 14, 1954; 1882, 15, 520, 854; Hesse, *ibid.* 1882, 15, 3010; Annalen, 1888, 243, 146).

Hydroquinine $C_{20}H_{26}O_2N_2$ occurs in cinchona bark and is almost invariably present in small quantity in modern commercial quinine sulphate. It can be prepared from this latter source by recrystallising the quinine sulphate from water when the more soluble hydroquinine salt remains in the mother liquors, together with the sulphates of other cinchona alkaloids (p. 669). The mother liquors are then treated with permanganate solution until a permanent red tint is produced. From the filtrate hydroquinine can be recovered by adding alkali and shaking out with ether. It is precipitated by alkalis either in amorphous form or in a crystalline form (with $2H_2O$) depending on the conditions.

Properties. Needles from chloroform, m.p. 172°, lævorotatory, readily soluble in most organic solvents, sparingly in water. Like quinine it forms 3 series of salts; the neutral sulphate B_2,H_2SO_4, 6 or $8H_2O$; and the acid sulphate $B,H_2SO_4,3H_2O$ are crystalline, but the disulphate $B,2H_2SO_4$ is amorphous.

Reactions and constitution. Hydroquinine closely resembles quinine in reactions: it fluoresces blue in dilute sulphuric acid solution, gives the thalleioquin reaction (p. 667), and yields a compound analogous to 'herepathite' (p. 667), and possessing similar properties. It also forms addition products with various organic substances, including cupreine (p. 673). Unlike quinine, it is not readily oxidised by permanganate. Hydroquinine is closely related to quinine, but is isomeric, not identical with the dihydroquinine obtained by the reduction of quinine (Hesse, Ber. 1882, 15, 854; Annalen. 1887, 241, 255, 273, 279; Pum, Monatsh. 1895, 16, 72). For estimation of hydroquinine in commercial quinine sulphate, see p. 669.

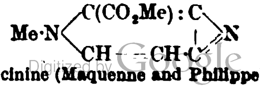
Quinamine $C_{19}H_{24}O_2N_2$. An alkaloid found by Hesse in *C. succirubra* (Pau.) bark, and in small quantity in many other cinchona barks, but notably in *C. Ledgeriana* (Hesse. Annalen, 1873, 166, 266; Ber. 1877, 10, 2157).

Preparation. The total alkaloids are dissolved in dilute sulphuric acid, and the solution neutralised with ammonia. The quinine and cinchonidine are removed by precipitating the liquid with a strong solution of Rochelle salt, and the filtrate is then precipitated with soda. The washed precipitate is extracted with ether, which dissolves the quinamine. The alkaloid thus obtained is purified by re-extracting it with dry ether and crystallising the ethereal residue from alcohol. The alkaloid is finally purified by conversion into the nitrate, which is re-crystallised from water, and the alkaloid regenerated from the pure salt (Hesse, *l.c.*; Oudemans, Annalen, 1879, 197, 50).

Properties. Long silky anhydrous needles; m.p. 172°. Slightly soluble in cold water; very soluble in boiling alcohol, ether, benzene or light petroleum. Dextrorotatory $[\alpha]_D = +93{\cdot}4°$ in chloroform. Quinamine is coloured yellow by warm sulphuric acid, and orange by nitric acid. The salts are crystalline, and soluble in water.

Rheadine $C_{21}H_{21}O_6N$. Colourless needles, m.p. 245°–247° (Pavesi). Occurs in red poppy, also in opium poppy, opium, and *P. hybridum* (Linn.). Not poisonous. On treatment with acids it is converted into *rheagenine*, m.p. 235° (Hesse, *ibid.* 1866, 140, 146; Pavesi, Chem. Soc. Abstr. 1906, 90 ii. 483). *Papaver dubium* (Linn.), according to Pavesi (Chem. Soc. Abstr. 1905, 88, [i.] 368; 1907, 92, [i.] 870), contains *aporeine* $C_{18}H_{16}O_2N$, amorphous; yielding crystalline salts. Aporeine exercises in frogs a tetanising action similar to that of thebaine.

Ricinine $C_8H_8O_2N_2$ occurs in castor seed and in young castor seedlings (*Ricinus communis* [Linn.]) along with the toxalbumin 'ricin.' Crystallises from water or alcohol in rectangular prisms or tablets, m.p. 201°, sublimes without decomposition, and is optically inactive. It is precipitated by mercuric chloride or iodine solution, but not by the other usual alkaloidal reagents (Tuson. Chem. Soc. Trans. 1864, 17, 195; Soave, Chem. Zentr. 1895, i. 853; Evans, J. Amer. Chem. Soc. 1900, 22, 39). On hydrolysis by alkalis it yields 1 mol. each of methyl alcohol and ricininic acid $C_7H_6O_2N_2$ (brilliant slender needles decomposing at 320°); the latter when heated with hydrochloric acid at 150° decomposes forming carbon dioxide, ammonia, and hydroxymethylpyridone hydrochloride, whence Maquenne and Philippe (Compt. rend. 1904, 138, 506; 138, 840) assign the following constitution to ricinine:



Ricinine (Maquenne and Philippe).

Rubijervine. *See Cevadine and the Veratrum alkaloids* (p. 644).

Sabadilline, Sabadine, and **Sabadinine.** *See Cevadine and the Veratrum alkaloids* (p. 644).

Sanguinarine $C_{20}H_{15}O_4N$ occurs in *Sanguinaria canadensis* (Linn.) and other papaveraceous plants (Fischer, Arch. Pharm. 1901, 239, 409, 421; and Schmidt, *ibid.* 395). It is a colourless, optically inactive, crystalline monacidic base, m.p. 212°, forming red crystalline salts (König, Chem. Soc. Abstr. 1891, i. 843). Exerts a narcotic action, but causes tetanus and excitement.

Scopolamine. *See* under *Atropine* (p. 639).

SENECIFOLINE AND THE ALKALOIDS OF SENECIO SPP.

Of the various species of *Senecio* only three have been examined so far, viz. *Senecio latifolius* (Banks and Soland.) of South Africa, *S. Jacobaea* (Linn.) (ragwort), and *S. vulgaris* (Linn.) (groundsel), which are cosmopolitan in distribution. The two first-named plants are poisonous and cause hepatic cirrhosis in cattle and horses in South Africa, Canada, and New Zealand (Bull. Imp. Inst. 1911, 9, 346).

Senecifoline $C_{18}H_{27}O_8N$ was isolated from *S. latifolius* (Banks and Soland.) by Watt (Chem. Soc. Trans. 1909, 95, 466). It crystallises in colourless, rhombic plates, m.p. 194°–195°, $[a]_D +28° 8'$ in alcohol, and is soluble in ether or chloroform, insoluble in water or light petroleum. The salts crystallise well and are lævorotatory. On hydrolysis by heating an aqueous solution of the sulphate with alkali the alkaloid furnishes *senecifolinine* $C_8H_{11}O_2N$ (which is very soluble in water and yields a hydrochloride crystallising in rhombic prisms, m.p. 168°, $[a]_D -12° 36'$) and *senecifolic acid* $C_{10}H_{16}O_6$, m.p. 198°–199°, $[a]_D +28° 22'$, crystallising in six-sided plates.

Senecifolidine $C_{18}H_{25}O_7N$ accompanies senecifoline in *S. latifolius* (Banks and Soland.). It forms rhombic plates, m.p. 212°, $[a]_D -13° 56'$ in alcohol. Salts crystalline.

Senecifoline and senecifolidine are both poisonous; when given in large doses they affect the central nervous system like convulsive poisons, and in smaller doses produce hæmorrhage, which may occur in any organ, but is constant in the liver and is nearly always present in the stomach and bowels. Extracts of *S. vulgaris* produce similar results (Cushny, Proc. Roy. Soc. 1911, B, 84, 188).

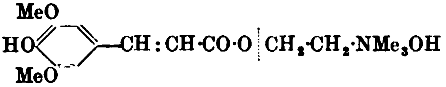
Senecionine $C_{18}H_{25}O_6N$ was isolated by Grandval and Lajoux from *Senecio vulgaris* (Linn.) (the common groundsel). It crystallises in rhombic plates, has $[a]_D -80{\cdot}49°$ in chloroform, furnishes amorphous salts, and is bitter. It is accompanied by *Senecine*, which yields a sparingly soluble acid tartrate (Compt. rend. 1895, 120, 1120). From Cushny's preliminary observations on *Senecio vulgaris* recorded above, the alkaloids of this plant would appear to resemble senecifoline and senecifolidine in physiological action.

Septentrionaline. *See* under *Aconitine* (p. 634).

Sinalbine $C_{30}H_{42}O_{15}N_2S_2$, first isolated by Will and Laubenheimer from white mustard seed (Annalen, 1879, 199, 162). Crystallises with $5H_2O$, m.p. 83°–84°; anhydrous, m.p. 139°. Lævorotatory (Gadamer, Apoth. Zeit. 1896, 11, 752; Arch. Pharm. 1897, 235, 44, 570). Sinalbine is one of a series of closely related glucosides from plants belonging to the *Cruciferæ*, *e.g.* sinigrin (potassium myronate), gluconasturtiin, and glucotropæolin, all of which on hydrolysis by enzymes furnish dextrose, a mustard oil (alkylthiocarbimide) and a third substance. In the case of sinalbine the third substance is the alkaloid *Sinapine* (*see* below), whilst in the three other glucosides mentioned it is potassium hydrogen sulphate. According to Gadamer (*l.c.*) sinalbine is hydrolysed into *p*-hydroxybenzylthiocarbimide, dextrose, and sinapine hydrogen sulphate, and has the following constitution, in which the dotted lines show the residues of the three components.

$$HO{\cdot}C_7H_6N:C(S \,\vdots\, C_6H_{11}O_5) \,\vdots\, O{\cdot}SO_2{\cdot}O{\cdot}NMe_3{\cdot}CH_2 {\cdot}CH_2{\cdot}O{\cdot}CO{\cdot}CH:CH{\cdot}C_6H_2(OH)(OMe)_2.$$

Sinapine $C_{16}H_{25}O_6N$ occurs in white mustard seed from which it may be isolated by extraction with alcohol and precipitation as the thiocyanate, m.p. 176°, which is stable, though the alkaloid itself is so unstable that it cannot be kept in the free state. It is an ester of choline and sinapic acid, and, according to Gadamer, has the following constitution—



Sinapic acid residue. Choline residue.

Sinapine.

The acid sulphate $B{\cdot}H_2SO_4,3H_2O$ forms rectangular leaflets, m.p. 127°. The chief papers relating to this alkaloid are as follows: von Babo and Hirschmann, Annalen, 1852, 84, 10; Will and Laubenheimer, *ibid.* 1879, 199, 162; Remsen and Cole, J. Amer. Chem. 1884, 6, 52; and Gadamer, Arch. Pharm. 1897, 235, 44, 570; Apoth. Zeit. 1896, 11, 752).

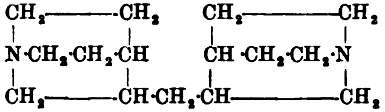
Solanine. This name was first applied by Desfosses (B. J. 1820, 2, 114) to a base isolated from *Solanum nigrum* (Linn.), and subsequently from *Solanum Dulcamara* (Linn.), and, later on, from other *solanaceous* plants, including potato and tomato plants. The composition and the homogeneity of solanine from different sources have not yet been ascertained beyond doubt, but it seems likely, as Firbas has stated (Monatsh. 1889, 10, 541), that at least two substances of this type are present in these various plants, viz. *solanine* and *solaneine*, and these may be accompanied by *solanidine*, a basic decomposition product of solanine. All authorities are agreed that solanine is an alkaloidal glucoside, but there is good reason to believe that the substances from different plants that have been named solanine are not all identical. The principal recent papers relating to solanine and the related substances are Cazeneuve and Breteau, Compt. rend. 1899, 128, 887; Schulz, Zeit. Zuck-Ind. Böhm. 1900, 25, 89; Sage, Pharm. J. 1902, [iv.] 14, 174; Davis, *ibid.* 1902, [iv.] 15, 160; Oddo and collaborators, Gazz. chim. ital. 1905, 35, i. 27; 1906, 36, i. 310; 1911, 41, i. 490; Atti. R. Accad. Lincei. 1906, [v.] 15, ii. 312; 1907, [v.] 16, ii. 683; Wittmann (Monatsh. 1905, 26, 445; Romeo, Gazz. chim. ital. 1905, 35, ii.

579. Oddo deals chiefly with solanine-S $(C_{27}H_{46}O_9N)_2H_2O$, m.p. 275°–280°, from *Solanum sodomæum* tubers, which he regards as distinct from potato-solanine $C_{32}H_{51}O_{11}N$, m.p. 262°.

Sparteine $C_{15}H_{26}N_2$, a liquid alkaloid obtained from broom (*Cytisus scoparius* (Link.) or *Spartium scoparium* [Linn.]) (Stenhouse, Annalen, 1851, 78, 15; Mills, *ibid.* 1863, 125, 71); subsequently shown to be identical with lupinidine from yellow lupin seeds (*L. luteus*) by Willstätter and Marx (Ber. 1904, 37, 2351). It may be obtained from broom tops by extraction with very dilute sulphuric acid, concentration of the extract and steam-distillation of the residue, after addition of alkali. The crude alkaloid may be purified by distillation in a current of hydrogen.

Properties. A colourless liquid, sp.gr. 1·034 at 0°, b.p. 188° under 18·5 mm., or 325° in a current of hydrogen under 754 mm. pressure (Moureu and Valeur, Compt. rend. 1903, 137, 194), 180·5° under 18 mm. (W. and M. *l.c.*). Slightly soluble in water, soluble in alcohol, ether, or chloroform; insoluble in light petroleum or benzene. The aqueous solution is alkaline and very bitter. $[\alpha]_D = -14{\cdot}6°$ in alcohol (Bamberger, Annalen, 1886, 235, 368), $-16{\cdot}42°$ (M. and V. *l.c.*) at 20°. Sparteine is a diacidic base, which forms difficultly crystallisable salts. The alkaloid and its salts are toxic. *V.* also p. 101.

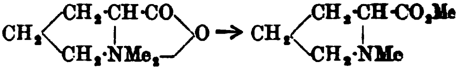
Reactions and constitution. Sparteine behaves towards alkyl iodides as a ditertiary diamine but contains no methyl linked to N (Herzig and Meyer, Monatsh. 1894, 15, 613; 1895, 16, 599; M. and V. *l.c.*). It furnishes no reduction products, and is unaffected by permanganate. Sparteine reacts with methyl iodide to form two monomethiodides, which are regarded as stereoisomerides. On 'exhaustive methylation' sparteine furnishes hemisparteilene $C_{15}H_{23}N$ and trimethylamine and finally sparteilene $C_{15}H_{20}$. On oxidation with chromic acid it yields spartyrine $C_{15}H_{24}N_2$, and eventually oxysparteine $C_{15}H_{24}ON_2$. From these and other data Moureu and Valeur (Compt. rend. 1905, 141, 261, 328) have assigned the following formula to sparteine—



Sparteine.

The principal papers relating to sparteine are as follows: Ahrens, Ber. 1887, 20, 2218; 1888, 21, 825; 1891, 24, 1095; 1892, 25, 3607; 1893, 26, 3035; 1897, 30, 195; Moureu and Valeur, Compt. rend. 1903, 137, 194; 1905, 140, 1601, 1645; 141, 49, 117, 261, 328; 1907, 145, 815, 929, 1184, 1343; 1908, 146, 79; 1911, 152, 386, 527; 1912, 154, 309; Bull. Soc. chim. 1909, [iv.] 5, 31, 37, 40; Wackernagel and Wolffenstein, Ber. 1904, 37, 3238; Willstätter and collaborators, *ibid.* 1904, 37, 2351; 1905, 38, 1772.

Stachydrine $C_7H_{13}O_2N$ occurs with glutamine, tyrosine and other amino acids in the tubers of *Stachys tuberifera* (von Planta and Schulze, Ber. 1890, 23, 1699; 1893, 26, 939); and in orange leaves (Jahns, *ibid.* 1896, 29, 2065); Schulze and Trier, Zeitsch. physiol. Chem. 1910, 67, 59). It crystallises from alcohol, on adding ether, in hygroscopic crystals with $1H_2O$ m.p. 210° (dry) and yields crystalline salts; aurichloride $B{\cdot}HCl{\cdot}AuCl_3$ rhombic leaflets, m.p. 225°. The base is neutral and optically inactive. Schulze and Trier (*ibid.* 1909, 59, 233) have assigned to it the following formula—



Stachydrine (Schulze and Trier). Methyl hygrinate.

which receives support from its conversion into methyl hygrinate on distillation (Trier, *l.c.* 1910, 67, 324), and its synthesis by treating ethyl hygrinate methiodide with silver oxide (S. and T. Ber. 1909, 42, 4654; *cf.* Engeland Arch. Pharm. 1909, 247, 463). *See* also p. 149.

Staphisagroine and **Staphisagroidine.** *See* under *Delphinine* (p. 651).

STRYCHNINE AND THE STRYCHNOS ALKALOIDS (*see* also NUX VOMICA, vol. iii. p. 719).

Strychnine $C_{21}H_{22}O_2N_2$, the principal alkaloid of *Strychnos Nux-vomica* (Linn.), *S. Ignatii* (Berg.), *S. colubrina* (Linn.), *S. Tieuté* (Lesch.), and other *Strychnos* spp. The nearly allied alkaloid brucine usually occurs with strychnine in these plants, but *S. Rheedei* contains brucine only. The seeds of the first two alone are used as sources of strychnine. Strychnine was discovered by Pelletier and Caventou in 1817. The seeds of *S. Nux-vomica* vary in the amount of total alkaloid (strychnine and brucine) they contain. As little as 1 p.c. has been found, and as much as 5 p.c. in the seeds of the Ceylon nux-vomica. About one-third of the total alkaloid is strychnine and two-thirds brucine (Dunstan and Short, *ibid.* 1882–1883, [iii.] 13, 1053; 1884–1885, 15, 1). The total alkaloids from the seeds of *S. Ignatii* are richer in strychnine than those of *S. Nux-vomica*. The leaves of *S. Nux-vomica* contain *strychnicine*, needles, m.p. 240° (van Boorsma, Bull. Inst. bot. Buit. 1902, 14, 3).

Preparation. The following process may be used for the extraction of strychnine and brucine from the seeds of *S. Nux-vomica* or *S. Ignatii* (*see* also NUX VOMICA). The finely-powdered seeds are made into a paste with water and one-fourth of their weight of slaked lime. The mixture is thoroughly dried on the water-bath and the dry mass finely powdered. The alkaloids are now dissolved from it by hot percolation with a suitable solvent (amyl alcohol, benzene, or chloroform) in an extraction apparatus. The solvent is shaken with dilute sulphuric acid, which removes the alkaloids as sulphates. These salts may be crystallised from the neutral solution, or the alkaloids may be regenerated, and the mixture (strychnine and brucine) extracted with dilute (25 p.c.) alcohol, which dissolves the brucine, and leaves nearly the whole of the strychnine undissolved. It is purified by recrystallisation from alcohol.

Properties. Rhombic prisms, m.p. 268° (Loebisch and Schoop, Monatsh. 1885, 6, 858). At higher temperatures some of the alkaloid sublimes unchanged. According to Loebisch (*l.c.*), the alkaloid distils without decomposition at 270° under 5 mm. pressure. Lævorotatory, $[\alpha]_D$ −36° in neutral salts (Tykociner, Rec. trav. chim. 1882, 1, 46). Very slightly soluble in water (1 in 6667, at 15°; 1 in 2500 at 100°). The aqueous solution is alkaline, and even when largely diluted, has a persistent bitter taste; the bitterness is perceptible in a solution containing 1 part of strychnine in 700,000 parts of water. The alkaloid is sparingly soluble in absolute alcohol (0·302 in 100 at 8·25°), ether (1 in 5500 at 25°), but is dissolved by chloroform (1 in 6), benzene (1 in 150 at 25°), amyl alcohol (1 in 180 at 25°), or 90 p.c. alcohol (1 in 170).

Strychnine is a violent poison, giving rise to tetanic spasms, owing to the greatly increased excitability of the spinal cord. Half a grain of the alkaloid has proved fatal to man.

Strychnine is a monacidic base: its salts are, as a rule, crystalline and soluble in water. The hydrochloride $B{\cdot}HCl,2H_2O$ forms small colourless prisms, and is soluble in 35 parts of cold water; the nitrate $B{\cdot}HNO_3$ forms colourless, glancing prisms, and is soluble in 80 parts of water at 18°–19°; the sulphate $B_2{\cdot}H_2SO_4,5H_2O$ forms colourless prisms, soluble in 31 parts of water at 25°. All the salts are neutral in aqueous solution.

Reactions and Detection. Strychnine, which is one of the most stable of alkaloids, is not coloured by sulphuric acid, and gives at most only a yellow coloration with nitric acid. It may be heated to 100° with sulphuric acid without being appreciably affected. When brought into contact with certain oxidising agents it exhibits a striking colour reaction, which is generally relied on for its detection. If the alkaloid is dissolved in a drop of strong sulphuric acid, and a small piece of potassium dichromate, manganese dioxide, ceric oxide, or potassium permanganate is stirred into the mixture, a play of colours is observed, beginning with blue, which gradually passes through violet and red to yellow (Marchand, J. Pharm. Chim. [iii.] 4, 200). The only other alkaloids which behave exactly like strychnine in this respect are curarine and gelsemine. Several alkaloids, however, give a somewhat similar colour reaction, but most of these are coloured by sulphuric acid alone, and may thus be readily distinguished from strychnine. The presence of foreign organic compounds frequently obscures the colour, and the alkaloid to be tested must, therefore, first be isolated in a nearly pure state, and separated, as far as possible, from any other alkaloid that may be present. This colour reaction cannot be obtained in the presence of much brucine, the alkaloid which accompanies strychnine in the plant, since it gives a deep-red coloration when oxidised which obscures the play of colours produced by the strychnine. This alkaloid may, however, be removed by oxidation with dilute nitric acid, the strychnine being recovered from the acid liquid by adding ammonia and extracting with chloroform (Shenstone, Pharm. J. 1877–1878, [iii.] 8, 445; Hanriot, Compt. rend. 1883, 97, 267), or the mixed alkaloids may be washed with chlorine water, when the brucine is converted into the soluble dichlorobrucine, which dissolves, leaving a residue of strychnine (Beckurts, Arch. Pharm. 1890, 228, 326). In toxicology, where traces of impurity in the alkaloidal residue would give rise to darkening when the sulphuric acid is added, the residue may be moistened with the strong acid and heated on the water-bath until the impurity is completely decomposed; water is then added, and the strychnine recovered by adding ammonia and extracting with chloroform.

Estimation of total alkaloids. For the estimation of the total alkaloids in nux vomica, Ignatius beans, &c., and in the medicinal preparations made from these plants the following processes have been devised.

For the seeds of *S. Nux-vomica* or *S. Ignatii* 5 grms. of the seeds dried at 100°, and finely ground, are exhausted of alkaloidal salts by hot percolation in an extraction apparatus with chloroform, to which has been added 25 p.c. by volume of alcohol. The solution is mixed with about half its volume of dilute sulphuric acid (5 p.c.) and well shaken. The mixture separates into two layers, the alkaloids being in the upper aqueous layer and the colouring matter, &c., in the lower layer of chloroform. When the alkaloidal salts have been completely removed from the chloroform by a repetition of this process, the solution of the acid sulphates of strychnine and brucine is made alkaline with ammonia, and extracted with chloroform until the alkaloids are removed. The alkaloidal residue left by the evaporation of the chloroform is dried at 100° and weighed (Dunstan and Short, Pharm. J. 1882–1883, [iii.] 13, 665, 1053).

For the tincture of nux vomica 50 c.c. of the tincture are evaporated almost to dryness on the water-bath. The residue is dissolved in dilute sulphuric acid, and to the clear acid liquid, ammonia is added in excess, and the alkaloid removed by shaking with chloroform. The residue of alkaloid left by the evaporation of the chloroform is dried at 100° and weighed (Dunstan and Short, Pharm. J. 1883–1884, [iii.] 14, 292).

For the liquid extract of nux vomica, 10 c.c. is evaporated nearly to dryness at 100° and dissolved in about 50 c.c. of 5 p.c. aqueous sodium carbonate, and the liquid twice extracted with half its volume of chloroform. The solution of the alkaloid in chloroform is shaken with half its volume of dilute sulphuric acid, and the chloroform, which contains fat and resin, removed. The clear acid liquid is made alkaline with ammonia, and the alkaloid extracted with chloroform. The solution of the alkaloids in chloroform is evaporated, dried at 100°, and weighed (Dunstan and Short, Pharm. J. 1883–1884, [iii.] 14, 621).

Estimation of strychnine. The alkaloid obtained by all these processes is a mixture of strychnine and brucine. The two alkaloids possess very similar properties, and are not easy to separate. On the large scale an approximate separation may be effected by extracting the residue with dilute alcohol (25 p.c. by volume), which readily dissolves the brucine but only traces of the strychnine.

For quantitative purposes advantage may be taken of the great difference in the solubilities of the ferrocyanides of strychnine and brucine; the strychnine salt, being very slightly soluble in water, separates from dilute acidified solutions as a characteristic granular precipitate, whilst the brucine ferrocyanide, being readily soluble in water, does not separate except from concentrated solutions. When both alkaloids are present the separation is not quite so sharp as might be anticipated, but it has been proved that sufficiently accurate results for ordinary analytical purposes may be obtained, if the following directions are adhered to (Dunstan and Short, Pharm. J. 1883–1884, [iii.] 14, 621; *cf.* Carr and Wright, *ibid.* 1900, [iv.] 11, 82). Any quantity less than 0·2 grm. of the mixed alkaloids (the British Pharmacopœia, 1898, uses the total alkaloid from 10 c.c. of the liquid extract or from 100 c.c. of the tincture of nux-vomica) is dissolved in about 10 c.c. of dilute sulphuric acid (5 p.c. by volume). The solution is diluted with water to about 175 c.c., and finally made up to 200 c.c. with 5 p.c. aqueous potassium ferrocyanide. The liquid is stirred occasionally, and allowed to stand for about 6 hours, by which time the strychnine ferrocyanide will have separated as a white granular precipitate. The precipitate is collected and washed with water just acidified with sulphuric acid until the washings are scarcely bitter. Since strychnine ferrocyanide is difficult to dry without decomposition, the moist salt is decomposed by the addition of ammonia solution, in which it is completely soluble. The alkaline liquid is twice extracted with chloroform, which removes the strychnine. The solution in chloroform is evaporated on the water-bath to a small volume, the remainder of the chloroform spontaneously evaporated, and the residue finally dried in a covered dish (to avoid loss by spurting) and weighed. The brucine may be estimated by difference, or it may be dissolved from the filtrate and washings, made alkaline with ammonia, by shaking with chloroform, separating, evaporating, and weighing in the usual manner. The British Pharmacopœia, 1898, requires that tincture of nux-vomica and liquid extract of nux-vomica shall contain 0·24 to 0·26 grm. and 1·5 grms. of strychnine in 100 c.c., respectively, when assayed by the above process.

Beckürts and Holst (Arch. Pharm. 1887, [iii.] 25, 313) have proposed to apply this method volumetrically.

A method of separation depending on the greater solubility of brucine picrate has also been proposed (Gerock, *ibid.* 1889, [iii.] 27, 158). Keller has suggested a method for the estimation of strychnine in presence of brucine depending on the readiness with which the latter alkaloid can be destroyed by dilute nitric acid, and modifications of this have been advocated by Stoeder (Ned. Tijd. Ph. 1899, 11, 1), Gordin (Arch. Pharm. 1902, 240, 641), Howard (Analyst, 1905, 30, 261), and Reynolds and Sutcliffe (J. Soc. Chem. Ind. 1906, 25, 512).

Brucine $C_{23}H_{26}O_4N_2$. This alkaloid occurs with strychnine in *S. Nux-vomica* (Linn.) and in other species of *Strychnos*. In the seeds of *S. Nux-vomica* about two-thirds of the total alkaloid is brucine (Dunstan and Short, Pharm. J. 1884–1885, [iii.] 15, 1). In the seeds of *S. Ignatii* the proportion of brucine appears to be smaller.

Preparation. The total alkaloid having been extracted from the plant by the method described for strychnine, the mixture is repeatedly washed with dilute alcohol (25 p.c. by volume) and the brucine crystallised from the solution, and recrystallised several times from the same solvent or from water, the fractions which crystallise latest being almost, if not quite, pure brucine.

According to Flückiger (Pharm. Chem.), if the mixture of the two alkaloids is converted into the acetates and the solution is evaporated to dryness on the water-bath the strychnine acetate undergoes dissociation into the alkaloid and acetic acid, which volatilises. The brucine acetate remains unchanged, and may be dissolved from the residue by cold water and crystallised. For another method which is said to furnish quite pure brucine, *see* Shenstone, Chem. Soc. Trans. 1881, 39, 453; and also Nux-Vomica, vol. iii. p. 719.

Properties. Brucine separates from its solutions in water or aqueous alcohol in monoclinic prisms containing $4H_2O$, m.p. 105°, or with $2H_2O$ from alcohol (Moufang and Tafel, Annalen, 1899, 304, 24). The crystals lose their water at 100°, or on standing over sulphuric acid. The anhydrous substance melts at 178° (Claus, Ber. 1881, 14, 773); lævorotatory, $[\alpha]_D =$ in alcohol −85°, in chloroform −119° to 127° (Oudemans, Annalen, 1873, 166, 69). Slightly soluble in cold water (1 in 320), twice as soluble in boiling water, very soluble in alcohol, chloroform, or amyl alcohol; insoluble in ether. Brucine and its salts are bitter, and when subcutaneously injected in animals produce a physiological action resembling in kind that of strychnine, but much feebler. When administered internally to animals it produces little or no effect, owing chiefly to the rapidity with which it is eliminated (Brunton, Chem. Soc. Trans. 1885, 47, 143).

Brucine is a monacidic tertiary base; the ordinary salts are crystalline, and readily dissolve in water.

Reactions. Brucine is readily distinguished from strychnine, since it does not give rise to the characteristic play of colours when oxidised with chromic acid, &c., only an intense red coloration being produced, whilst brucine is further differentiated from strychnine by giving a deep-red coloration when mixed with nitric acid; this is a very delicate test for brucine, and conversely for nitric acid. This red coloration of brucine is distinguished from that produced when some other alkaloids (*e.g.* morphine) are mixed with nitric acid, by the action of stannous chloride or certain other reducing agents, which when cautiously added change the red coloration to violet.

When heated with strong hydrochloric acid brucine evolves two molecular proportions of methyl chloride (Shenstone, Chem. Soc. Trans. 1883, 43, 101; Hanssen, Ber. 1884, 17, 226).

Detection and estimation. Brucine may be detected by means of the properties and reactions described above. It may be estimated in plants and in medicinal preparations by the methods described in connection with strychnine (p. 677).

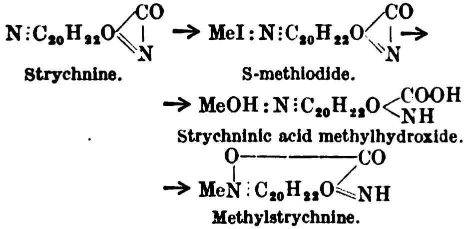
Constitution of strychnine and brucine. In spite of the fact that these two alkaloids were isolated nearly a century ago it is only quite recently that it has been possible to put forward constitutional formulæ for them. The principal facts so far ascertained in the chemistry of these alkaloids, and which bear directly on the problem of their constitution, are as follows:—

Both alkaloids contain two atoms of nitrogen, but behave as tertiary monacidic bases and contain no methyl linked to nitrogen. On treatment with alkalis they each take up 1 mo of water and form *strychninic* and *brucinic acids* respectively.

Brucine differs from strychnine by $(\cdot OCH_2)_2$, and in yielding 2 mols. of methyl iodide or methyl chloride when heated with concentrated hydriodic or hydrochloric acid. Apart from this the reactions of brucine are exactly parallel with those of strychnine, and the whole series of brucine derivatives correspond with those of strychnine and show a constant difference $(\cdot OCH_2)_2$.

These facts warrant the following assumptions: (1) of the two nitrogen atoms one is present as an imino group: N·CO, and this is converted into: NH·COOH in the transformation of strychnine $N{:}C_{20}H_{22}O\!<\!\begin{array}{l}CO\\ |\\ N\end{array}$ into strychninic acid $N{:}C_{20}H_{22}O\!<\!\begin{array}{l}CO_2H,\\ NH\end{array}$ and of brucine into brucinic acid. The N- atom concerned in the change is devoid of basic properties, and consequently the alkaloids are monacidic, this property depending on the second nitrogen atom. (2) Since the second nitrogen atom is tertiary, and yet has no methyl group attached, it must be linked up with a third carbon atom in a ring. (3) Brucine is probably a dimethoxy-derivative of strychnine.

On treatment with methyl iodide strychnine forms a methiodide, which, when warmed with barium hydroxide, forms methylstrychnine, which behaves as a betaine and is a secondary base; thus it furnishes a nitrosoamine and reacts with methyl iodide to form dimethylstrychnine, a substance which closely resembles N-methyltetrahydroquinoline in its properties, whence it may be concluded that strychnine contains a reduced quinoline nucleus. These changes may be represented thus—



$$N{:}C_{20}H_{22}O\!<\!\begin{array}{l}CO\\ |\\ N\end{array} \rightarrow MeI{:}N{:}C_{20}H_{22}O\!<\!\begin{array}{l}CO\\ |\\ N\end{array} \rightarrow$$

Strychnine. S-methiodide.

$$\rightarrow MeOH{:}N{:}C_{20}H_{22}O\!<\!\begin{array}{l}COOH\\ NH\end{array}$$

Strychninic acid methylhydroxide.

$$\rightarrow \begin{array}{l}O\text{———————}CO\\ |\\ MeN{:}C_{20}H_{22}O\!<\!NH\end{array}$$

Methylstrychnine.

The conclusion that strychnine contains a quinoline nucleus receives confirmation from the fact that the alkaloid is readily nitrated and sulphonated, and that on treatment with nitric acid it yields dinitrostrycholcarboxylic acid, which by loss of CO_2 passes into dinitrostrychol, which appears to be a dinitrodihydroxyquinoline $(NO_2)_2C_9H_3N(OH)_2$.

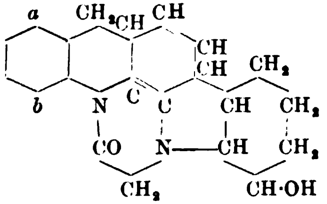
The study of the oxidation products of strychnine and brucine has also afforded useful data. When either alkaloid is oxidised with chromic acid it furnishes an acid

$$C_{15}H_{17}O_2N_2(COOH),$$

which contains no methoxyl, so that in the formation of this acid it must be the portion of the molecule containing the two $\cdot OCH_3$ groups of brucine that has been destroyed thus—

$C_{15}H_{17}O_2N_2\cdot C_6H_5$ Strychnine. $C_{15}H_{17}O_2N_2\cdot C_6H_3(OMe)_2$ Brucine.

The yield of this acid is unfortunately small, but on distillation with zinc-dust it yields diphenylimide (carbazole), a substance which also occurs among the products of the destructive distillation of strychnine. On the basis of these results Perkin and Robinson have suggested that strychnine and brucine must contain both a quinoline and a carbazole nucleus (Chem. Soc. Trans. 1910, 97, 305), and have suggested the following formula for strychnine—



Strychnine (Perkin and Robinson).

The formula for brucine differs from this only in having methoxyl groups substituted at positions *a* and *b*.

The principal papers relating to the chemistry of strychnine and brucine are as follows: Gerhardt, Annalen, 1842, 44, 279; Compt. rend. 1844, 19, 1105; Nicholson and Abel, Chem. Soc. Trans. 1850, 2, 241; Schützenberger, J. 1858, 373; Stahlschmidt, *ibid.* 1859, 395; Gal and Etard, *ibid.* 1878, 910; 1879, 820; Bull. Soc. chim. 1879, [ii.] 31, 98; Schiff, J. 1878, 910; Claus and collaborators, Ber. 1881, 14, 766, 774; Shenstone, Chem. Soc. Trans. 1881, 39, 456; 1883, 43, 101; 1885, 47, 139; Oechsner de Coninck, Compt. rend. 1882, 95, 298; 1884, 99, 1077; Hanriot, *ibid.* 1883, 96, 1671; Bull. Soc. chim. 1884, [ii.] 41, 235; Plugge, Ber. 1883, 16, 2683; Hanssen, *ibid.* 1884, 17, 2266, 2849; 1885, 18, 293, 777, 1917; 1886, 19, 521; 1887, 20, 451; Loebisch and Schoop, Monatsh. 1885, 6, 855; 1886, 7, 75, 609; 1888, 9, 629; Stoehr, Ber. 1885, 18, 3429; 1887, 20, 810, 1108, 2727; J. pr. Chem. 1890, [ii.] 42, 405; Tafel, Ber. 1890, 23, 2734; 1892, 25, 412; 1893, 26, 333; 1900, 33, 2216; Annalen, 1891, 264, 33; 1892, 268, 229; 1898, 301, 285; with Moufang, 1899, 304, 26; with Naumann, Ber. 1901, 34, 3291; Leuchs and collaborators, *ibid.* 1908, 41, 1711, 4393; 1909, 42, 770, 2494, 2681, 3067, 3703; 1910, 43, 1042, 2362, 2417; 1911, 44, 2136, 3040; 1912, 45, 201; Perkin and Robinson, Chem. Soc. Trans. 1910, 97, 305 (this paper gives a résumé of the principal facts bearing on the constitution of strychnine and brucine); Pictet and collaborators, Ber. 1905, 38, 2782, 2787; 1907, 40, 1172.

Taxine $C_{37}H_{52}O_{10}N$, an amorphous alkaloid contained in the seeds and leaves of the yew (*Taxus baccata* [Linn.]), m.p. 80°–82°. Almost insoluble in water; soluble in alcohol, ether, or chloroform. A monacidic base forming amorphous salts. A brown to purplish-blue coloration is produced when the alkaloid is dissolved in concentrated sulphuric acid (Marmé, Med. Cent. 1876, 14, 97; Bull. Soc. chim. 1876, [ii.] 26, 417; Hilger and Brande, Ber. 1890, 23, 464; Thorpe and Stubbs, Chem. Soc. Trans. 1902, 81, 874; Moss, Sci. Proc. Roy. Dubl. Soc. 1909, 12, 92). Taxine is a narcotic poison causing depression of the action of the heart and interference with respiration. *V.* also p. 420.

Thebaine. *See* under *Morphine* (p. 659).

Theobromine and **Theophylline.** *See* under *Caffeine* (pp. 641, 642).

Trigonelline $C_7H_7O_2N$ (*see Caffearine*, p. 640), an alkaloid existing in fenugreek, the powdered seeds of *Trigonella Foenum-graecum* [Linn.] (Jahns, Ber. 1885, 18, 2521; 1887, 20, 2840), various leguminous plants (Schulze and Frankfurt, *ibid.* 1894, 27, 769), in strophanthus seeds (Thoms, *ibid.* 1898, 31, 271, 404), and in coffee (Gorter, Annalen, 1910, 372, 337).

Properties. Prismatic crystals, with $1H_2O$, m.p. 130°; 218° (dry). Very soluble in water, slightly soluble in cold alcohol; very slightly soluble in ether, chloroform, or benzene. When heated with concentrated hydrochloric acid it yields methyl chloride and nicotinic acid (pyridine-β-carboxylic acid).

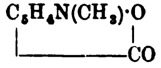
Jahns has proved that trigonelline is identical with the methylbetaine of nicotinic acid first prepared by Hantzsch (Ber. 1886, 19, 31; Jahns, 1887, 20, 2840). Nicotinic acid

$$(C_5H_4N{\cdot}COOH)$$

is heated with potash and methyl iodide, when methyl nicotinatemethiodide

$$C_5H_4N(CH_3I)CO{\cdot}OCH_3$$

is formed. On decomposition with silver oxide, this compound furnishes the betaine



$$\begin{array}{l}C_5H_4N(CH_3){\cdot}O\\ \quad|\qquad\qquad|\\ \quad\rule{0pt}{0pt}\text{—————}CO\end{array}$$

which is identical with trigonelline. The latter is also produced in the oxidation of nicotine methylhydroxide (Pictet and Genequand, Ber. 1897, 30, 2122). *V.* also p. 529.

Tropacocaine. *See* under *Cocaine* (p. 647).

Truxillines. *See* under *Cocaine* (p. 647).

Ulexine $C_{11}H_{14}ON_2$, found in *Ulex europæus* (L.) (Gerrard, Pharm. J. 1886–1887, [iii.] 17, 101, 229), is identical with cytisine from laburnum (p. 651).

Veratridine and **Veratrine.** *See Cevadine* (p. 644).

Vernine. *See* under *Caffeine* (p. 642).

Vicine $C_{20}H_{36}O_{15}N_8$, obtained by Ritthausen from *Vicia* spp. (J. pr. Chem. 1870, [ii.] 1, 336; 1873, [ii.] 7, 374; 1881, [ii.] 24, 202). Needles with $2H_2O$, m.p. 180° anhydrous (decomp.). Weakly basic. Undergoes hydrolysis by acids, yielding dextrose (?) (R. *l.c.*; 1899, [ii.] 59, 482), and *divicine* $C_8H_{14}O_4N_8$, which is readily oxidised by nitric acid to allantoin (?). *Convicine* $C_{20}H_{28}O_{16}N_6,2H_2O$ occurs with vicine (*l.c.*); rhombic leaflets. On hydrolysis it yields alloxantin, ammonia and a hexose (Ritthausen, *l.c.*; Schulze and Trier, Zeitsh. Physiol. Chem. 1910, 70, 143).

Xanthaline. *See* under *Papaverine* (p. 661).

Xanthine. *See* under *Caffeine, Theobromine, and the alkaloids of tea, cocoa, and coffee* (p. 642).

Yohimbine $C_{22}H_{30}O_4N_2$ or $C_{21}H_{26}O_3N_2$ occurs with *yohimbenine* $C_{35}H_{45}O_6N_3$ (crystalline, m.p. 135°), and possibly two other alkaloids in yohimbehe bark (*Corynanthe Yohimbi*) obtained from Kamerun (Spiegel, Chem. Zeit. 1896, 20, 970; 1897, 21, 833; 1899, 23, 59, 81; Ber. 1904, 37, 1759; Thoms, Chem. Soc. Abstr. 1898, 74, i. 455; Siedler, Chem. Zentr. 1902, ii. 1215). It crystallises in needles, m.p. 234°, $[a]_D +50{\cdot}9°$ in alcohol, forms a colourless solution with sulphuric acid, which becomes violet and then green when a crystal of potassium dichromate is stirred in it. Yohimbine is a monacidic, tertiary base, contains one methoxyl group, and probably one hydroxyl group. On heating at 120°–130° it loses $1H_2O$, forming an anhydrobase $C_{22}H_{28}O_3N_2$, and it is this base, not yohimbine itself, which forms salts. When heated with alcoholic potash, yohimbine is converted into noryohimbine (yohimboaic acid) $C_{20}H_{26}O_4N_2$, prisms, m.p. 257°–260°, and this on treatment with excess of diazomethane is reconverted into yohimbine (Spiegel, Ber. 1903, 36, 169; 1904, 37, 1759; 1905, 38, 2825; *cf.* Winzheimer, Ber. Pharm. Ges. 1902, 12, 391). The alternative formula $C_{21}H_{26}O_3N_2$ has been suggested by Fourneau and Fiore (Bull. Soc. chim. 1911, [iv.] 9, 1037) for yohimbine. Yohimbine produces local anæsthesia, and taken internally acts as an aphrodisiac; it is highly toxic. The chief papers relating to its physiological action are: Oberwarth (Virchow's Archiv. 1898, 153, 292); Gunn (Chem. Soc. Abstr. 1908, 94, i. 412); Tait (*ibid.* 1910, 98, ii. 434); Waller (*ibid.* 1911, 100, ii. 138).
W. R. D. and T. A. H.

VELOCITY OF REACTION *v.* CHEMICAL AFFINITY.

VENTILAGO MADERASPATANA (Gaertn.) is a large climbing shrub belonging to the order *Rhamnaceæ*, the root bark of which furnishes a dyestuff much valued in Southern India. It is very common in the Western Peninsula from the Konkan southwards, as well as in Ceylon and Burma, and, according to Lostard, it is largely collected in Mysore at certain periods of the year and exported to other districts of India.

The following are a few of its vernacular names: pitti (*Hindi*); raktapita (*Bengali*); pappili-chakka, surralpattai (*Tamil*); poplichukai (*Kan*); lokandi, kanwail (*Bomb*).

The root bark appears as dark purplish-brown scales, ribbons, or filaments, the dust from which, when it is ground to powder, irritates the throat in a marked manner. When treated with boiling water or alcohol it gives a red solution, which on addition of caustic alkali, changes to a deep crimson.

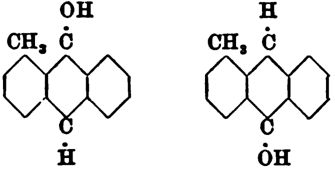
Perkin and Hummel (Chem. Soc. Trans. 1894, 65, 923), who examined this dyestuff, extracted the root bark with carbon disulphide, and obtained in this manner a resinous colouring matter *ventilagin*, together with the crystalline non-tinctorial substances described below.

Ventilagin $C_{15}H_{14}O_6$ consists of a reddish-brown brittle resin, which, when distilled with zinc-dust, gives a-methylanthracene, and when treated with zinc-dust in alkaline solution behaves as a derivative of *methylanthraquinone*. Dilute alkalis dissolve it with a purple-violet coloration, and the corresponding salts are obtained as violet precipitates on adding sodium or potassium chlorides to these solutions. According to Perkin and Hummel, ventilagin is possibly allied to alkannin $C_{15}H_{14}O_4$, the colouring matter of alkanet, *Anchusa tinctoria* (Lam.), and may differ from this merely by the possession of two additional hydroxyl groups.

Emodin monomethyl ether $C_{16}H_{12}O_5$, m.p. 200°, consists of orange-red needles, and is identical with that subsequently isolated from the root of the *Polygonum cuspidatum* (Sieb. and Zucc.) (Perkin, Chem. Soc. Trans. 1895, 67, 1084). A similar, if not identical, substance was isolated by Schwabe (Arch. Pharm. 1888, 26, 569), and by Thorpe and Miller (Chem. Soc. Trans. 1892, 64, 6) from the bark of the *Rhamnus Frangula* (Linn.).

Trihydroxy-*a*-methylanthranole monomethyl ether (A) $C_{16}H_{14}O_4$, colourless needles, decomposes about 260° before melting, and is soluble in alkaline solutions with a yellowish-brown coloration. On gentle oxidation with chromic acid it is converted into emodin methyl ether, m.p. 200° (*l.c.*), and the same reaction takes place when its alkaline solution is oxidised with hydrogen peroxide.

Trihydroxy-*a*-methyl anthranole monomethyl ether (B) $C_{16}H_{14}O_4$, pale yellow needles, m.p. 173°, when oxidised with chromic acid is also converted into the emodin methyl ether, m.p. 200°. As two *a*-methylanthranols are capable of existence, the isomerism of these compounds may possibly be thus explained.



Substance $C_{16}H_8O_8$, orange-red crystalline powder, m.p. 275°–280°, is soluble in alkaline solutions with an orange-red coloration, and when heated with zinc-dust gives a hydrocarbon which resembles *a*-methylanthracene.

Substance $C_{17}H_{12}O_5$ (?) is a chocolate, crystalline powder, soluble in dilute alkalis with a yellow coloration, and these solutions, on exposure to air, deposit a blue amorphous precipitate.

Dyeing properties. On striped printed calico the root bark gives with alumina mordant a claret red, not unlike that of alizarin bordeaux; with iron mordant a greyish lilac, which in strong colours approaches a black; and with a mixture of the two a very purplish dark chocolate. The colours are moderately fast to soap, although considerably behind the alizarin colours in this respect. On oil prepared calico ventilago gives with alumina mordant a rich claret brown, with chromium mordant a very black purple, and with iron mordant a good purplish black shade. On wool chromium mordant gives a good purplish brown, alumina a bordeaux red, tin a brighter red similar to an alizarin red with alumina mordant, and iron mordant gives dark dull purple and black. On silk similar colours are produced. No difficulty is experienced in dyeing with ventilago, and no additions to the dye-bath are necessary, except in the case of wool, with which it is desirable to add calcium acetate in order to correct the strong acidity of the mordanted fibre. Owing to the slight solubility of the colouring matter in water, the dyeing does not commence until the temperature reaches 70°–80°. The root bark appears to contain from 8 to 10 p.c. of ventilagin. A. G. P.

VENETIAN CHALK *v.* STEATITE.

VENETIAN LAKE. *Crimson lake v.* PIGMENTS.

VENETIAN RED. Ferric oxide.

VENETIAN WHITE. A white lead pigment containing a large percentage of barium sulphate.

VERATRINE *v.* VEGETO-ALKALOIDS.

VERATROLE (o-*dimethoxybenzene*)

$$C_6H_4(OMe)_2$$

is best obtained by dissolving catechol (100 grms.) in methyl alcohol (200 grms.) mixed with 75 grms. of methyl sulphate. The mixture is cooled to −5°, and 150 grms. of potash dissolved in 350 grms. of water are then added all at once. In 3 mins. the methylation is complete. The product is diluted with water, extracted with ether, and the extract is dried and distilled (Perkin and Weizmann, Chem. Soc. Trans. 1906, 1656). Veratrole is also formed by the distillation of guaiacol with lead oxide (Pschorr and Silberbach, Ber. 1904, 37, 2149). Veratrole forms a crystalline mass, m.p. 15°, b.p. 205°. It yields a number of halogen derivatives (Cousin, Compt. rend. 1898, 127, 759; 1902, 135, 967; Ann. Chim. Phys. 1898, [vii.] 13, 483); also nitro derivatives (Cousin, Compt. rend. 1902, 134, 290; 135, 967; Salway, Chem. Soc. Trans. 1909, 1163), a *phthalide*

$$CO<\begin{matrix}C_6H_4\\-O-\end{matrix}>O<\begin{matrix}C_6H_3(OMe)_2\\C_6H_3(OMe)_2\end{matrix}$$

(Perkin and Weizmann, *l.c.*) and other compounds (Kropp and Decker, Ber. 1909, 42, 1184).

Veratrole reacts with hippuryl chloride in presence of aluminium chloride, forming a crystalline product, m.p. 155°

$$C_6H_3(OMe)_2CO{\cdot}CH_2{\cdot}NH{\cdot}COPh,$$

from which valuable therapeutic products are said to be obtained (D. R. P. 185596; Frdl. 1905–1907, 1184).

VERBENALIN. A crystalline glucoside found in *Verbena officinalis* (Linn.), m.p. 181·5°; $a_D = -180{\cdot}3°$. Hydrolysed by emulsin, yielding dextrose (Bourdier, J. Pharm. Chim. 1908, 27, 49, 101).

VERDIGRIS, VERT-DE-GRIS, VERT DE MONTPELIER. *Basic acetates of copper v.* ACETIC ACID.

VERDITER, GREEN AND BLUE, *v.* COPPER.

VERIDIAN. *Guignet's green v.* CHROMIUM.

VERJUICE. A kind of vinegar containing malic acid made from the juice of the crab-apple.

VERMILION *v.* MERCURY.

VERMILIONETTE. A red pigment made by adding eosin to white lead, barium sulphate or zinc white.

VERONAL. Trade name for diethylmalonylurea $(C_2H_5)_2C[CO{\cdot}NH]_2CO$, prepared by the condensation of urea and diethyl malonyl chloride. A white crystalline powder of bitter taste, m.p. 191°. Soluble in water, ether, acetone, acetic ester. Used as a soporific (*v.* SYNTHETIC DRUGS and PYRIMIDINES).

VERT DE GUIGNET *v.* CHROMIUM.

VESIPIRIN. Trade name for phenyl acetosalicylate, *v.* SALICYLIC ACID and SYNTHETIC DRUGS.

VESTORIEN *v.* EGYPTIAN BLUE; also ENAMELS.

VESUVIANITE or **IDOCRASE.** A mineral consisting of a complex silicate of calcium and aluminium, together with iron, magnesium, water, fluorine, boron, &c. F. W. Clarke's formula is $R'_4Al_2Ca_7Si_6O_{24}$, where $R'_4 = Ca_2, (AlOH)_2, H_4$, &c. Crystals are tetragonal and usually green or brown in colour, sp.gr. 3·35–3·45; H. 6½.

The mineral is of common occurrence in contact-metamorphic rocks, particularly crystalline limestones. Lustrous, brown crystals are common at Monte Somma, Vesuvius (hence the name vesuvianite). Green crystals from Ala in Piedmont are cut as gems at Turin. A compact, massive variety has been found abundantly as blocks and boulders, measuring up to 6 by 3 ft., at several places in California (Siskiyou, Butte, Fresco, and Tulare counties). This has been called *californite* (G. F. Kunz, 1903), and is much used as a gem-stone and for larger ornamental objects. It is somewhat translucent, takes a high polish, and ranges from bright green to yellowish-green and white in colour, thus closely resembling jade in appearance (D. B. Sterrett, Min. Res. U.S., annual reports for 1909 and 1910). L. J. S.

VICIANIN *v.* GLUCOSIDES.

VICIANOSE *v.* CARBOHYDRATES.

VICTORIA YELLOW. *Gold yellow, Aniline orange, Saffron surrogate.* This colouring matter, introduced by Mettenzwei, under the name of *Victoria yellow* or *aniline orange* (Wag. Jour. 1869, 593), consists of the potassium or ammonium salt of a dinitrocresol (Martius and Wichelhaus, Ber. 2, 206; v. Sommaruga, *ibid.* 2, 579). It is prepared by heating cresol, boiling at about 795°, with three times its weight of sulphuric acid at 100°, until the product is soluble in water. After removing the excess of sulphuric acid by means of barium carbonate, the cresolsulphonic acid is converted into potassium salt, which in the dry state is nitrated by introducing it rapidly into about three times its weight of dilute nitric acid (sp.gr.=1·2), and is then poured into water, neutralised with potassium carbonate, and the resulting potassium dinitrocresol crystallised out. Obtained in this way, the colouring matter is a mixture of the potassium salts of dinitro-*o*- and dinitro-*p*-cresol, and varies in colour according to the proportions of these. Thus Victoria yellow is yellowish in colour, and consists chiefly of the potassium salt of dinitro-*o*-cresol (m.p.=86°), which crystallises in yellow needles (Wichelhaus, *ibid.* 7, 176; Piccard, *ibid.* 8, 685), whereas saffron surrogate is distinctly reddish in colour, and consists chiefly (80 p.c. according to Piccard) of the potassium salt of dinitro-*p*-cresol (m.p.=84°), which crystallises in red needles (Armstrong and Field, Chem. News, 27, 318; Hofmann and v. Miller, Ber. 14, 567; Staedel, *ibid.* 14, 900, 906; Nölting and Salis, *ibid.* 14, 986).

Victoria yellow is soluble in water and dyes wool and silk orange, but owing to the fugitive nature of the colour is no longer employed for this purpose. Saffron surrogate is still used to some extent as a colouring matter for butter, margarine, vermicelli, cheese, &c. (Piccard), but this is to be deprecated, since Weyl's experiments show that the compound is poisonous (Ber. 20, 2835; 21, 512). *Cf.* NITITROPHENOLS AND THEIR HOMOLOGUES.

VIENNA BLUE. *Cobalt blue v.* PIGMENTS.

VIENNA GREEN. *Emerald green v.* PIGMENTS.

VIENNA PASTE. A mixture of lime and potash used as a caustic to extirpate malignant growths.

VINASSE *v.* SUGAR.

VINE BLACK. *Blue black v.* PIGMENTS.

VINEGAR, AROMATIC, *v.* ACETIC ACID.

VINEGAR PLANT *v.* ACETIC ACID; FERMENTATION.

VINOLINE. A mixture of coal-tar reds, mostly rosaniline salts, used for colouring wines.

VINOPYRIN *v.* SYNTHETIC DRUGS.

VIOFORM. Trade name for iodochlorohydroxyquinoline. A greyish-green powder used as a bactericide and antiseptic, and as a substitute for iodoform (*v.* SYNTHETIC DRUGS).

VIOLANTHRENE *v.* INDANTHRENE.

VIOLET DE PARIS or **VIOLET DIRECT.** *Methyl violet v.* TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET 5 B, 6 B, *v.* TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET R and **R R** and **5 R.** *Hofmann's violet v.* TRIPHENYLMETHANE COLOURING MATTERS.

VIOLIN. An emetic substance contained in the common violet, supposed to be identical with emetine from ipecacuanha root.

VIOLINE or **VIOLEÏN.** A synonym for mauve or aniline purple.

VIOLURIC ACID *v.* PYRIMIDINES.

VIRIDIAN. Hydrated chromium sesquioxide, *v.* CHROMIUM.

VIRIDINIC ACID *v.* TANNINS.

VISCOSE *v.* SILK, ARTIFICIAL.

VITELLIN *v.* PROTEÏNS.

VITEXIN. The *Vitex littoralis* (A. Cunn.) or 'Puriri' is a large tree, 40–60 ft. high, and 3–5 ft. in diameter, which grows only in the northern portion of the North Island of New Zealand. The wood affords a very durable timber, and is chiefly used for house blocks, fencing posts, piles for bridges, railway sleepers, &c.

Vitexin, the main colouring matter, is present in the wood in the form of a glucoside which has not yet been isolated. It is prepared by digesting a purified extract of the dyestuff with boiling dilute hydrochloric acid, and by this means separates in the form of a yellow viscous mass. By extracting this crude product with boiling alcohol a pale yellow crystalline powder remains undissolved, and this, owing to its sparing solubility, is most readily purified by acetylation, and the subsequent hydrolysis of the pure acetyl derivative (Perkin, Chem. Soc. Trans. 1898, 74, 1020).

Vitexin consists of minute canary-yellow prismatic or fine hair-like needles, soluble in alkaline solutions with a pale yellow coloration, and from these solutions when boiled it is deposited by acidification in a crystalline condition.

On fusion with alkali vitexin yields *phloroglucinol* and p-*hydroxybenzoic acid*, and when digested with boiling 50 p.c. potassium hydroxide solution p-*hydroxyacetophenone* is also produced. Boiling 15 p.c. nitric acid gives *dinitro*-p-*hydroxybenzoic acid*, together with a small quantity of *tetranitroapigenin*, m.p. 239°–241°. The formula first assigned to vitexin by Perkin was $C_{15}H_{14}O_7$, and the *acetyl* derivative, colourless prismatic needles, m.p. 251°–256°, was consequently represented as $C_{15}H_9O_7(C_2H_3O)_5$. In a later communication in view of its relationship to apigenin, and the difficulty of accounting for the large number of hydroxyl groups which are present, it is suggested by this author (Chem. Soc. Trans. 1899, 77, 422) that vitexin is probably a very stable glucoside of apigenin represented by the formula $C_{21}H_{20}O_{10}$. Vitexin is a somewhat feeble colouring matter, and dyes shades similar to those given by apigenin; these employing woollen cloth mordanted with chromium, aluminium, and tin, are respectively greenish yellow, pale bright yellow, and pale brown.

In addition to vitexin the wood of *Vitex littoralis* contains (as glucoside) a small quantity of a second colouring matter *homovitexin*. It was obtained as a pale yellow powder, m.p. 245°–246°, and is distinguished from vitexin by its ready solubility in alcohol. Fused with alkali it gives *phloroglucinol* and p-*hydroxybenzoic acid*, and is possessed of feeble dyeing property. The analytical figures approximate to $C_{16}H_{16}O_7$ or $C_{18}H_{18}O_8$.

According to Barger (Chem. Soc. Trans. 1906, 89, 1120) the glucoside saponarin, which is present in the *Saponaria officinalis* (Linn.) yields on hydrolysis glucose, saponaretin, and a small quantity of vitexin. It is possible that saponaretin and homovitexin are identical.

A. G. P.

VITRIFIABLE PIGMENTS *v.* POTTERY; also PORCELAIN.

VITRIOL (*vitrum*, 'glass'). An old name for a sulphate, and still frequently applied to the sulphates of certain common metals on account of their vitreous lustre, *e.g.* white or zinc vitriol $ZnSO_4,7H_2O$; blue or copper vitriol $CuSO_4,5H_2O$; green or iron vitriol $FeSO_4,7H_2O$; red or cobalt vitriol $CoSO_4,7H_2O$. Basic ferric or ferroso-cupric sulphates obtained in the extraction of copper sulphate from ferruginous minerals are known as Admont, Bayreuth, Salzburg vitriols, &c.

VITRIOL, OIL OF. *Vitriolic acid.* Sulphuric acid (*q.v.*).

VITRIOL STONE and **COLCOTHAR.** Vitriol is the material from which the so-called fuming or Bohemian sulphuric acid was formerly manufactured, and it is obtained from the rock known as vitriol slate ('vitriolschiefer') in the following manner. Large masses of pyritous slate (which belongs to the Silurian formation, and consists of a quartzose matrix containing pyrites, carbon, and clay) are exposed to the weathering action of the atmosphere for three years. The products of oxidation so formed are ferrous sulphate and sulphuric acid, which latter acts upon the clay, yielding aluminium sulphate and other sulphates. The ferrous sulphate at first formed becomes by oxidation ferric sulphate, which, together with the aluminium sulphate, is the principal product of the weathering of the vitriol slate. Ferrous sulphate remains only in small quantities. The next operation is lixiviation of the mass with water, after which the liquor obtained is concentrated to a density of 40°B., and finally evaporated in pans until, on cooling, a crystalline cake of vitriol stone is obtained. The vitriol stone is now calcined, in order to remove the greater part of its water. The resulting product, when heated to a high temperature in clay retorts, yields sulphur trioxide; and a residue, termed *colcothar*, remains in the retorts. The composition of vitriol stone and colcothar may be seen from the following analyses:—

Vitriol stone. Fe_2O_3 20·07, Al_2O_3 4·76 FeO 0·64, MnO traces, CaO 0·14, MgO 0·39, K_2O 0·07, Na_2O 0·05, CuO 0·10, SiO_2 0·10, P_2O_5 traces, SO_3 40·51, As traces, H_2O 32·58. Total 99·32; or combining acid oxides and bases: $Fe_2(SO_4)_3$ 50·17, $Al_2(SO_4)_3$ 11·94, $FeSO_4$ 1·35, $MgSO_4$ 1·17, $CaSO_4$ 0·33, $CuSO_4$ 0·20, K_2SO_4 0·13, Na_2SO_4 0·11, H_2SO_4 1·49, MnO, As, and P_2O_5 traces, SiO_2 9·10, H_2O 3·31–99·29.

Colcothar. Fe_2O_3 7·62, Al_2O_3 12·53, MgO 3·23, CaO 0·82, SO_3 5·17, SiO_2 1·17, CuO 0·20, H_2O 1·30–99·04 (F. Stolba, B. Königl. Böhm. Gesells. 1885; J. Soc. Chem. Ind. 6, 30).

VIVIANITE *v.* BLUE IRON-EARTH.

VOLBORTHITE *v.* VANADIUM.

VOLEMITOL *v.* CARBOHYDRATES.

VOLUMENOMETER *v.* SPECIFIC GRAVITY.

VOROBYEVITE *v.* BERYL.

VRAIC. *Varech.* The French name for kelp, *v.* IODINE.

VULCANISED OILS *v.* OILS, FIXED, and FATS.

VULCANITE *v.* RUBBER. Also applied to a nitroglycerin explosive.

VULCAN POWDER *v.* EXPLOSIVES.

VULPIC or **VULPULIC ACID** *v.* LICHENS.

VULPINITE. A variety of anhydrite mixed with silica. That from Vulpino near Bergamo, known as the *Marmo Bardiglio di Bergamo*, takes a fine polish and is used for ornamental purposes.

W

WAD or **BOG-MANGANESE.** A black, earthy mineral consisting mainly of hydrated manganese dioxide, but of variable composition, barium and various other constituents being often present. Many varieties have consequently been distinguished by special names. *Asbolite* or 'earthy cobalt' is a cobaltiferous variety, and *lampadite* contains copper. The mineral may be regarded as an earthy form of psilomelane (*q.v.*); it is so soft and sooty that it soils the fingers, and is sometimes so porous that it floats on water. It has resulted by the weathering and decomposition of other manganese minerals, and is sometimes deposited from solution by springs and in swamps. It is of wide distribution and is mined at many places together with other oxides of manganese. Asbolite is of importance as an ore of cobalt (up to 35 p.c. CoO), as much as 5000 tons per annum having been exported from New Caledonia.

L. J. S.

WALNUT HUSKS (*Brous des noix*, Fr.) are employed by the French dyers to give dun colours. The green shells contain *juglone* or *hydroxy*-[*a*]-*naphthaquinone*; *v.* NAPHTHALENE.

WALNUT OIL *v.* OILS, FIXED, AND FATS.

WALSRODE POWDER *v.* EXPLOSIVES.

WARAS, also called 'wars' and 'wurrus,' consists of a purplish, resinous powder which covers the seed pods of *Flemingia congesta* (Roxb.), an erect woody shrub growing in the thickets and forests of the warmer part of India. According to Watt (Dictionary of Economic Products of India, iii. 482), it is collected also in Africa in the neighbourhood of Harrar, and is sent to Arabia, chiefly to Yemen and Hadbramant, where it is used as a dye, as a cosmetic, and as a specific against colds. According to Wardle, waras is distinctly inferior as a dye to kamala, which it closely resembles, and contains only a small amount of colouring matter compared with the yellow vegetable dyes of commerce. It is suitable as a dye for silk rather than for wool, but is quite useless with cotton. It has been introduced into England from Aden as an adulterant or substitute for kamala (Flückiger and Hanbury's Pharmacographica, 1879, 576). Under the microscope waras appears as orange-brown lumps, frequently circular and closely resembling kamala.

Flemingin $C_{12}H_{12}O_3$ (provisional) is a dull orange-red crystalline powder consisting of star-shaped groups of minute prismatic needles, which melt at 171°–172°, and closely resembles the rottlerin of kamala. Solutions of the alkali hydroxides dissolve it with an orange-brown tint, but these solutions when boiled do not deposit resinous matter, as is the case with rottlerin. On fusion with alkali salicylic acid and acetic acid are produced.

Silk suspended in a solution of flemingin in dilute sodium carbonate, and the whole gradually raised to the boiling temperature, is dyed golden yellow slightly duller than the shade given by rottlerin; but, on the other hand, flemingin possesses much the stronger dyeing power of the two.

In addition to flemingin waras contains a trace of a yellow crystalline colouring matter, *homoflemingin*, m.p. 165°–166° (C=69·97; H=5·75), together with some quantity of two resinous substances: (*a*) $C_{12}H_{12}O_3$, m.p. 162°–167°, and (*b*) $C_{13}H_{14}O_3$, melting below 100°. Fused with alkali these latter gave salicylic and acetic acids, and appear to be allied to flemingin.

Added to a boiling solution of its own weight of sodium carbonate, waras dyes silk golden yellow shades, which are brightened by rinsing in very dilute acetic acid. Contrary to the statement of Wardle, it is to be regarded as a decidedly superior dyestuff to kamala (Perkin, Chem. Soc. Trans. 1898, 73, 659). A. G. P.

WASH. The name given to the fermented wort of the distiller.

WATER. Water is absolutely indispensable to both animal and vegetable life; it is the cause of many of the most striking phenomena in nature, and is employed for countless purposes by man. Its distribution is as wide as that of the air itself, whilst its amount on the earth is enormously greater. In an absolutely pure state it is never met with in nature. The impurities in natural water are derived from the materials—solid, liquid, or gaseous—with which it comes in contact, and they may be present either in suspension or in solution or in both. Inasmuch, therefore, as the interest attaching to different waters depends upon the impurities they contain, and these are dependent upon the matters with which they have been in contact, it is most convenient to classify waters according to their origin.

1. *Rain-water, snow, hail, dew, and hoar-frost.* All these forms of water are obtained by the condensation of the aqueous vapour which is invariably present in the air. The amount of aqueous vapour which can be contained in a given volume of air is solely dependent upon the temperature. If the atmosphere has become saturated with aqueous vapour at any given temperature and is cooled below that temperature, the excess of aqueous vapour will condense, according to circumstances, as rain, hail, snow, mist, dew, or hoar-frost. This condensation is promoted by the presence of dust and electrically charged particles. All these forms of water having been only in contact with the air and not with the earth are characterised by the small proportion of solid matter which they contain, although the amount found, especially in the vicinity of towns, is often considerably greater than would be anticipated, and the rain-water falling in the neighbourhood of the sea is often mixed to a considerable extent with sea-spray, which with favourable winds is carried many miles inland. In the following table are recorded the maximum, minimum, and average proportions of the several ingredients in samples of rain-water collected at Rothamsted and elsewhere, expressed in parts per 100,000—

—	Total solid impurity	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum . . .	0·62	0·021	0·003	0·005	0	0	0
Maximum . . .	8·58	0·372	0·121	0·155	0·044	1·65	1·7
Average . . .	3·42	0·095	0·021	0·049	0·007	0·33	0·5
Rain-water collected at Land's End, Cornwall, Jan. 2, 1873 . .	42·80	0·131	0·034	0	0·020	21·8	10·0
Rain-water collected near Hyde Park, London, Nov. 8, 1873 . .	2·76	0·383	0·040	0·210	0·008	0·5	1·1

It is thus seen that the composition of rain-water, even in the open country, is liable to great fluctuations, and that the amount of impurity, both mineral and organic, is occasionally surprisingly large. The amount of organic impurity in dew and hoar-frost is even still greater owing to these forms of water being condensed out of the lowest and most-contaminated couches of the atmosphere. Thus—

SEVEN SAMPLES OF DEW AND HOAR-FROST, ROTHAMSTED, 1869 AND 1870.

(Results of Analysis expressed in parts per 100,000.)

——	Total solids	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum	2·64	0·195	0·026	0·130	0	0·35	1·3
Maximum	8·00	0·450	0·196	0·280	0·050	0·80	2·5
Average	4·87	0·264	0·076	0·198	0·023	0·53	1·9

Two other impurities, not referred to above, which are generally present in the rain-water and snow of towns are sulphurous and sulphuric acids derived from the combustion of coal. Angus Smith found in the rain-water of London 2·05, of Liverpool 3·06, in that of Manchester 4·48, and in that of Glasgow 7·02 parts of sulphuric acid per 100,000, to a considerable extent in the free state. Sendtner found freshly-fallen snow in Munich to contain 0·7 part sulphuric acid (SO_3) per 100,000, on the following day 1·76 parts, after 10 days 6·22 parts, and after 16 days 9·18 parts. The presence of this free acid in the rain-water of towns is, of course, not only detrimental to vegetation, but also to sculptures and buildings in which marble or limestone are employed. The proportion of ammonia increases in the snow after lying on the ground (Wagner, Technologie, 305).

2. *Upland surface water* most nearly approaches in composition to that of the atmospheric waters dealt with in the last section. It is, in fact, rain-water which has undergone minimum contact with the earth, although in consequence of its solvent action even this contact is sufficient to impart to the water in many cases such proportions of dissolved matter as are never found in rain-water. The amount and nature of these ingredients depend, of course, mainly upon the kind of soil over which the water has travelled, and consequently it becomes convenient to sub-divide this class according to the geological character of the ground from which the upland surface water has been obtained.

In the following tables are recorded the maximum, minimum, and average amounts of impurity found in the examination of a large series of samples of waters principally derived from land not under cultivation, so as to represent the characters naturally acquired by water passing over the various geological formations.

[1] Owing to the compact nature of the limestone in these old formations, the hardness is very moderate.

[2] Hardness not excessive, but large amount of organic matter (peaty), rendering the waters coloured and unpalatable.

[3] Of very variable character; generally of only moderate hardness, but containing much peaty matter, and hence coloured and unpalatable.

[4] Slightly turbid.

[5] Slightly turbid. Owing to the porous nature of Oolite formation, surface water is very rare.

The above analyses show that upland surface waters generally contain a considerable amount of dissolved matters only when they are derived from calcareous strata. The organic matter is subject to great variation, but in every case contains only a very small proportion of nitrogen in comparison with the carbon, indicating that the organic substances present are of vegetable origin, which is further attested by the almost entire absence of ammonia, nitrates, and nitrites, all of which, when present in amount beyond that in which they occur in rain-water, are nearly exclusively derived from the decomposition of animal matters. The chlorine is also low, the upland gathering grounds being generally beyond the reach of sea-spray and not receiving the liquid excrements of animals, which are particularly rich in chlorides, whilst from their mere surface contact with the soil they have not extracted any considerable quantities of the salts present in the latter, as is the case with spring- and well-water.

3. *Surface water derived from cultivated land.* This includes the great body of river-waters, inasmuch as practically all streams flow through and receive accessions from land under cultivation before reaching the sea. The composition of such waters is very varied, depending upon local circumstances, and being liable to great fluctuations at different seasons of the year. This group may be conveniently divided into two sub-groups, according as the water is derived from calcareous or non-calcareous districts. The following results of analyses of British waters of this description are compiled from the Sixth Report of the Rivers Commission, 1874:—

SURFACE WATERS FROM CULTIVATED LAND.

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
			(*a*) *Water from non-calcareous districts.*[1]

Average (144 samples)	30·08	0·268	0·053	0·005	0·257	0·314	2·24	12·4	8·2	20·6

[1] Usually turbid, organic matter generally moderate in amount, but partially of animal origin.

[2] This result is extremely improbable, more especially as the particular water in question (a sample of the water supplied to Bury and Radcliffe, Lancashire) contained 0·229 organic carbon, 0·032 ammonia, and 0·066 nitrogen as nitrates and nitrites.

[3] Generally turbid, the organic matter is much the same in amount as in the water from non-calcareous districts, but generally more nitrogenous, in consequence of calcareous soils being usually under higher cultivation than non-calcareous ones. The total combined nitrogen is also for the same reason considerably greater, and the hardness is, of course, very much higher.

In connection with the effect of cultivated and upon the water which comes in contact with it, it is instructive to note the nature of the water which drains from such land, as this throws light upon the composition of subterranean waters (from springs and wells), which will be considered below.

In the following table is recorded the composition of the water obtained from drain-pipes placed from 18 ins. to 5 ft. below a plot of land at Rothamsted which had remained both unmanured and uncropped for a period of 11–15 years :—

COMPOSITION OF WATER FROM LAND UNMANURED AND UNCROPPED FOR ELEVEN TO FIFTEEN YEARS.[1] (6th Rep. Riv. Com. p. 62.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . .	63·28	0·235	0·116	0·026	4·936	4·981	3·80	7·2	11·9	16·6
Minimum . .	18·00	0·096	0·026	0	0·607	0·654	0·60	0·3	3·2	3·5
Average (15 samples distributed over four years) . .	32·06	0·154	0·053	0·006	2·195	2·253	1·65	4·1	8·5	12·6

[1] The samples varied from clear to turbid.

It will be seen that the conversion of the original nitrogenous organic matter in the soil nto mineral products is a very slow process, large quantities of nitrates being still present in the drainage waters after the lapse of so many years.

It is interesting to compare with the above the composition of the water draining from a plot of land unmanured for 16–21 years, but continuously bearing an annual wheat crop during that time :—

COMPOSITION OF WATER FROM LAND UNMANURED FOR SIXTEEN TO TWENTY-ONE YEARS, BUT CONTINUOUSLY BEARING WHEAT CROPS. (6th Rep. Riv. Com. p. 60.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . .	48·40	0·242	0·058	0·006	2·268	—	3·80	14·1	22·4	32·7
Minimum . .	13·80	0·099	0·010	0	0	—	0·80	8·9	3·9	13·5
Average (11 samples distributed over five years) . .	24·96	0·170	0·034	0·002	0·645	—	1·37	10·8	8·4	19·2

As might have been anticipated, the proportions of ammonia and nitrates finding their way into the drainage water in this case were much less, and in the summer months during the growth of the crop the amount of this mineral nitrogen found in the drainage water was practically *nil.*

We will, in the next place, compare with the above the composition of the drainage water from land which had been manured annually with 14 tons of farmyard manure per acre over a period of 24–29 years, and bearing wheat continuously during that time :—

Composition of Drainage Water from Land manured with 14 Tons Farmyard Manure per Acre for Twenty-four to Twenty-nine Years. (6th Rep. Riv. Com. p. 58).

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . .	51·20	1·243	0·335	0·052	2·592	2·754	3·35	12·1	20·6	32·1
Minimum . .	14·00	0·181	0·036	0	0·082	0·130	0·60	1·4	5·4	8·7
Average (13 samples over five years) .	25·90	0·519	0·115	0·009	0·528	0·665	1·30	6·8	8·6	15·4

Thus the difference between the drainage waters from the unmanured and manured land is not nearly so great as might have been expected, being principally confined to the larger proportion of organic matter found in the latter.

The above results may be compared with those obtained in the analysis of a number of samples of the drainage water from sewage farms, in all of which the town sewage is, or was, applied to land, with the double object of purifying the sewage and deriving a profit out of the crops raised. Thus :—

Composition of Drainage Water from Sewage Farms. (6th Rep. Riv. Com. pp. 55–57.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . .	103·00	2·160	0·517	1·366	6·499	6·833	13·40	36·9	39·3	56·6
Minimum . . .	18·60	0·108	0·034	0·005	0	0·069	2·15	0	3·9	3·9
Average (72 samples)	64·02	0·982	0·191	0·388	0·756	1·266	6·36	17·6	15·4	33·0

It will be seen that the drainage water from sewage farms is generally richer in organic and inorganic impurities than the water draining from manured or unmanured land, the passage of the water through the ground being in the latter case a much slower one, and thus allowing time for more perfect purification by soil and plants. Occasionally, as indicated by the above minimum results, the drainage water from sewage farms is remarkably free from impurities. A much purer drainage water is often yielded in the intermittent downward filtration of sewage through suitable land.

The knowledge thus gained of the composition of waters draining from cultivated land becomes of special value in studying the nature of the next group of waters (shallow well water).

4. *Shallow well water.* It has been estimated that about twelve millions of the inhabitants of Great Britain are supplied with water for domestic purposes from shallow wells. This class of water is very liable to serious contamination with sewage and refuse animal matters, inasmuch as such wells are almost invariably sunk in the vicinity of human dwellings, and frequently within a few feet of the cesspool receiving their drainage. It is these waters which have most frequently caused serious outbreaks of typhoid fever. In consequence of the great practical interest attaching to these waters, their composition will be considered in connection with the principal geological formations upon which such shallow wells may be sunk.

The results recorded on the next page serve to show the general composition of shallow well waters as met with in Great Britain. The composition of these waters varies within very wide limits, even when derived from one and the same geological formation, which is due to their being not generally an aqueous extract of a soil in its natural condition, but of ground which is often saturated with sewage and other animal refuse. In consequence of the oxidising power of soil, the organic matter of this refuse is not unfrequently almost entirely destroyed before reaching the wells, and even the ammonia which is one of the first products of its decomposition, has often disappeared, having generally become converted into nitrates and nitrites. Of nitrates and nitrites these shallow well waters generally contain some, and often a large amount, which thus, together with the ammonia

Shallow Well Waters.

[1] In almost all cases clear and palatable. [2] Generally clear and palatable. [3] Almost all clear and palatable.

[4] In many cases clear and palatable; but in others turbid, and even very turbid.

[5] All clear or slightly turbid and palatable.

[6] Generally clear, or only slightly turbid and palatable. In a few cases saline taste.

[7] Even this water clear and palatable. [8] In nearly all cases clear, or slightly turbid and palatable.

[9] Varying from clear and palatable to very turbid. In some cases saline taste.

[10] Mostly more or less turbid. Palatable.

[11] Clear to very turbid. Palatable, or occasionally slight saline taste.

[12] Generally more or less turbid and palatable. Occasionally slight saline taste.

[13] Generally more or less turbid and palatable. [14] More or less turbid and palatable.

[15] Generally clear or only slightly turbid and palatable. Occasionally slight saline taste.

testify to the water having previously been in contact with nitrogenous organic matter which has subsequently undergone destruction. In shallow well waters, even when the organic matter is only small in amount, it is generally highly nitrogenous, pointing to its probable animal origin, and in some exceptional cases the organic nitrogen found is actually in excess of the carbon. These waters, which are generally suspicious from the presence of mineral nitrogen, become in the highest degree dangerous when the proportion of organic matter is large.

5. *Deep well waters.* It is convenient to distinguish for sanitary purposes between waters which are obtained from comparatively shallow wells and those which are derived from wells, say, upwards of 100 ft. in depth, and sometimes reaching to the distance of more than 1000 ft. below the surface of the earth. The presumption is that waters obtained from such a depth have undergone perfect filtration through porous strata, and consequently it is not usual to view the evidence of previous contact with animal matters afforded by the presence of mineral nitrogen with so much suspicion as in the case of the waters from the shallower wells. The great efficiency of the filtration which most of these deep well waters have undergone is attested both by their freedom from organic matter, and from every kind of suspended material, whether organic or inorganic. In consequence of the excellent water obtainable from such deep wells, they have been multiplied greatly during past years, so that at the present time not only are many towns (including a part of London) and villages supplied from this source, but also nearly all larger breweries and many private establishments. In some cases these deep wells are of the kind known as 'Artesian' (from Artois, in France, where they were probably first employed); that is to say, on reaching the water-bearing stratum the water

rises to the level or even considerably above the level of the ground, due to the underground water being confined under pressure beneath an impervious stratum of clay or the like, and through the outcrop of the water-bearing stratum being at a considerably higher altitude than the point at which the boring has been made. Thus, in the London basin, 'Artesian wells' are obtained by sinking through the London clay into the chalk beneath, which has its outcrop at considerable altitudes in the chalk hills on the north and south of the Thames valley. Owing to the large abstraction from such water-bearing strata, the water of many wells which formerly rose to the surface has now to be pumped. In the majority of deep wells the water does not rise nearly to the surface, and the pumps have often to be placed at considerable depths in the shaft. It is usual to line these wells with closely-fitting iron cylinders, in order to exclude surface water, as unless this is done the deep wells may become as objectionable and dangerous as shallow ones.

The preceding tables afford a survey of the general character of the deep well waters obtained in Great Britain. In nearly all the samples of which the maximum, minimum, and average results are given, it may be taken that the wells were unpolluted by surface water, but for the sake of comparison there are appended to most of the sections analyses of deep well waters from the same strata in which pollution by surface or imperfectly-filtered water is highly probable.

These results demonstrate the great superiority from a chemical point of view of the subterranean waters obtained at great depths to those derived from shallow wells. Indeed, these deep well waters are, as regards organic matter, amongst the purest to be found in nature, and hence, unless extremely hard, are of the best quality for drinking purposes.

Closely associated with these deep well waters is the next group of spring waters.

6. *Spring water.* In the following table is given the composition of, presumably unpolluted, British spring waters arranged according to the geological nature of the ground from which they are derived, whilst for the sake of comparison the composition of probably polluted spring waters from the same geological source is in many cases appended.

7. *Mineral spring waters.* Many spring waters possess marked medicinal properties in consequence of the materials they hold in solution. Until the discovery of radium it was generally supposed by chemists that the therapeutic value of such waters containing only an insignificant amount of mineral matter must be imaginary, but it is now known that some of these, such as the waters of Bath and Buxton, are pronouncedly radioactive, and it is generally accepted at the present time that the old-established efficacy of these waters in the treatment of gout and rheumatism is due to their content of radioactive material (*see* Nature, 1911, 86, 157). Indeed, radium-salt is now much employed for the artificial production of radioactive water for medicinal purposes. An immense number of mineral waters are in use, and have been submitted to careful analysis; a very extensive collection of such analyses is to be found in Raspe's Heilquellen Analyse, Dresden, 1885.

These mineral waters are conveniently classified by Hermann Weber (Quain's Dictionary of Medicine), according to the ingredients which characterise them, into—(1) Simple thermal waters; (2) common salt or muriated saline waters; (3) alkaline waters; (4) sulphated saline waters; (5) iron or chalybeate waters; (6) sulphur waters; (7) earthy and calcareous waters.

(1) *The simple thermal waters*, whilst containing only a moderate proportion of dissolved solids, are characterised by a high temperature, from 27°–65°, and sometimes by the presence of an unusually large proportion of nitrogen, which is now known to be mixed with appreciable quantities of helium. Doubtless the medicinal reputation of most, if not all, of these waters depends on their radioactivity. The principal springs of this class are: Panticosa, Leukerbad, Bormio, Gastein, Pfäffers, Johannisbad, Ragatz, Wildbad, Plombières, Buxton, Bath, Lucca, Teplitz, Schlangenbad, &c.

(2) *Common salt or muriated saline waters* contain sodium chloride as the principal constituent, although this also occurs often in large quantity in many of the other classes of mineral waters. These salt waters or brines are very common in almost all countries. Some of the principal ones in England are: Droitwich, Nantwich, Middlewich, Woodhall, and Harrogate; Leamington and Cheltenham along with sodium sulphate. In Germany: Kissingen, Homburg, Nauheim, Kreuznach, Soden, Pyrmont, Wiesbaden, Ischl, Kreuth, Baden-Baden, &c. In France: Bourbonne-les-Bains, Lamotte-les-Bains, Balaruc, Salins. In Italy: Castellamare, Ischia, Monte Catini, La Porretta. In Switzerland: Bex.

(3) *Alkaline waters* are characterised by the presence of sodium carbonate, almost always with more or less free carbon dioxide, and sometimes with a large quantity also of sodium chloride. Of the simply alkaline waters, there are—(*a*) *Hot*: Vichy, Neuenahr, Mont-Dore, Chaudesaigues, Néris; (*b*) *Cold*: Apollinaris, Vals, Salzbrunn, Bilin, Wilhelmsquelle, Taunus, Marcolo; whilst the chief muriated alkaline waters are: (*a*) *Hot*: Ems, Royat, La Bourboule; and (*b*) *Cold*: Luhatschowitz, Selters, Gleichenberg, Rosbach, Vic-sur-Cere. Several of these, but especially La Bourboule and Mont Dore, contain a marked proportion of arsenic.

(4) *Sulphated waters* contain either sodium or magnesium sulphate, or both, as the prominent ingredients, in some cases also associated with sodium carbonate and chloride. They are often called '*bitter waters*.' The chief simple sulphated waters are: Galthof, Pullna, Saidschutz, Sedlitz, Birmensdorf, Ivanda, Hunyadi Janos, Epsom, Aranjuez, Friedrichshall, Mergentheim; the two latter are also rich in chlorides. Weaker springs of the same kind are found at Leamington, Cheltenham, Scarborough, and at Purton Spa. Of alkaline sulphated waters there are: Carlsbad, Marienbad, Tarasp-Schuls, Franzensbad, Elster, and Bertrich.

(5) *Iron or chalybeate waters* are those in which an unusual proportion of this element is present, either in otherwise comparatively pure water or associated with other mineral matter

SPRING WATER. (6th Rep. Riv. Com. p. 107.)

---

[1] Water supply of Weston-super-Mare; these exceptionally high results doubtless due to access of sea water.

Thus, of comparatively pure chalybeate waters, there are those of Schwalbach, Spa, Brückenau, Schandau, Liebwerda, Flinsberg, Freienwalde, Recoaro, Königswarth, Liebenstein, Altwasser, Alexisbad, Muskau, Tunbridge Wells, and some of the springs at Harrogate; whilst of waters in which the iron is associated with a considerable quantity of other salts, there are those of Aratapak, Orezza, Pyrmont, Driburg, Rippoldsau, Griesbach, Antogost, Petersthal, Bocklet, St. Moritz, Reinerz, Godesberg, Cudowa, Imnan, and Santa Catarina.

(6) *Sulphur waters* are those containing appreciable quantities of either sulphuretted hydrogen or the sulphides of sodium, potassium, calcium, or magnesium. Some of the more important thermal sulphur waters are those of Eaux Chaudes, Cauterets, Saint Sauveur, Barèges, Bagnères-de-Luchon, Ax, Escaldes, Le Vernet, Amélie-les-Bains, Uriage, Allevard, Aix-les-Bains, Aix-la-Chapelle, Baden (Austria), Baden (Switzerland), Lavey, Schinznach, Battaglia and Abano in the Euganean Mountains, Panticosa, Mehadia, Helouan, near Cairo; whilst of cold sulphur springs there are those of Eilsen, Neundorf, Langenbrücken, Weilbach, Meinberg, Reutlingen, Enghien, Challes, Stachelberg, Heustrich, Gurnigel, some of the Harrogate springs, Llandrindod, Builth, Moffat, Strathpeffer, Lisdunvarna.

(7) *Earthy and calcareous waters* are characterised by the presence of large proportions of calcium carbonate and sulphate, and magnesium carbonate. Some of the more important are found at Wildungen, Lippspringe, Weissenburg, Contrexéville, Bagnères-de-Bigorre, St. Arnaud, Crausac, whilst the table waters of Couzan, St. Galmier, and Taunus are of the same character.

8. *Sea water.* The ocean is a great evaporating-basin, which is constantly receiving waters, more or less impure, in the shape of rivers, whilst at the same time it is constantly losing pure water in the form of vapour, the impurities remaining behind and imparting to the sea its well-known saline character. This also distinguishes all lakes which are devoid of outlet, like the Dead Sea, Caspian, Aral, Great Salt Lake, Utah, &c., in which the same process of concentration by evaporation is going on. As will be seen from the table on the next page, the composition of the ocean varies considerably in different places and at different depths, whilst land-locked seas, like the Mediterranean, Black Sea, and Baltic, present even still greater differences.

Thus in the vicinity of the poles the proportion of salt is less than near the equator; similarly, land-locked seas, such as the Black Sea and Baltic, which receive large rivers are less salt; whilst the Mediterranean in most places is more salt than the great oceans. Of salt lakes the Dead Sea is far more and the Caspian far less salt than the oceans. In addition to sodium chloride, the principal substances present in sea water are the sulphates and carbonates of calcium and magnesium, and salts of potassium, whilst in very minute quantities there are found also a number of others, amongst which may be mentioned bromides, iodides and fluorides, silica, phosphoric and nitric acids, iron, silver, gold, copper, lead, arsenic, zinc, cobalt, nickel, lithium, rubidium, and caesium.

The volume of gas dissolved in sea water is, according to Hunter (Chem. Soc. Trans. 187, 20), only from 2·2 to 3·5 vols. in 100 vols. of water.

	CO_2 per cent.	O per cent.	N per cent.
2·2 vols. consisted of	28·62	49·44	21·94
3·5 ,, ,,	48·28	17·22	34·50

A very extensive observation of the composition of sea water was made in connection with the voyage of H.M.S. *Challenger*, and the elaborate report prepared thereon by Dittmar should be consulted for detailed information on this subject. From 77 complete analyses, the following numbers for the average composition of ocean-water salts are calculated:—

Average composition of ocean-water salts, in parts per 00 of total salts (Dittmar).

Chlorine	55·292
Bromine	0·1884
Sulphuric acid (SO_3)	6·410
Carbonic acid (CO_2)	0·152
Lime (CaO)	1·676
Magnesia (MgO)	6·209
Potash (K_2O)	1·332
Soda (Na_2O)	41·234
(Basic oxygen equivalent to the halogens)	(−12·493)
	100·000

The salinity of the ocean, expressed in parts of total salts per 1000 parts of sea-water, was found to vary between the following limits: Minimum (from the southern part of the Indian Ocean, south of 66° lat.), 33·01; maximum (from the middle of the North Atlantic, at about 23° lat.), 37·37.

As regards the carbon dioxide in sea water, Dittmar comes to the following conclusions: (1) Free carbonic acid in sea water is the exception; as a rule, the carbonic acid is less than the proportion corresponding to bicarbonate. (2) In surface waters the proportion of carbonic acid increases when the temperature falls, and *vice versâ*. (3) Within equal ranges of temperature it seems to be lower in the surface water of the Pacific than it is in the surface water of the Atlantic Ocean.

Drinking water. As has long been known, the palate is by no means a safe guide in the choice of drinking water, for although unpalatable waters are obviously unsuitable for drinking, palatable waters may contain materials capable of doing serious injury. It is now established beyond question that the diseases termed 'zymotic' are due to minute forms of life known as micro-organisms, and in a number of cases the specific forms responsible for such diseases have been discovered, identified, and studied. Of zymotic diseases there are two—Asiatic Cholera and Typhoid Fever—which are with certainty known to be propagated by drinking water, and in the case of these two diseases authorities are agreed as to the particular organisms to which they are due. The propagation unquestionably takes place through the excreta of persons suffering from these diseases gaining access to water which is afterwards used for drinking, whilst water contaminated with the sewage of healthy persons is generally believed to be capable of producing

(Results of Analysis expressed in parts per 1000.)

diarrhœa and other minor disturbances in those drinking it.

In selecting water for drinking purposes it is necessary, therefore, in the first instance, to make a careful inquiry as to the possibility of the water having been in contact with refuse animal matters, and if possible all waters open to such suspicion should be discarded. For the same reason it is of the first importance in the examination of water to discover what evidence, if any, there is of the water having been in contact with such refuse substances. In the present state of knowledge this is a difficult matter, as, although the results of chemical analysis frequently point to such contamination when on a sufficiently large scale, it is occasionally and indeed generally impossible to prove the negative. The bacteriological examination, on the other hand, is of extreme delicacy, but, inasmuch as we have at present no means of ascertaining whether the bacteria indicative of fæcal contamination are derived from man or from the lower animals, the results obtained by this means also are often of restricted value from a hygienic point of view. It becomes, therefore, of the greater importance to make a thorough inspection of the source and to trace out the further history of the water, for unless this be done the results of the scientific examination may often receive an erroneous interpretation. As, however, it is comparatively rarely that natural waters are to be met with which are absolutely above suspicion of *any* contamination with refuse animal matters, it is generally necessary to be satisfied with relative purity, and thus the examination, chemical and biological, of drinking waters becomes a matter of the highest importance and utility. The natural waters which can lay claim to the greatest degree of safety for drinking purposes are of two kinds.

1. Unpolluted surface waters (generally upland waters).
2. Naturally filtered waters (spring and deep well waters).

In the first case the waters, both by inspection and analysis, must bear no evidence of animal contamination, and this is generally only possible in the case of waters which are found at altitudes above that of human habitations. A number of our large towns are supplied with water of this kind, although the gathering-grounds do in most cases contain some houses, so that absolute freedom from sewage contamination cannot generally be guaranteed. In the table on p. 697 the chemical composition of some of these upland surface water supplies is recorded.

The majority of upland surface waters are either very soft or of only very moderate hardness, and as in many of these towns extensive manufactures are carried on, these supplies are not only valued because of their safety for drinking, but also on account of their fitness for industrial purposes. It should always be remembered, however, that these surface waters may at times receive more or less sewage contamination, and that the ova of animal parasites derived from the cattle grazing on the gathering-grounds may also be present, and that, therefore, to reduce these sources of danger to a minimum, it is highly desirable that such waters should be subjected to prolonged storage in reservoirs, followed by careful filtration through sand before delivery to the consumer.

In the second class of water its original purity is a matter of secondary consequence, the guarantee of safety resting upon the exhaustive process of filtration which the water has undergone in passing through porous strata of the earth's crust. This filtration effects, on the one hand, the more or less complete chemical purification of the water from organic substances, and on the other hand the mechanical removal of organised matters, such as bacteria and animal parasites. The most perfectly-filtered waters of this kind are those obtained from springs and from deep wells, and, again, many of our towns are supplied with water of this kind—more especially from the chalk, greensand, Oolite, and New Red Sandstone formations, which constitute efficient filter beds. In the table on p. 698 is recorded the chemical composition of the water supplied to some of our towns from such sources.

Of other forms of drinking water we have river waters and shallow-well waters, upon both of which a very large portion of the population is dependent for domestic supply. Both of these classes of water are open to grave objections, and nearly all the best authenticated cases of the propagation of cholera and typhoid through drinking water have been traced to shallow wells. There are, however, many potent influences tending to remove bacteria from water which, on *a priori* reasoning, would have been regarded as almost, if not wholly, inoperative. These causes are mainly the process of devitalisation which pathogenic bacteria undergo in natural, and more especially in surface waters, and the resistance offered by even a comparatively small thickness of soil or other porous material to the passage of micro-organisms. But although these causes are to be looked upon as tending to keep the evils which can result from contaminated drinking water within narrower limits than might have been anticipated, still the possibility of their failure must be constantly kept in view, and they must not be allowed to check the endeavour to substitute unimpeachable for suspicious sources of supply.

Every effort should be made to exclude avoidable sources of contamination, to select the best water which the source affords, and to submit it to the most effective purification available. The improvements which can thus be brought about in water supplies obtained from suspicious sources is conspicuously exemplified in the case of the London supply derived from the rivers Thames and Lea. Here, on the one hand, increasing vigilance has been exercised by the Thames and Lea Conservancy Boards in the exclusion of dangerous matters from the rivers and their tributaries, whilst on the other hand the authorities supplying water have removed their intakes to points on these streams above the most serious pollutions; by increasing their storage capacity they are enabled not only to avoid drawing from the rivers in times of flood, but also to bring about a great amelioration in the quality of the water during its sojourn in the reservoirs, whilst by improving their filtering appliances they secure a more perfect purification

of the water which they have abstracted. Thus the water supplied to London to-day is both chemically and hygienically very different from what it was 60 years ago, although still derived from the same streams, which in the ordinary course of events would be more polluted now than they were then.

Importance to be attributed to various ingredients of drinking water. It is only possible here to give a brief account of the importance which is usually attributed to the several ingredients which are commonly determined in the analysis of drinking waters.

Dissolved gases. The gases present in ordinary drinking waters are those of the atmosphere—oxygen, nitrogen, and carbon dioxide. Their quantitative determination is of little or no significance in connection with the quality of the water for drinking, excepting that through the absence of dissolved gases a water has the flat taste of that which has been recently boiled. It is sometimes supposed that the absence of a due proportion of dissolved oxygen in water is an indication of the presence of decomposing organic substances, but this can only be the case with surface waters, as the very purest subterranean waters are almost entirely destitute of it. In the following table the proportion of the several dissolved gases in different kinds of water is recorded :—

Gases dissolved in 100 cub. ins. of water	Rain-water	Cumberland mountain water	Loch Katrine water	Thames water	Deep chalk well water
	cub. ins.	cub. ins.	cub. ins.	cub. ins.	cub. ins.
Oxygen	1·308	1·424	1·731	1·325	1·944
Nitrogen	0·637	0·726	0·704	0·588	0·028
Carbon dioxide . . .	0·128	0·281	0·113	4·021	5·520
	2·073	2·431	2·548	5·934	7·492

The large proportion of dissolved carbon dioxide in the Thames and deep chalk well water is mainly combined with calcium carbonate as bicarbonate.

Total solid residue. It is only rarely that the amount of the residue left by a water on evaporation affords any evidence of its fitness for drinking. As a general rule, it may be stated that waters which contain very small residues are probably pure and unpolluted, but on the other hand many waters of organic purity contain large proportions of mineral matter in solution. It is impossible to assign limits to the proportion of mineral matter which may be present in water without interfering with its fitness for drinking, more especially as opinion is divided as to the influence of the several constituents on health (*v.* also *Hardness of water*). Nearly all the best drinking waters in the United Kingdom yield less than 50 parts of solid residue per 100,000, and most of them very considerably less. The use of waters yielding much larger residues is generally excluded by the inconvenience which attends their employment for general domestic purposes, in consequence of their unfitness for boilers and washing.

Organic matter. As will be pointed out (under *Water analysis*), the accurate determination of the organic matter in water is attended with great difficulties, and none of the methods of analysis in use claims to effect more than a partial determination. Thus in the 'combustion process' the organic carbon and nitrogen are determined with more or less accuracy; in the alkaline permanganate process that portion of the organic nitrogen is discovered which is readily convertible into ammonia; whilst in the 'permanganate' or 'oxygen' process the proportion of permanganate destroyed by the organic matter is taken into account. Although it may be stated generally that the smaller the proportion of organic matter the more desirable is the water for drinking, still of greater importance is the determination of the origin of the organic matter present, whether animal or vegetable. The presence of vegetable matter is of comparatively little consequence, more especially as even small amounts interfere with the palatability of the water, what is known as a 'peaty taste' being imparted by any amount yielding much in excess of 0·2 part per 100,000 of organic carbon. Sometimes much light may be thrown on the origin of the organic matter in water by the proportion which the carbon and nitrogen exhibit towards each other, especially when this is considered in connection with the proportions of ammonia, nitrates, nitrites, and chlorine. Inasmuch as animal matter in general contains a much higher proportion of nitrogen to carbon than does vegetable matter, it follows that the higher the ratio of nitrogen to carbon in the organic matter present in a sample of water, the more probability is there, *cæteris paribus*, of its being derived from animal sources and *vice versâ*. The possibility of such diagnosis, however, is considerably limited by the fact that in the oxidation of peaty matter the organic carbon disappears much more rapidly than the nitrogen; whilst, on the other hand, in the oxidation of animal matter there is conversely a tendency for the organic carbon to become concentrated, thus leading to a simulation of animal matter in the case of vegetable, and a simulation of vegetable matter in the case of animal substances after oxidation.

It is thus essential that the evidence afforded by the proportion of organic carbon to nitrogen should be supplemented by an inspection of the source, and by a consideration of the mineral nitrogenous ingredients—ammonia, nitrates, and nitrites—all of which are principally derived from the decomposition of animal matters.

Albuminoid ammonia. The ammonia yielded on distillation with alkaline permanganate is so frequently made the only measure of the organic matter present in water that a few words are necessary to indicate what is the importance to be attached to the results obtained in this simple process. According to its author, the late Mr. Wanklyn, 'deep spring water is often so pure as not to yield 0·01 part of albuminoid ammonia per million; and unless mixed with surface water does not yield so much as 0·05 part.' 'The filtered water supplied by water companies—no matter whether derived from a lake, from clean mountain streams, or from defiled rivers—yields from 0·05 to 0·10 part of albuminoid ammonia per million; and, indeed, if the filtration be efficient, approximates to 0·05.' 'When the filters are over-taxed, as happens in the rainy season and in the winter, water companies supply imperfectly-filtered water, in which as much as from 0·10 to 0·20 part of albuminoid ammonia is found.' This statement must be accepted with great reserve, for in the winter months such surface waters almost invariably contain a much larger proportion of organic matter than during the dry season, thus accounting for the increase in albuminoid ammonia quite irrespective of any over-taxing of the filters. On the other hand, the albuminoid ammonia is the chemical ingredient in water which is most affected by filtration. It would appear, therefore, that suspended particles of vegetable and animal matter, which are removed by sand filtration, are particularly productive of ammonia on distillation with alkaline permanganate. In fact, the *chemical* difference between a water before and after sand filtration is often only attested by the diminished proportion of albuminoid ammonia yielded by the filtered water.

Oxygen, or permanganate process. The analytical value of measuring the proportion of organic matter in water by the amount of permanganate it is capable of decolorising is discussed in the section of this article on *Water analysis*, and it will be sufficient here to give some idea of how the results are to be interpreted. As in the case of the organic elements determined by combustion, it has here again been attempted to establish a scale of classification, which, however, must also be used with the greatest caution and in conjunction with the other analytical data, as well as with regard to the water's source and history. Thus the following artificial standards have been suggested:—

—	Oxygen absorbed in three hours at room temperature from potassium permanganate by 100,000 parts of water	
	For Upland Surface Water	For other Water
Class I. Water of great organic purity . .	0–0·1 part	0–0·05 part
„ II. „ medium „ . .	0·1–0·3 „	0·05–0·15 „
„ III. „ doubtful „ . .	0·3–0·4 „	0·15–0·2 „
„ IV. Impure water	above 0·4 „	above 0·2 „

It will be readily understood that a great drawback to this permanganate process consists in its not distinguishing between nitrogenous and non-nitrogenous organic matter. Hence it is very desirable that, if the combustion process cannot be resorted to, it should be supplemented by a determination of the 'albuminoid ammonia,' or of the Kjeldahl nitrogen (*see* p. 719).

Mineral nitrogen (ammonia, nitrates, and nitrites). The importance of these ingredients is an indirect one. In themselves they in no way influence the wholesomeness of drinking water; but, on the other hand, they are of consequence as indicating what the previous history of the water has been. Thus, in the ordinary process of decomposition to which organic matters are subjected in nature, the nitrogen is principally liberated in the form of ammonia, and this, by subsequent fermentative oxidation, may become converted into nitrites and nitrates. Moreover, owing to the far greater average richness in nitrogen of animal over vegetable matters, it is evident that these primary and secondary products of decomposition furnish valuable evidence as to the previous contact of water with nitrogenous, and more especially animal, substances. As a general rule, the presence of ammonia indicates a more recent contact with such matters than does that of nitrates or nitrites, although in the case of ome deep subterranean waters it appears that the nitrates originally present in the water have undergone reduction to ammonia, and hence the latter in such cases must be regarded as evidence of a more remote character even than the nitrates themselves. Again, in the ordinary course of nitrification in nature the ammonia is wholly converted into nitrate, the preliminary oxidation to nitrite being rapidly passed over; but if water containing nitrates is brought in contact with organic matter, these nitrates become more or less reduced to nitrites through the agency of certain micro-organisms (P. F. Frankland, Chem. Soc. Trans. 1888, 373; Warington, *ibid.* 742), and hence the presence of nitrites generally constitutes evidence of contamination with organic matter subsequent to the original nitrification, rather than to the latter having been imperfect. The fact must also not be lost sight of that nitrates can be reduced by certain microbes in the presence of organic matter with elimination of the nitric nitrogen in the free state, or as oxides of nitrogen, and that a contamination of the nitrified water may thus lead to the more or less complete removal of the mineral nitrogen. The absence of nitrates may thus, under some circumstances, actually indicate contact with animal matter instead of freedom from it (Munro, Chem. Soc. Trans. 1886, 632).

It must also be remembered that, in the case of surface waters, the mineral nitrogen may undergo removal through being taken up as food by plant-life, and thus the evidence of previous contact with animal matters be destroyed.

As the hygienic significance of contact with animal matters consists in the possibility of the ingress of pathogenic microbes (which may at any time be present in sewage and similar animal refuse), it is obvious that the evidence of such previous contact afforded by the presence of mineral nitrogen in any excessive proportion must be viewed as serious, if the history of the water furnishes no guarantee that any such organised poisons which may have gained access would have been subsequently removed, whilst the evidence is of far less consequence, or may indeed become entirely negligible, if in the subsequent history of the water it has undergone processes of purification which practically preclude the possibility of such poisons being still present. Until the application of bacteriology to questions of water supply, it was not possible to ascertain the efficiency of processes of water purification in this respect. But we now know that the exhaustive filtration through porous strata which spring and deep well water has undergone practically guarantees the removal of any micro-organisms which may have been originally present; in the case of river and shallow well waters, on the other hand, the chance of such removal is much less, and hence in such waters the evidence afforded by mineral nitrogen of previous contact with animal matters must be viewed with suspicion, whilst in the spring and deep well waters it may often be disregarded altogether.

Chlorine. This element is invariably in a state of combination—generally as sodium chloride, and hence quite innocuous. Its determination in potable water, however, is of importance as often affording information as to whether the water has been in contact with refuse animal matters or not. In this respect it is often more useful than the mineral nitrogen, as, once present in water, it cannot by any natural processes be removed. Its diagnostic value is due to the fact that human urine contains 500 parts of chlorine, or 824 parts of common salt, in 100,000 parts. It is, of course, inapplicable in the vicinity of the sea and of natural salt deposits. In British waters free from animal pollution the average proportion of chlorine may be taken as 1 part per 100,000; but it is subject to very great variations.

There are, however, many other refuse liquids besides sewage which contain large quantities of chlorides, such as the effluents from dye and bleach-works, tanneries, paper-mills, alkali-works, and especially tin-plate and galvanising works, the proportion being often far in excess of anything ever found in sewage.

In America much attention has been bestowed on the proportion of chlorine present in unpolluted water at different distances from the sea-board. The points at which such waters exhibit the same amount of chlorine are joined by lines termed 'isochlors,' and these isochlors are found to be roughly parallel to the coast-line. Any water submitted for examination is then remanded for further inquiries if it exhibits more chlorine than is normal for the isochlor upon which the source of the particular water is situated. This is an attempt to make the chlorine a measure of the sewage contamination past and present, in much the same way as the proportion of total combined nitrogen has been employed by others. It has the advantage over the latter, inasmuch as the chlorine is practically permanent whilst the nitrogen is removable in various ways; but, on the other hand, the chlorine is subject to great variations within a small area, according to local circumstances, more especially geological. The chlorine, moreover, only testifies to contamination by liquid, and not by solid, excrements, and in this respect also is of less general applicability than the total combined nitrogen.

Hardness. This term is applied to those ingredients in water which react with soap and produce an insoluble 'curd,' the principal substances in question being the various salts of calcium and magnesium, which, entering into double decomposition with sodium stearate (hard soap) or potassium stearate (soft soap), give rise to calcium and magnesium stearates, both of which are insoluble bodies, and soluble salts of sodium or potassium. On this account the salts of calcium and magnesium are manifestly detrimental to the fitness of the water for washing. As regards the influence of these salts upon the quality of drinking water, opinion is divided. Some consider the presence of a certain proportion of these salts desirable as furnishing the materials necessary for bone-formation; others contend that if present in more than a moderate proportion they tend to cause calcareous concretions in the system, whilst, lastly, others regard their presence or absence as immaterial from a hygienic point of view. Further, by some authorities the sulphates and chlorides of calcium and magnesium (the so-called 'permanent hardness') are regarded as more objectionable than the bicarbonates or 'temporary hardness.' Again, there are many who view the presence of the salts of magnesium with more suspicion than those of calcium, and, indeed, magnesian waters are very generally credited with the power of causing phosphatic calculi, goitre, and cretinism. On this account it has sometimes happened that waters which were otherwise of most unimpeachable quality have been discarded in consequence of their containing a few parts per 100,000 of magnesia. All these views concerning the influence of calcium and magnesium salts are, however, based upon very unsatisfactory evidence. The Rivers Pollution Commissioners, in prosecuting their inquiry into this subject, found that 'where the chief sanitary conditions prevail with tolerable uniformity, the rate of mortality is practically uninfluenced by the softness or hardness of the water supplied to the different towns, and the average rate of mortality in the different water divisions varies far less than the actual mortality in the different towns of the same division. They were of opinion that, whilst waters of excessive hardness may be productive of calculus and perhaps other diseases, soft and hard water, if equally free from deleterious organic substances, are equally wholesome.' The question of magnesia in drinking water has been discussed by the writer ('What is the Importance of Magnesia in Drinking Water,' P. F. Frankland, Transactions of the Internat. Congress of Hygiene and

Demogr. London, 1891), from whose inquiry it appears that whilst the amount of magnesia in the water supplied to most large towns is very small—generally not more than 1–2 parts of MgO per 100,000—it is much larger than is generally supposed in the well-water consumed by such a large portion of the population. Thus in the case of fifty brewery waters from all parts of the kingdom, the average amount of magnesia (MgO) was 3·41 parts per 100,000. It must also be remembered that the geological formation richest in magnesia (the magnesian limestone) is only very slightly represented in this country, so that the proportions of magnesia met with in the dolomitic districts of the Continent must be much larger.

Until, therefore, a far more searching inquiry than hitherto has been made into the alleged effect of such waters upon health, it would appear undesirable that any importance should be attributed to such proportions of magnesia as the above in drinking waters which are otherwise of unimpeachable purity.

The effect of Clark's process on magnesian waters is noteworthy. As a general rule, the proportion of magnesia removed by the treatment with lime is small—much smaller than that of the lime removed; but it is particularly worthy of notice that in cases where caustic soda was used in conjunction with lime, as is now frequently done in the softening of water for industrial purposes, the magnesia may be removed in greater proportion than the lime, and as a matter of fact magnesium hydroxide is less soluble even than calcium carbonate.

The hardness of water not unfrequently throws light upon its previous history, for the food of both man and animals is of necessity rich in lime, and nearly the whole of this is in adult life again found in the liquid and solid excreta; hence water obtained from soil which has been much polluted with animal matters always exhibits a large amount of permanent hardness.

PURIFICATION OF DRINKING WATER.

Inasmuch as the impurities are either suspended or dissolved, mineral or organic, and the organic either animate or inanimate, it follows that the subject of purification may be considered from different points of view, according to the particular class of impurities the removal of which is under discussion. Until recently all the more important processes of drinking water purification were filtration processes, those depending upon precipitation being more especially of importance in connection with water for industrial purposes (*see* p. 706). Now, however, methods of more or less sterilising water by means of hypochlorites, ozone, or ultra-violet light are sometimes being resorted to (*see* p. 734).

Purification of drinking water on large scale. All surface water is liable to turbidity, and in times of rain and flood the amount of suspended matter may become excessive. It is, therefore, desirable that all surface water, even that from upland sources, should be submitted to purification before distribution for domestic purposes. The purification of surface water is best initiated by permitting the water to remain at rest in storage reservoirs for some days or even weeks, the greater part of the suspended matter thus becoming precipitated, and some destruction even of the dissolved organic matter also taking place. During storage most important biological changes also take place (*see* later). The process of filtration resorted to on the large scale is almost invariably that through sand of different degrees of coarseness. This method was inaugurated by Simpson, the engineer to the Chelsea Company in 1829, and has since been adopted in an ever-increasing number of places all over the world. The filter beds, as usually constructed, are 10–16 ft. in depth, often upwards of an acre in area, made water-tight with masonry, concrete, or puddled-clay walls. On the bottom are collecting drains, upon which is placed a layer of broken stone about 6 ins. in thickness, following upon which are layers of coarse gravel, fine gravel, and uppermost a stratum of fine sand, 1–4 ft. in thickness. The water is kept at a depth of 1–4 ft. above the surface of the fine sand, the rate of filtration varying in different works. For construction and cost of filtration plant, *see* Don and Chisholm, Modern Methods of Water Purification, London, 1911, 125. The greater part of the suspended impurities is retained in the downward passage of the water by the first few inches of fine sand, which sooner or later, sometimes in the course of a few weeks, causes the clogging of the filter. When the rate of filtration is too much retarded for practical purposes, the fouled surface of the sand is removed, after which the filtration can be continued until the filter is again choked, when the surface is again scraped off, the process being repeated until the stratum of sand becomes too thin to be efficient, after which the original thickness of the sand-layer is restored by means of washed sand. The sand scraped off is generally thoroughly washed, allowed to dry, and then used again. The particulars for the several sections of the Metropolitan supply, shown opposite, will serve to illustrate the method of working.

Besides the filter beds just described, some of the works drawing from the Thames are now using an auxiliary process of filtration through the natural gravel beds which form the banks of the Thames at Hampton. These gravel beds are at all times full of water, which forms, as it were, an underground river, and underground pipes are laid in this gravel and connected with a pumping well in order to utilise this water, which is always clear and bright in consequence of the natural filtration which it has undergone. In order to increase the supply of this underground water the gravel bed is flooded with water directly from the Thames, for which purpose a second series of perforated pipes are laid parallel to the first and placed at a distance of about 30 yards from them. This second series of pipes is placed in direct communication with the Thames, but at the point of ingress is placed a small vertical sand filter to arrest the coarser impurities.

Such sand filters, although very efficient in removing the suspended matter, have comparatively little action upon that which is dissolved. Thus the following figures exhibit the composition of the York water supply, before and after filtration through sand :—

(Results of analysis expressed in parts per 100,000.)

	Before filtration	After filtration
Total solid matters	28·40	26·20
Organic carbon	0·123	0·119
Organic nitrogen	0·025	0·022
Ammonia	0	0
Nitrogen as nitrates and nitrites	0·077	0·089
Chlorine	1·6	1·6
Temporary hardness	11·5	10·9
Permanent hardness	7·1	7·1
Total hardness	18·6	18·0
Micro-organisms (colonies yielded by 1 c.c. of water on cultivation with gelatin-peptone)	31,200	122

It was formerly supposed that such sand filtration could have little or no effect in removing the micro-organisms present in water, as the interstitial spaces between the grains of sand are so large in comparison with the minute dimensions of the microbes. It was first shown by Koch in Germany, and by the writer in this country, that nearly all the microbes in water may be removed by the sand-filters (Koch, Bericht der Deputat. f. die Verwaltung der Canalisationswerke, Berlin, 1883; P. F. Frankland, Proc. Roy. Soc. 1885; Proc. Inst. Civ. Engineers, 1885–6; J. Soc. Chem. Ind. 1885, 1887), and this result has been since confirmed by many other investigators.

It was, in fact, supposed by Koch and his pupils that the sand filtration really removed *all* the microbes originally present in the water, and that those always found in the filtered water had gained access subsequent to filtration. The writer had, however, from the first shown that in the case of his regular examinations of the London water supply there was an obvious relationship between the number of microbes in the unfiltered and filtered waters respectively, necessitating the conclusion, therefore, that the sand filters can only be credited with removing *a portion and not the whole of the micro-organisms present.* This is sufficiently conspicuous from the tables on next page, which record some of the writer's results obtained with the London water supply during the year 1886, and reported to the Local Government Board (P. F. Frankland, J. Soc. Chem. Ind. 1886). The unfiltered Thames water was in every case collected near the intakes of the several water companies at Hampton, and the filtered water from the mains of the Chelsea, West Middlesex, Southwark, Grand Junction, and Lambeth Companies respectively.

METROPOLITAN WATER SUPPLY, JANUARY, 1911.

District works	Number of days' storage	Filtering area per million gallons of the average daily supply of 1910	Thickness of sand on filters		Average rate of filtration per square foot per hour

Monthly Reports by Metropolitan Water Examiner to Local Government Board.

C. Fraenkel and Piefke (Zeitsch. Hygiene, 8, 1890, 1–40) subsequently demonstrated by direct experiment that particular species of bacteria purposely introduced into the unfiltered, were still present, although in greatly-diminished numbers, in the filtered water.

The wonderful efficiency of these sand filters in removing microbes was at first very difficult to account for, but it is now recognised to depend upon the impervious nature of the slimy deposit which forms upon the surface of the sand, and until such a coating has been established the filter has but little effect in removing micro-organisms (Piefke, Aphorismen über Wasserversorgung, Zeitsch. Hygiene, 7, 1889, 115–170). This slimy deposit consists not only of silt, mud, and colloidal matter, but also of a multitude of living forms—diatoms, green and blue algæ, innumerable bacteria, fungi, and protozoa. Many of these forms actually feed on bacteria. The rate at which filtration is carried on is also a most important factor, the more rapid the rate the less efficient being the purification (P. F. Frankland, Proc. Inst. Civ. Engineers, 1885–6). Although the removal of bacteria is not attributable to the sand particles as such, there is abundant evidence that the finer the sand and the greater its depth the more efficient is the filtration. This is doubtless due to a better support being given to the filtering skin, and to the finer and thicker layer of sand regulating the passage of water through the medium, whilst the water is also brought into more intimate and prolonged contact with the colloidal matter with which the sand of a matured filter is clothed. The statistics of the London waterworks show that the cost of filtration as carried out by them averages about 0·6*d.* per 1000 gallons.

In countries liable to extreme cold—indeed, even in cold winters in this country—the process of sand filtration offers great difficulties, in consequence of the freezing of the filters; and this has, in Berlin, been guarded against by the construction of a number of covered filter-beds. In the United States, where the same difficulty exists, the Hyatt system of filtration has been employed on a considerable scale. In this the water is first treated with a minute quantity of alum (about ¼ grain per gallon), after which it passes through a steel filtering chamber, consisting of a vertical cylinder the diameter of which is nearly twice its height. This cylinder is divided by a horizontal diaphragm, capable of withstanding the hydrostatic pressure necessary for rapid filtration. The lower half contains the filtering material, composed of 2 parts coke and 3 parts sand. The upper part of the cylinder is used for washing the filtering material, which at regular intervals is transferred into it in a state of violent agitation by hydraulic currents, the impurities flowing away through pipes situated near the top of the cylinder. In the process of filtration the water is admitted through pipes to the upper part of the lower section of the cylinder, and it is drawn off through perforated cups, which permit the water, but not the sand, to pass. It is claimed that the efficiency of the system depends more upon the successful precipitation and entanglement of germ life by the coagulant alumina than upon any special merits of the filter (Potable Water, Floyd Davis, Iowa, U.S. 1891). The cost of maintenance is said to be only one-fifth of that entailed by filter beds.

In recent years the use of mechanical filters has been gaining ground in Great Britain also, the Jewell, Bell, and Candy filters being those most commonly employed (*see* Modern Methods of Water Purification, Don and Chisholm, London, 1911; *see* also *Bacteriology of water*, below). The Puech-Chabal system consists in submitting the water to successive processes of filtration, sometimes as many as six stages, beginning with coarser grades of gravel and ending with fine sand, being employed. It is specially suitable for very turbid waters, as the life of the fine sand filter is greatly prolonged.

It has been used at Magdeburg and other places (*see* Don and Chisholm, *l.c.*).

Of other methods of drinking-water purification on the large scale the only one that need be mentioned is Anderson's. The method consists in passing the water slowly through revolving iron cylinders about two-thirds filled with iron borings. A small quantity of the iron continuously passes into solution, so that the water becomes impregnated with ferrous iron, which subsequently, when the water flows into a settling tank, is converted into the ferric state with precipitation, a large proportion of the organic matter in solution being removed in the process, whilst a very considerable diminution in the number of vital germs is also effected. After undergoing oxidation in the settling tank, the water is finally filtered through sand before distribution. It takes 3½ mins. for the water to pass through the rotating cylinder, the entire process occupying about 6 hours (Anderson, Proc. Inst. Civ. Engineers; Engineering, 39, 525). This process has been used on a large scale at Antwerp and Paris.

Purification of drinking water on the small scale. The filtration of water on the small scale was already known to the ancients. Thus Pliny mentions vessels in which water was clarified by passage through wool. An immense number of different materials have been employed during recent years, but space will only permit of the brief consideration of a few of the more important ones.

Animal charcoal is employed in a number of common household filters, and from the invaluable services which it yields in sugar-refining it was anticipated that it would be highly efficient as a water filter. Unlike sand, it not only acts upon the suspended matters, but also removes a considerable proportion of the dissolved organic matter, and even some of the temporary hardness. Unfortunately, however, its action is very transient, and it generally soon becomes the seat of numerous organic growths, which are favoured by the calcium phosphate it contains, and the filtered water is then often rendered more impure than the unfiltered.

Vegetable charcoal has but little effect on the dissolved organic matters, although if in a sufficiently fine state of division it is an excellent strainer for suspended impurities (*see* table below).

Bischof's spongy iron, obtained either by reduction of hæmatite or of roasted pyrites, has a remarkable power of removing dissolved organic matters, as well as temporary hardness and nitrates, and this power is far more permanent than that of animal charcoal. It was for some time also employed on the large scale, in conjunction with sand, at the Antwerp Waterworks. The effect of filtration through animal charcoal and spongy iron respectively is exhibited in the table below.

Since the recent great advances in bacteriological science, it has become evident that the removal of micro-organisms from drinking water is a matter of much greater importance than the removal of organic matter, and hence it is in respect of this property that the value of filters is now generally estimated. The writer has shown (The Removal of Micro-Organisms from Water, P. F. Frankland, Proc. Roy. Soc. 1885) that several substances—such as coke, wood-charcoal, spongy iron, &c.—in a sufficiently fine state of division are capable of entirely removing all microbes in water passed through a stratum of a few inches of these materials. This power, which is quite independent of any chemical action (thus in the case of coke and wood-charcoal there is little or no removal of dissolved organic matter), is, however, not maintained unless the materials are frequently renewed; and in the case of animal charcoal which has been in use for a short time (one month) the number of microbes was found to be far greater in the filtered than in the unfiltered water. The most conspicuous instance of biological, as opposed to chemical, filtration is furnished by Chamberland's unglazed porcelain filter, which entirely removes microbes, but has no chemical action whatever (*see* table below).

(Results of Analysis expressed in parts per 100,000.)

[1] Riv. Commis. 6th Rep.

[2] P. F. Frankland, J. Soc. Chem. Ind. 1885.

[3] P. F. Frankland, Proc. Roy. Soc., 1885, 390.

A number of household filters in actual use have been examined with regard to their power of removing microbes by Plagge (Public Health Section of Germ. Assoc. of Naturalists and Physicians, 1886), who divides them into six classes, according to the materials used: (1) *carbon filters*, (2) *stone and sand filters*, (3) *spongy-iron filters*, (4) *paper filters*, of several kinds, (5) *porous earthenware filters* (Chamberland), (6) *asbestos filters* (Breyer, Hesse, Arnold, and Schirmer). The carbon filters were found not only to admit of the free transmission of microbes, but in some cases the numbers in the filtrate greatly exceeded those in the unfiltered water. Thus in one case 68 colonies were obtained from 1 c.c. of the unfiltered, and 12,000 from 1 c.c. of the filtered, water. The stone and sand filters were all found to be worthless. The spongy-iron filter yielded the following results: unfiltered water, 38,000 colonies from 1 c.c.; filtered, 18,000–24,000 colonies from 1 c.c. The paper filters all yielded very unsatisfactory results; the earthenware and asbestos filters, on the other hand, gave in nearly every instance a filtrate practically free from microbes. (For particulars concerning the sterilising power of the Chamberland filter, *see* also Miquel, Analyse Bactériologique des Eaux, Paris, 1891.) The principal drawback to these porous earthenware filters is the rapid diminution in the rate of filtration which they exhibit. More satisfactory in this respect are the Berkefeld filters, similarly constructed of burnt infusorial earth (Nordtmeyer, Zeitsch. Hygiene, 1891, 10, 145; Bitter, *ibid.* 155). Neither the Chamberland nor Berkefeld filters permanently yield sterile water, some of the bacteria in the unfiltered water sooner or later growing through the pores. It is, however, doubtful whether any of the ordinary pathogenic bacteria would do this, as none of them are known to actually multiply extensively in ordinary drinking water (Kübler, Zeitsch. Hygiene, 1890, 10, 48).

Purification of drinking water by distillation. This is, of course, the most effectual mode of freeing water from all its impurities. It is resorted to, on a considerable scale, at sea, both for steam and sailing vessels. (For description of forms of apparatus in actual use *v.* Fischer, Technologie d. Wassers, Brunswick, 1880, 201–208.) The insipid taste of the distilled water can be removed either by aëration, or by filtration through animal charcoal or other porous substances. Distilled water is also employed to some extent for the manufacture of aërated waters and for artificial ice.

Purification of drinking water by boiling. The purification consists, of course, only in the destruction of living organisms present in the water, but this is from an hygienic point of view of the greatest importance. In its action it is far more reliable than any process of filtration, and should be invariably resorted to in the case of waters which bear any suspicion of sewage contamination. The vapid taste of the boiled water may be removed by passage through a filter, which, however, should be exclusively employed for this purpose and not for filtering unboiled water. A convenient form of apparatus for sterilising large quantities of water—*e.g.* for hospitals, barracks, &c.—is described by Miquel (Manuel d'Analyse bactériologique des Eaux, Paris, 1891, 188). The more extensive use of boiled instead of filtered water is one of the chief sanitary desiderata of the day. Although absolute sterility cannot be *guaranteed* by a few minutes' ebullition, yet the reduction in the number of microbes by this simple process is so great that it may be safely regarded as ample for practical purposes. Thus Miquel and Wada (*ibid.* 185) found in the case of the Ourcq canal water of Paris:—

WATER FOR INDUSTRIAL PURPOSES.

Of the numerous industrial uses to which water is put, the most general and important is the raising of steam. The composition of the water supplied to steam-boilers is a matter of great consequence, as the use of unsuitable water may cause the corrosion of boiler-plates and the formation of deposits, which not only occasion a serious loss of heat but may also lead to most disastrous explosions (*v.* BOILER INCRUSTATIONS AND DEPOSITS).

Water for other industrial purposes. (1) For *brewing*, *see* art. BREWING. For use in bakeries, the water should be in all respects of the same degree of purity as is demanded for drinking purposes.

(2) For the *textile industries* the character of the water employed is often of great consequence. Thus in bleaching and dyeing the presence of iron and manganese, even in very small quantities, is highly deleterious, giving rise to iron and manganese stains on the bleached goods, and causing spots and modifications in the shades of dyed materials. Hard water, again, involves the use of larger quantities of alkali and soap in the several operations of boaking, scouring, and milling, and the insoluble lime-soap is left adhering to the fibre, often preventing the subsequent application of mordant or dye. In those operations, again, in which dyed fabrics are soaped, the lime-soap often injures the brilliancy of the colour, whilst in other cases the earthy soaps precipitated on the fibre act as mordants, and attract the colouring matters on those parts of the goods where it is not wished to fix them. In general, hard water has the effect of dulling many colours, and if due to bicarbonates retards, or even prevents, the dyeing of such colours as require an acid bath (*e.g.* cochineal scarlet). In some cases hard water containing bicarbonates wastes the mordants by precipitation in the bath instead of on the fibre, whilst it is sometimes actually beneficial for the washing of goods which have been mordanted with basic mordants. Such water is unsuitable for the solution of many coal-tar colours—*e.g.* methyl violet—a portion of the latter being lost as a tarry precipitate, whilst the goods are often spotted. For dyeing with some colours—*e.g.* alizarin and logwood—the presence of a certain amount of lime is almost indispensable; a pure water to which a know

quantity of lime-salt has been added is, however, preferable to a naturally hard water, especially if the latter is of variable composition. Water containing alkaline carbonates is sometimes advantageous, *e.g.* in wool-scouring, and in those dyeing operations in which the addition of sodium carbonate is prescribed; but in mordanting, in the dyeing with many colours, and in the washing of dyed goods, it is often very prejudicial; in these cases it should be neutralised with sulphuric or acetic acid. Acid waters are generally highly injurious, and should be neutralised with sodium carbonate. Sulphuretted hydrogen in water is also very objectionable in many operations of dyeing, more especially in mordanting with metallic salts (Hummel, Dyeing of Textile Fabrics). For the manufacture of *paper*, water containing iron is highly objectionable, giving rise to stains, whilst the presence of hardness is objectionable in causing the decomposition of the rosin-soap.

(3) For *tanning*, pure water is also a desideratum. Water much contaminated with organic matter causes injury to the surface of the leather, and sometimes a corrosion from the flesh-side of the skin. Water containing carbonic acid, or the bicarbonates, or calcium and magnesium sulphates, causes the hides to swell, whilst the chlorides prevent the swelling, and hence sea-water cannot be employed for the purpose. Hard water occasions a less perfect utilisation of the tanning materials, and an excess of chlorides retards the tanning process and causes the leather to attract moisture; the presence of iron is not so objectionable as is commonly supposed (Fischer, Das Wasser, 49–51).

(4) In *sugar-refining* the sulphates and alkaline carbonates are more productive of molasses than the chlorides, whilst nitrates are specially objectionable, as they prevent the crystallisation of six times their weight of sugar (Fischer, Technologie d. Wassers, p. 286).

Purification of water for industrial purposes.

As already pointed out, some substances, although unobjectionable in drinking water, operate prejudicially when the water is employed for many industrial purposes, and numerous methods have been devised for removing these impurities or for counteracting their effects. But few methods of purification have found favour in actual practice, and to these alone will any attention be given here. The processes which have for their object the removal of matters in suspension and organic substances have been already described under *Purification of drinking water* (*v.* p. 702), whilst the processes intended for the improvement of industrial water supplies are chiefly directed to the removal of lime and magnesia salts in solution, which, as has been shown above, interfere with the success of so many industrial operations. This removal of lime and magnesia salts is frequently spoken of as 'water-softening,' in consequence of the water after such treatment requiring less soap when used for washing purposes.

Purification with lime (Clark's process). This method of purification was first proposed by Clark, of Aberdeen, in 1841, and consists in the decomposition of calcium bicarbonate or 'temporary hardness' of water by the addition of a suitable quantity of slaked lime, according to the equation

$$\underset{\text{Calcium bicarbonate}}{CaH_2(CO_3)_2}+Ca(OH)_2=\underset{\text{Calcium carbonate}}{2CaCO_3}+2H_2O.$$

Thus both the lime in solution as bicarbonate as well as that added in the form of hydroxide are precipitated as normal carbonate, which is almost insoluble in water. The calcium hydroxide is sometimes added in the form of milk of lime, sometimes in that of clear lime-water, but the latter is far preferable, as the quantity added can be more easily controlled and an excess avoided. The necessary quantity of calcium hydroxide is most easily ascertained by adding such an amount that, after thorough mixing, a small quantity of the water taken out yields a yellow or brown colour with a solution of silver nitrate, more water is then added, until, on similarly testing, no coloration with the silver nitrate is obtained. This test should invariably be resorted to even in the case of such waters as are of very constant composition, and which, therefore, admit of the lime being proportioned by experience, as otherwise an excess or deficiency of lime is nearly sure to result. In its original form the Clark process is carried out in large tanks in which the water can remain at perfect rest for about 16 hours, although by the use of a floating exit-pipe the clear surface water can often be drawn off after 2 or 3 hours, and before the whole of the precipitate has reached the bottom. This method has been most successfully employed on a large scale at the Colne Valley Waterworks, near Bushey, at Canterbury, Caterham, and many other places on a small scale. The 'temporary hardness' only is, of course, removed, and even this not completely, as under the most favourable circumstances a small proportion of calcium carbonate remains in solution, whilst in the case of waters containing magnesium bicarbonate the removal of the latter is generally far less complete. In addition to these bicarbonates, the salts of iron and much organic matter are also removed.

In order to obviate the large amount of storage capacity required for Clark's process, several modifications have been introduced, in which the precipitate formed by the treatment with lime is either removed by filtration or made to rapidly subside by artificial means. The most notable of these improved processes are the so-called 'Porter-Clark,' in which the precipitate is removed with a filter-press, and Gaillet and Huet's process, in which subsidence is promoted by causing the water to take a circuitous zig-zag and upward path after the addition of the lime. In this latter process both lime and caustic soda are frequently employed in conjunction as the softening agents; in this manner both 'temporary' and 'permanent' hardness can be, to a great extent, removed, thus:—

$$CaH_2(CO_3)_2+2NaOH=CaCO_3+Na_2CO_3+2H_2O$$
$$CaSO_4+Na_2CO_3=CaCO_3+Na_2SO_4.$$

Space does not permit the description of a number of other water-softening apparatuses which are now on the market, and which only differ from each other in the special mechanical devices for supplying the chemicals (milk of lime, lime water, sodium carbonate, or caustic soda, as the case may be) and for removing the deposit. The Archbutt-Deeley process, however, possesses certain features of interest. In this the clarification of the treated water is accelerated by stirring it up with the sludge of calcium carbonate obtained in previous precipitations, this being effected by blowing in compressed air through perforated pipes. The subsequent sedimentation takes place very rapidly, and the clear water is drawn off from the surface by means of a floating arm. Further, the danger of subsequent deposition of calcium carbonate in the service pipes, which often occurs when an insufficient time is allowed for sedimentation, is avoided by injecting carbon dioxide (obtained from a coke-stove, the gas being scrubbed with limestone to remove sulphur compounds) into the clarified water as it is drawn from the settling tank.

Magnesia has also been employed to a limited extent for softening instead of lime. Under these circumstances the following reactions may take place, especially if heat is applied :—

$$CaH_2(CO_3)_2+MgO=CaCO_3+MgCO_3+H_2O$$
$$MgCO_3+CaSO_4=CaCO_3+MgSO_4$$
$$MgCO_3+CaCl_2=CaCO_3+MgCl_2$$

(Fischer, Chem. Technol. d. Wassers, Brunswick, 1880, 264).

The formation of magnesium chloride is obviously disadvantageous for boiler purposes.

A number of other processes of chemical purification have from time to time been suggested, but none of them has met with any great success. Thus attempts have been made to utilise the following reactions :

$$CaH_2(CO_3)_2+Ba(OH)_2=CaCO_3+BaCO_3+2H_2O$$
$$CaSO_4+Ba(OH)_2=BaSO_4+Ca(OH)_2$$
$$CaSO_4+BaCl_2=BaSO_4+CaCl_2$$
$$CaH_2(CO_3)_2+\underset{\substack{\text{Sodium}\\ \text{oxalate}}}{C_2O_4Na_2}=\underset{\substack{\text{Calcium}\\ \text{oxalate}}}{C_2O_4Ca}+\underset{\substack{\text{Sodium}\\ \text{bicarbonate}}}{2NaHCO_3}$$
$$CaSO_4+C_2O_4Na_2=C_2O_4Ca+Na_2SO_4$$
$$CaCl_2+C_2O_4Na_2=C_2O_4Ca+2NaCl$$
$$CaH_2(CO_3)_2+2HCl=CaCl_2+2CO_2+2H_2O$$

In the *Permutite* process, devised by Dr. Gans of Berlin, the water is softened by filtration through artificial zeolite (a hydrated silicate of alumina and soda) to which the name of *Permutite* has been given. The latter is made by fusing together silica or quartz, alumina or china-clay, and sodium carbonate. The fused mass is extracted with water, a crystalline body ($SiO_2=46$, $Al_2O_3=22$, $Na_2O=13{\cdot}6$, $H_2O=18{\cdot}4$ p.c.) being obtained. When waters containing calcium or magnesium salts are filtered through this material, the following reactions take place :—

$$Na_2Al_2Si_2O_8+CaCO_3=Na_2CO_3+CaAl_2Si_2O_8$$
$$Na_2Al_2Si_2O_8+CaSO_4=Na_2SO_4+CaAl_2Si_2O_8$$

It is claimed for this process that the whole of the hardness is removed and that the calcium or magnesium zeolite formed can be reconverted into the original permutite or sodium zeolite by treatment with a strong solution of common salt.

Gans uses a manganese-permutite (silica, alumina, and a higher oxide of manganese) for the removal of iron and manganese in water. This material can be regenerated by treatment with a solution of potassium or calcium permanganate. The manganese-permutite can also be employed for the sterilisation of wat the water is treated with permanganate sufficient concentration to destroy bacteria, and on subsequent filtration through mangane permutite, the whole of the manganese is sa to be retained by the filter. Calcium-permuti has been used for removing potash from molass lime passing into solution; the lime may replaced by soda by passing through sodium permutite.

For the effect of softening processes on th bacteria in water, *v.* p. 732.

The action of water on lead, zinc, copper, an aluminium. The action of water on thes metals, and especially on lead, is of grea importance in connection with the distribution and storage of water. The Roman employed leaden pipes, and Vitruvius and Gale were aware that some waters were thereby rendered deleterious. On the other hand certain waters have so little action on lead tha pipes of this material have been in use for upwards of 200 years without showing any trac of corrosion (Fischer, Technologie d. Wassers 317). As a general rule, hard waters, and mor especially those containing bicarbonates, do n act on lead; the greater number of activ waters are soft, and generally entirely destitut of bicarbonates. The activity has been ascribe by different authorities to the presence absence of a great variety of ingredients in th water—*e.g.* the presence of dissolved air (Yorke ammonium nitrite (Medlock), ammonium carbonate (Böttcher). Some have contended tha organic matters diminish the activity (Horsford others that they increase it (Hofmann, Graham Miller, and Noad). The latter authorities wer of opinion also that the presence of dissolve oxygen and the absence of more than 3 vol of carbon dioxide in 100 vols. of water ar amongst the conditions necessary for the attac upon lead. It has also been contended that minute proportion of calcium phosphate prevent a soft water from attacking lead (Riv. Pollu Commiss. 6th Rep. 224), whilst according others, again, the protecting ingredient is sili (Crookes, Odling, and Tidy, Report on the Acti of Water on Lead, London, 1886). In man cases the activity of the water is due to th presence of organic acids (Allen), this bein doubtless a fruitful cause of moorland wate acting on lead. The activity of many waters confined to new untarnished lead, whilst othe continue to act, sometimes with increas vigour, on the old and tarnished metal (P. Frankland, The Action of Water on Lead. Soc. Chem. Ind. 1889, 241).

Numerous expedients have been resorted in order to destroy this activity of some waters. When acidity is the presumable ca the most obvious remedy is the filtration of water through finely-divided limestone; in prac tice, however, this is found to be only of tem porary service, as the surfaces of the limest become coated with a film which prevents th being further acted on by the water. It has be found more effective to continuously mix water with a milk of finely-divided calc carbonate, and allowing this to subside be the water is distributed.

It is now generally admitted that the ac of water on lead is of two different kinds.

these the most obvious is that due to the acidity[1] of some waters, such acidity may be due to organic or even mineral acids, and can be determined by titration with appropriate indicators. Such acid waters have, in general, a continuous action on lead. The acidity can, of course, be neutralised by the addition of lime, finely-divided calcium carbonate, or most effectively by sodium carbonate. It was, however, shown many years ago by the writer that such neutralisation does not necessarily entirely stop the action of the water on lead, and that this is often only secured by adding a considerable excess of sodium carbonate. Similarly there are many natural waters, which, although slightly alkaline with small proportions of calcium bicarbonate, nevertheless act on lead. Such action of neutral or even slightly alkaline waters is now usually termed '*erosive*' as distinguished from the '*plumbosolvent*' action of acid waters. These remarkable phenomena have only received a satisfactory explanation since the recent advances in physical chemistry have illuminated the subject of chemical equilibrium.

This matter is very ably dealt with in an important paper by Paul, Ohlmüller, Heise, and Auerbach (Arbeiten a. d. kais. Gesundheitsamte, 1906, 23; Untersuchung über die Beschaffenheit des zur Versorgung der Haupt- und Residenzstadt Dessau benutzten Wassers, insbesondere über dessen Bleilösungsfähigkeit). The conclusions arrived at by these authors are :—

1. *Dissolved oxygen* is necessary for the solution of metallic lead in pure water. Experiments made with distilled water, which had been saturated with air freed from carbon dioxide, showed that nearly the whole of the oxygen (amounting to about 9 mgms. per 1 litre) was taken up presumably according to the equation :

$$2Pb+2H_2O+O_2=2Pb(OH)_2.$$

The water, which was at 18°, took up about 115 mgms. of lead per 1 litre. By increasing the proportion of oxygen in the air used for saturating the water the amount of lead taken up was at first also increased (up to about 140 mgms. Pb per 1 litre), but this was followed by a sudden drop to an amount which remained practically constant (about 108 mgms. per 1 litre for about 14·5 mgms. O_2 dissolved in 1 litre water). This sudden drop is referred to the appearance of a precipitate (*solid phase*) preventing further supersaturation of the water with lead hydroxide. (The authors did not determine the exact composition of the solid phase, which may have been $Pb(OH)_2$, or more probably one of its anhydrides.)

2. *Free carbonic acid* diminishes the plumbosolvent effect of the simultaneously present dissolved oxygen. Thus, in an experiment with distilled water made to contain about 8 mgms. O_2 and 40 mgms. CO_2 in 1 litre, the amount of lead taken up was about 11 mgms. per 1 litre, or about $\frac{1}{10}$ of that dissolved when the same proportion of dissolved oxygen was present in the absence of carbonic acid. This diminished plumbosolvency is, of course, attributable to the formation of a more insoluble solid phase, viz. either $PbCO_3$, or more probably some basic carbonate such as $2PbCO_3,Pb(OH)_2$.

3. *Sodium bicarbonate* in the absence of any appreciable quantity of free carbonic acid greatly reduces the plumbosolvency of water, thus in similar experiments, in which the same proportion (about 9 mgms. O_2 per 1 litre) of dissolved oxygen was retained, but along with 35 mgms. of $NaHCO_3$ per litre, the amount of lead taken up was only 0·6 mgms. per litre of water. This, again, is attributable to the diminished solubility of the solid phase in the solution of the sodium bicarbonate. The amount of lead taken up by the water is limited by the *solubility product;* thus a saturated solution of lead carbonate will contain a small concentration of $PbCO_3$ molecules, together with $Pb^{\cdot\cdot}+CO_3''$ ions, of which only the $PbCO_3$-molecules are in direct equilibrium with the solid phase (precipitated lead carbonate). The concentration of the $PbCO_3$ molecules will always remain constant as long as there is any of the solid phase present, but this concentration is very small. The concentration of the ions, on the other hand, is determined by the dissociation equilibrium. Thus, representing the molecular concentrations of the respective bodies by the formulæ enclosed in brackets, we have—

$$[Pb^{\cdot\cdot}]\times[CO_3'']=k\times[PbCO_3],$$

in which k is a constant. But in saturated solutions, as already seen above, $[PbCO_3]$ is constant, therefore $k\times[PbCO_3]$ is also constant, and can be represented by S, which is termed the *solubility product*, thus—

$$[Pb^{\cdot\cdot}]\times[CO_3'']=S$$

$$\therefore\ [Pb^{\cdot\cdot}]=\frac{S}{[CO_3'']}$$

which obviously signifies that the concentration of the $Pb^{\cdot\cdot}$-ions will be the smaller the greater the concentration of the CO_3''-ions. (If the solid phase is a basic carbonate, then it can be shown that the concentration of the $Pb^{\cdot\cdot}$-ions must be inversely proportional to the concentrations of the CO_3''- and the OH'-ions.)

In solutions of free carbonic acid the concentration of CO_3''-ions is very small (because carbonic acid being a very weak acid is only very slightly dissociated into ions), whilst in solutions of $NaHCO_3$ the concentration of CO_3''-ions is much greater, and, therefore, the concentration of the $Pb^{\cdot\cdot}$-ions will be correspondingly diminished, or, in other words, a much smaller proportion of lead will pass into solution. (It should be mentioned that the phenomena may be complicated by the circumstance that the nature of the solid phase may be different according as the metallic lead is placed in contact with a solution of free carbonic acid or bicarbonate respectively.)

4. The simultaneous presence of *free carbonic acid and sodium bicarbonate* leads to the following considerations :—

$$CO_2+H_2O \rightleftarrows H_2CO_3$$

further $H_2CO_3 \rightleftarrows H^{\cdot}+HCO_3'$, whilst to a much less degree $HCO_3' \rightleftarrows H^{\cdot}+CO_3''$. These dissociations are regulated by the equations

$$(1)\ [H^{\cdot}]\times[HCO_3']=k_1\times[H_2CO_3]$$

$$(2)\ [H^{\cdot}]\times[CO_3'']=k_2\times[HCO_3'].$$

in which the values

$$k_1=3{\cdot}04\times10^{-7}$$

$$k_2=1{\cdot}3\times10^{-11}$$

---

[1] See a very important paper on 'The Acidity and Alkalinity of Natural Waters,' by James Walker and S. A. Kay (J. Soc. Chem. Ind. 1912, 31, 1013).

are known (J. Walker and W. Cormack, Chem. Soc. Trans. 1900, 77, 5; Bodländer, Zeitsch. physikal. Chem. 1900, 35, 23).

From equation (2)

$$[\mathrm{CO}_3''] = k_2 \times \frac{[\mathrm{HCO}_3']}{[\mathrm{H}^{\cdot}]}$$

and combining this with equation (1) we have

$$[\mathrm{CO}_3''] = \frac{k_2}{k_1} \times \frac{[\mathrm{HCO}_3']^2}{[\mathrm{H}_2\mathrm{CO}_3]}$$

but with PbCO_3 as solid phase we had

$$[\mathrm{Pb}^{\cdot\cdot}] = \frac{\mathrm{S}}{[\mathrm{CO}_3'']}$$

which can, therefore, be written

$$\mathrm{Pb}^{\cdot\cdot} = \frac{\mathrm{S} \times k_1}{k_2} \times \frac{[\mathrm{H}_2\mathrm{CO}_3]}{[\mathrm{HCO}_3']^2}$$

But, inasmuch as free carbonic acid is very little, and sodium bicarbonate very much dissociated, the value of $[\mathrm{H}_2\mathrm{CO}_3]$ may be taken as proportional to the molecular concentration of the free carbonic acid, and $[\mathrm{HCO}_3']$ to that of the sodium bicarbonate, and thus *the concentration of the* $\mathrm{Pb}^{\cdot\cdot}$*-ions will be directly proportional to that of the free carbonic acid, and inversely proportional to the square of that of the sodium bicarbonate.*

This important theoretical deduction was experimentally verified by placing lead in contact with water containing 8·3 mgms. O_2, 35·3 mgms. NaHCO_3, and about 33 mgms. CO_2 per 1 litre, with the result that the amount of lead in solution was found to be about 1 mgm. per 1 litre, and thus slightly but distinctly greater than in the previous experiment in which there was no free carbonic acid present, and in which 0·6 mgm. Pb per 1 litre was taken up by the water.

In ordinary natural waters the phenomena are complicated by the simultaneous presence of other salts, especially chlorides and sulphates. Both PbCl_2 and PbSO_4 are considerably more soluble than the carbonate. On adding 71 mgms. $\mathrm{Na}_2\mathrm{SO}_4$ per 1 litre to the last artificial water mentioned above, it was found that the proportion of lead taken up was about tripled, being about 3 mgms. per litre. This increase must, of course, depend on the presence of PbSO_4 molecules in solution, and not on an increase in the concentration of the $\mathrm{Pb}^{\cdot\cdot}$-ions, which it was shown was already fixed by the concentrations of the carbonic acid and bicarbonate. Now by removing some of the free carbonic acid (*e.g.* by adding $\mathrm{Na}_2\mathrm{CO}_3$) the concentration of the $\mathrm{Pb}^{\cdot\cdot}$-ions will be diminished, and this will have the effect of also diminishing the amount of lead in solution due to the solubility of the PbSO_4, for the amount of undissociated PbSO_4 is dependent on the concentration of the $\mathrm{Pb}^{\cdot\cdot}$-ions, and if the latter be, through any cause, diminished, the amount of undissociated PbSO_4 must be diminished also, with the result that the total amount of lead passing into solution will be less. This was experimentally verified by using the same artificial water as in the last-mentioned experiment, excepting that by the addition of $\mathrm{Na}_2\mathrm{CO}_3$ the free carbonic acid was reduced to about 9·5 mgms. CO_2 per litre, and the NaHCO_3 consequently raised to about 128 mgms. per litre, with the result that the lead taken up amounted to only 1·3 mgm. per litre of water.

Experience has also shown that some waters act powerfully on lead when the pipes are charged intermittently, whilst the action becomes very much diminished if they are kept under constant pressure. The effect of pressure on the action ought, therefore, always to be specially determined (P. F. Frankland, J. Soc. Chem. Ind. 1889).

In investigating the action of water on lead, the water should either be put in contact with strips of the metal or placed in leaden pipes for a definite period of time, after which it should be removed and tested for lead *both in solution and suspension*, fresh portions of the water under examination are then placed in contact with the metal and again tested after a definite interval of time, this procedure being repeated a number of times. Thus it is often found that a water has a considerable initial action on the metal, but as the latter becomes coated with deposit, the action moderates and may practically cease altogether. Some waters, on the other hand, act continuously on the metal.

Some polluted waters have a very strong and continued action on lead (Riv. Pollut. Commiss. 6th Rep. 226), and in such cases the obvious remedy is the abandonment of the source.

It is worthy of note that hot water generally acts much more violently on lead than cold, and further that the lead dissolved in water is entirely removed by passage through any of the numerous forms of animal charcoal filters.

As regards the quantity of lead in water from which danger to health is to be apprehended, it is now generally admitted that water containing anything above one-twentieth grain of lead per gallon, or 0·07 part per 100,000, may, by continued use, produce mischief.

Of the action of water on zinc but little is known beyond the fact that many waters do act on it, and that it is therefore not to be recommended for the construction of cisterns, &c., in which drinking water is to be stored. The solution of the zinc takes place with special facility if metallic iron is also in contact with it (Heaton, Chem. News, 49, 85; P. F. Frankland, *ibid.* 115; Stevenson, *ibid.* 107).

Copper appears to be continuously acted on by water, especially if simultaneously in contact with air, and hence should not be used in connection with drinking water.

The action of water and other liquids on aluminium is now a matter of some importance owing to its use for domestic and industrial purposes (*see* An Investigation of Aluminium with Special Reference to its Suitability for the Construction of Brewery Plant, A. C. Chapman, J. Inst. Brewing, 1911). Although acted on by moist air the layer of oxide exerts a marked protection to further attack; alkalis and alkaline chlorides increase the tendency to corrosion. Chapman considers that it may be safely used for the construction of brewery plant, especially fermenting tuns and vessels intended for the treatment of chilled and filtered beers.

THE CHEMICAL ANALYSIS OF WATER.

As the qualitative analysis of the ingredients of water is of no practical importance, and involves no special methods, the quantitative examination will alone be considered here. In order that the analysis may be of any value, especially for sanitary purposes, it is of the greatest importance that the samples should have been collected with care.

Suspended matter. The suspended matter, if considerable in amount, should be separately determined, but if only present in minute quantity it is advisable to regard it as part of the dissolved matter, in which case it is necessary that the sample should be well shaken before taking out each portion for analysis, so that the suspended particles may be uniformly distributed. If it is decided to determine the suspended matter separately, the sample should be well shaken, and 250 or 500 c.c. measured out and passed through a filter previously dried at 100° and weighed. The matter on the filter is washed with distilled water, and dried at 100° until of constant weight. Some analysts prefer to dry at 105°, 110°, or even 120°, but in all cases the temperature should be specified. The filter and its contents are then incinerated in a coil of platinum wire and dropped into a weighed platinum crucible, gently ignited until free from organic matter, and then treated with a few drops of a solution of ammonium carbonate, and dried at 150°. The loss in weight represents organic matter and water of hydration. It is sometimes of importance to determine the proportion of carbon to nitrogen in the organic part of the suspended matter. For this purpose some of the suspended matter is collected on an ignited plug of asbestos or glass wool, transferred to a small flask, and boiled with 20 c.c. of sulphurous acid and some distilled water free from ammonia and organic matter, and then further treated, as in the determination of organic carbon and nitrogen, by the combustion process (*v.* p. 717). If the suspended matter has been thus separately determined, the remainder of the analysis should be performed on the water, after filtration through Swedish paper, rejecting the first 250 c.c. which pass through; or if the suspended matter completely settles on standing the clear water may be siphoned off. The suspended matter may, of course, in exceptional cases also have to be submitted to a complete mineral analysis, or examined for some special ingredient.

An ingenious method of determining minute traces of suspended matter has been devised by Dibdin (Analyst, 1896, 21, 2). In this method the volume of the moist suspended matter is measured in a capillary tube.

MATTERS IN SOLUTION.

Total solids. 250 or 500 c.c. of the water are evaporated to dryness in a weighed platinum dish on a water- or steam-bath, the dish being supported on a glass or porcelain, but not on a metallic, ring. The dish and residue are then dried until constant at 100°, 105°, 110°, 120°, or even at 180°. The residue may be further utilised for the determination of nitrates and nitrites by the mercury method (*v. infra*).

Ammonia. A measured volume of the water (varying from 100–1000 c.c., according to the proportion of ammonia present) is distilled in a capacious flask or retort connected with a Liebig's condenser, about 1 grm. of recently ignited sodium carbonate having been previously added. It is essential that the whole apparatus should have been carefully freed from ammonia immediately before use, which can be done by distilling some water in the apparatus until the distillate gives no reaction with Nessler solution. The remainder of the water in the flask or retort is then thrown away, and the measured quantity of the sample under examination introduced along with the sodium carbonate. The distillation should be carried on briskly, and the distillate collected in colourless glass cylinders of 50 c.c. capacity. If less than 500 c.c. has been used, this volume should be made up with distilled water free from ammonia before distillation. If the quantity of water has been well chosen, the whole of the ammonia will be found in the first three cylinders of the distillate, and in most cases it will all be contained in the first. The quantity of ammonia in each cylinder is estimated by adding 1 c.c. of Nessler solution, and comparing the coloration obtained with that similarly produced by known quantities of a standard solution of ammonium chloride, added to 50 c.c. of distilled water free from ammonia. The Nessler reaction is so delicate that by its means 1 part of NH_3 in 100,000,000 parts of water can be easily detected. The colour produced by more than 10–15 c.c. of a solution of NH_4Cl (containing 0·00001 grm. NH_3 per litre) is too deep for accurate comparison, and should one of the cylinders require more than this the determination must be repeated on a smaller volume of water. This may be generally avoided, however, by adding the Nessler solution to the second and third cylinders of distillate before the first, and if it is found that the second cylinder gives a colour requiring more than 5 c.c. of the above solution of ammonium chloride for its imitation the first cylinder should be diluted, and an aliquot part taken for testing with the Nessler reagent.

The Nessler solution is prepared by dissolving 62·5 grms. of potassium iodide in 250 c.c. of distilled water; set aside 10 c.c. of this, and run into the remainder a cold saturated solution of mercuric chloride until a permanent precipitate is formed, then add the above 10 c.c. of potassium iodide, which will cause its solution, after which very carefully add more of the mercuric chloride until a slight precipitate remains on stirring. Now add 150 grms. of potassium hydroxide dissolved in distilled water, and dilute the whole to 1000 c.c. After settling, decant the clear liquid into a bottle for use.

As the 'albuminoid ammonia' is commonly determined in one operation with the 'free' ammonia, the method of estimating the former will now be described, instead of considering it under the methods for determining organic matter, where it more properly belongs.

'Albuminoid ammonia' process. Whilst the determination of the free ammonia is being proceeded with as above, the solution of alkaline permanganate must be prepared for this process, as it is required immediately the free ammonia has passed over. The volume of the alkaline permanganate (for preparation *v.* below) taken must be at least one-tenth of the volume of the sample being distilled for ammonia, and it should not exceed that volume unless the water contains a very large amount of organic matter. The alkaline permanganate taken is then diluted with

four times its volume of distilled water, and boiled in a flask during the whole of the time that the distillation for free ammonia is going on as above, and when the latter is finished it is added to the water remaining in the distilling flask or retort (the whole volume in this must now be not less than 500 c.c.), and distillation is then continued until the distillate is free from ammonia. The distillate is collected and Nesslerised, as in the determination of free ammonia above. The ammonia thus evolved by distillation with alkaline permanganate is generally recorded as 'albuminoid ammonia' (*v.* p. 719). The alkaline permanganate solution is prepared by dissolving 200 grms. of potassium hydroxide and 8 grms. of pure potassium permanganate in 1100 c.c. of distilled water, then boiling the solution rapidly until concentrated to about 1000 c.c.

Chlorine. (*a*) *Mohr's method.* 50 or 100 c.c. of water are treated with a few drops of a solution of potassium chromate, and a standard solution of silver nitrate is then run in from a burette until the precipitate becomes of a faint but distinctly red colour. The water must be well agitated after each addition of the nitrate, the reaction depending upon the decomposition of the red silver chromate by dissolved chlorides with formation of silver chloride and soluble chromate. As soon as the last trace of chloride is precipitated as silver chloride, the red colour of the silver chromate makes its appearance. By using a solution of silver nitrate containing 2·3944 grms. per litre, the number of c.c. employed gives at once (if 50 c.c. of water have been taken) the parts of Cl per 100,000, whilst if 100 c.c. of water are taken the silver nitrate solution should be of double this strength.

Mohr's method cannot be employed if the water is acid, and if this is the case a given volume of the water should be boiled with an excess of pure calcium carbonate (free from chlorides), filtered, the filtrate made up to known volume, and the chlorine determined in a part of this. In the presence of reducing substances, much organic matter, sulphuretted hydrogen, and sulphites, the method is also inapplicable, and in such cases it is desirable to determine the chlorine gravimetrically, which should also be done if the proportion of chlorine is large.

(*b*) *Volhard's method.* 50 or 100 c.c. of the water are treated with an excess of decinormal silver nitrate, the mixture being well agitated so as to cause the silver chloride to settle in flakes; the latter is filtered off and washed, and then to the filtrate about ten drops of a cold saturated solution of iron-alum are added, and subsequently enough strong nitric acid (free from nitrous acid) to remove the colour of the ferric salt. Decinormal ammonium thiocyanate is then added from a burette, stirring well all the time, until the liquid acquires a light-yellow brown colour, which remains permanent on leaving the liquid at rest for about 10 mins. By deducting the number of c.c.'s of thiocyanate from that of the silver nitrate added, the remaining silver nitrate indicates the proportion of chlorine present in the water. The advantage of this method consists in its being applicable to acid liquids. The method depends upon there being no formation of red ferric thiocyanate until the whole of the silver in solution has been precipitated as thiocyanate (Annalen, 190, 24).

Nitrogen as nitrates and nitrites. A number of different methods have been devised for the determination of oxidised nitrogen; there are, however, only a few which have been largely adopted in practice, and such alone will be described here.

(*a*) *Crum's method.* This depends on the decomposition which nitrates and nitrites undergo when dissolved in strong sulphuric acid on being shaken up with mercury, and which leads to the evolution of the whole of the nitrogen as nitric oxide, the volume of which is then determined. The residue obtained in the estimation of the total solids (*see* p. 711) may be conveniently used for this determination also. This residue in the platinum or glass dish is repeatedly treated with a very small quantity of hot distilled water, which is brought into thorough contact with the residue by detaching the latter with a small glass rod covered with a piece o india-rubber. The aqueous extracts, which should in all not exceed about 10 c.c., ar passed through a small filter and collected in a little beaker. This aqueous extract, containing all the soluble salts in the water residue, is evaporated nearly to dryness on a water-bath after which it is dissolved again in a minimum quantity (1 or 2 c.c.) of water, and introduced into a Lunge nitrometer (Ber. 11, 434); the beaker is repeatedly rinsed with a few drops of hot water, and these rinsings added to the nitrometer. The beaker is then further rinsed with pure strong sulphuric acid (free from oxides of nitrogen), and this also is transferred to the nitrometer. About 1½ volumes of sulphuric acid must in all be used to 1 volume of aqueous extract. If the water contains soluble carbonates there will be an evolution of carbon dioxide when the sulphuric acid mixes with the aqueous extract; the gas should be allowed to collect *without shaking the tube*, and should then be expelled. The contents of the nitrometer tube are now violently agitated with the mercury, and then in the course of a minute or so the evolution of nitric oxide will commence, and the agitation should be continued as long as any gas continues to come off. If the water contains a considerable quantity of chlorides some hydrogen chloride may have been given off with the nitric oxide, but this may be removed by admitting a little water into the nitrometer. When the gas has cooled to the temperature of the air, its volume is measured at atmospheric pressure. The determination is rendered more accurate, especially if the quantity of nitrates and nitrites is only small, by measuring the nitric oxide in Frankland's gas apparatus, in which case the decomposition with mercury and sulphuric acid is effected in a small tube standing in a mercury trough, the evolved nitric oxide being then transferred to the gas apparatus (*see* Sutton's Volumetric Analysis). This method, which is by far the most convenient for ordinary water analysis, becomes inapplicable in the presence of very large quantities either of organic matter or of chlorides.

(*b*) *Methods of Schulze-Tiemann, and of Schlösing-Reichardt,* depend upon the decomposition of nitrates and nitrites by ferrous chloride and hydrochloric acid, and the measurement of the evolved nitric oxide. Of these methods, which closely resemble each other, the former, as the more convenient, need be alone considered here.

100–500 c.c. of the water are concentrated by evaporation to about 50 c.c., which are then introduced into a flask of about 150 c.c. capacity, provided with an india-rubber stopper, perforated by two narrow pieces of glass tubing, of which one (A) extends about an inch into the flask, and is constricted below, whilst the other (B) only just penetrates the stopper; the tube (B) is externally connected by means of a short piece of india-rubber tubing provided with a pinch-cock, with a delivery tube dipping into a trough containing 10 p.c. caustic soda solution previously boiled to expel air. The tube (A) is also connected with india-rubber and pinch-cock to another piece of glass tubing, which is allowed to hang vertically downwards. The water in the flask is vigorously boiled with the pinch-cocks open until the air is completely expelled by the steam, then the pinch-cock on (B) is closed whilst that on (A) is left open until the volume of water in the flask is reduced to about 10 c.c.; this pinch-cock is then also closed, and the flame removed from beneath the flask. The glass tube attached to (A) is carefully filled with water up to the pinch-cock; 15–20 c.c. of a saturated solution of ferrous chloride are introduced into the flask, in which there is now a partial vacuum, by siphoning from a small beaker through (A), the pinch-cock being temporarily opened, and about an equal quantity of strong hydrochloric acid is made to follow in the same manner into the flask. The flask is now carefully heated, and when the internal pressure rises the pinch-cock on (B) is opened, and the evolved gas allowed to pass through the delivery tube into a measuring tube filled with the 10 p.c. caustic soda solution standing in the trough. The heating of the flask is continued until the volume of gas in the measuring tube ceases to increase. The measuring tube is transferred to a tall glass cylinder full of water, and after the gas has acquired the temperature of the room the volume is measured at the atmospheric pressure, a correction being of course made for the tension of aqueous vapour.

This method is specially applicable to the case of water containing excessive quantities of organic matter and chlorides (Ber. 1873, 1041; Tiemann and Gärtner's Untersuchung d. Wassers, 170).

For Schlösing-Reichardt's method, *v.* Zeitsch. anal. Chem. 1870, 24, or Tiemann and Gärtner's Untersuch. d. Wassers, 175.

(*c*) ***The aluminium and zinc-copper couple methods*** depend upon the conversion by nascent hydrogen of the oxidised nitrogen in the water into ammonia, and estimation of the latter by Nessler solution.

Aluminium method. 100 c.c. of the water are introduced into a flask together with 10 c.c. of caustic soda solution free from nitrates and nitrites, the mixture being boiled until it is reduced to about one-fourth of its volume. It is then diluted to about its original bulk with distilled water free from ammonia, and a piece of aluminium foil, about 2 ins. square and wrapped round a piece of glass rod, is dropped into the flask, which is then fitted with a stopper and small U-tube containing glass beads moistened with hydrochloric acid free from ammonia. After the evolution of hydrogen has continued for about 6 hours, the glass beads and washings of the U-tube are transferred to the liquid in the flask, the latter is then attached to a Liebig's condenser, and the ammonia determined by distillation and Nesslerising in the ordinary way (*see* p. 711). According to Tiemann and Gärtner (Untersuchung d. Wassers, 208), only the equivalent of 72–90 p.c. of the nitric acid is thus recovered as ammonia.

Zinc-copper couple method. The residue obtained in the determination of 'total solids' is extracted with about 25 c.c. of hot distilled water, and this is boiled down with a fragment of recently-ignited pure lime about the size of a hemp-seed to one-fourth of its bulk. This liquid, together with the washings of the dish containing the residue, is transferred through a stoppered funnel into an eight-ounce Wurtz flask, attached to a Liebig's condenser, and containing the requisite amount of the zinc-copper couple. The distillation is carried on until the greater part of the water has passed over, after which hot distilled water is repeatedly run into the flask and the distillation continued until about 100 c.c. of distillate have been collected; the latter is then 'Nesslerised' in the ordinary way (Thorpe, Chem. Soc. Trans. 1873, 541). According to Tiemann and Gärtner, from 88 to 95 p.c. of the nitric acid is thus obtained.

In the writer's laboratory the process is carried out as follows: A stoppered bottle (about 200 c.c. capacity) is loosely filled with strips of zinc, which, after cleaning with dilute sulphuric acid, are covered with copper sulphate solution (1 p.c.). The copper-coated strips are repeatedly washed with distilled water, and finally with the water under examination, care being taken not to detach the copper film. The bottle is then completely filled with the sample of water and a crystal of oxalic acid is added, and the bottle, loosely stoppered, is allowed to stand over night. A definite volume is withdrawn by means of a pipette, and this is distilled with a suitable volume of ammonia-free water in the ammonia apparatus as usual, a small quantity of ignited sodium carbonate being added. Before withdrawing the water from the bottle for distillation, a small quantity should be tested for nitrite to ensure that the reduction to ammonia is complete. Waters containing free or saline ammonia must have this distilled off before being placed in contact with the zinc-copper couple.

A rapid method of estimating nitrates in water is due to Harrow (Chem. Soc. Trans. 1891, 320), depending on the reduction to nitrite by zinc-dust and estimation of the nitrous acid by sulphanilic acid and *a*-naphthylamine (Griess' test). This reagent is prepared by dissolving 1 grm. of *a*-naphthylamine, 1 grm. sulphanilic acid, and 25 c.c. strong hydrochloric acid in about 200 c.c. distilled water; boil with a small quantity of animal charcoal, filter, and make up to 500 c.c. The process is conducted thus: 50 c.c. of the water are placed in a beaker of 100 c.c. capacity, and in three similar beakers 50 c.c. of three standard solutions of potassium nitrate, containing (1) 1·

part N, (2) 0·1 part N, (3) 0·01 part N per 100,000; to each beaker 10 c.c. of the above test-solution are added, and afterwards a very small quantity (7–8 mg.) of zinc-dust. If nitrate is present in the water a pink colour appears, which must be compared with that yielded by the three standard solutions after 15 mins. This gives an approximate idea of the amount of nitrate present, whilst in order to obtain an accurate result the water must be diluted until the colour produced is almost identical with that given by one of the standards. The results appear to be accurate, but it is especially necessary to avoid the addition of large quantities of zinc-dust, which would decolorise the solution.

(*d*) *The indigo method* differs from those previously described in being a simple volumetric method depending upon the decolorising action of nitric acid on indigo solution. The results are only accurate when the greatest uniformity is preserved in the conditions under which the experiments are made—the process is, in fact, entirely empirical. It may be carried out as follows: 25 c.c. of the water are mixed with 50 c.c. of pure strong sulphuric acid; a dilute solution of indigo is then immediately added from a burette, shaking the whole time, until the solution acquires a bluish-green colour. In a second experiment nearly the whole volume of indigo which was found necessary in the first experiment is added at once, and the blue colour is then obtained by further small additions, and in this manner, by shortening the time taken in the titration, a more accurate result, generally higher than in the preliminary experiment, is obtained. The solution of indigo must be standardised under precisely similar conditions by means of a solution of potassium nitrate of known strength. The indigo solution should be chosen of such strength that 6–8 c.c. correspond to 0·001 grm. N_2O_5; and if 25 c.c. of the water contains more than 0·003–0·004 grms. N_2O_5, it should be diluted before a final titration is made. The method is only suitable for use by an operator in continual practice (Warington, Chem. Soc. Trans. 1879, 578; Water Analysis, E. Frankland, 31). The results are too low if there is a large amount of organic matter in the water.

The methods described above do not distinguish between nitrous and nitric acids. Indeed, the indigo method is altogether unreliable in the presence of any notable proportion of nitrous acid, as is also Crum's method, should it be necessary to allow any carbon dioxide to escape before shaking with mercury (*see* p. 712). As nitrous acid is, however, generally only present in natural waters in minute traces, these difficulties do not frequently arise, and the nitrous acid may be most conveniently estimated by colorimetric methods, of which there are several in vogue. Of these may be mentioned:

(*a*) *Preusse-Tiemann's method,* depending upon the production of Bismarck brown when an acid solution of a nitrite acts upon *m*-phenylenediamine. 100 c.c. of the water are placed in a colourless glass cylinder, 1 c.c. of dilute sulphuric acid (1 : 3) is added, and then 1 c.c. of solution of *m*-phenylenediamine (5 grms. in 1000 c.c. distilled water, decolorised if necessary with animal charcoal); if the colour appears in less than 1 or 2 mins. the experiment must be repeated with a smaller quantity of water, in each case diluted, however, to 100 c.c. The coloration is then imitated under precisely similar conditions with a standard solution (the standardisation can be effected either by the potassium permanganate, or, better, by the urea method) of potassium or sodium nitrite. The final tint is not arrived at until the mixture in the glass cylinder has stood for 20–25 mins., which is the great drawback of the process (*see* also Warington, The Detection of Nitric and Nitrous Acids, Chem. News, 1885, 51, 39).

A preferable method (Zambelli, Chem. Soc. Abstr. 1887, 533) consists in adding to the water a few drops of a saturated solution of sulphanilic acid in dilute sulphuric acid, then a few drops of a saturated aqueous solution of phenol, after which the mixture is rendered alkaline with ammonia. The presence of nitrous acid is indicated by the appearance of a coloration, varying from faint yellow to intense reddish yellow, according to the quantity of nitrous acid present. The author claims that this method is capable of revealing the presence of 1 part of nitrous nitrogen in 40,000,000 parts of water. It has the great advantage that the reagents employed are permanent in solution.

For larger quantities of nitrous acid, as also for the standardisation of solutions of sodium and potassium nitrite, the urea method devised by the writer is to be recommended (Chem. Soc. Trans. 1888, 364).

Hardness. The determination of the hardness of a water consists in empirically ascertaining the amount of soap which has to be destroyed by a given volume of the water before a lather can be obtained, and expressing this in terms of the amount of calcium carbonate which must be dissolved in the same volume of water to destroy the same amount of soap. Accurate results can only be obtained by preserving uniformity in the conditions of experiment.

50 c.c. of the water are measured into an 8-oz. stoppered bottle, which is then violently agitated and the air sucked out by means of a glass tube to remove any carbon dioxide which may be given off by the water. A standard solution of soap (*v. infra*) is then added in diminishing quantities *not exceeding* 0·5–0·10 c.c. *at a time, even at first,* violently shaking after each addition, until the froth produced remains unbroken over the surface for a period of 5 mins. when the bottle is placed at rest on its side. The quantity of calcium carbonate corresponding to the volume of soap solution employed can then be ascertained by reference to the empirical table shown opposite.

In performing the titration as above, the experienced operator is guided by the ear as well as by the eye, for the sound produced on shaking serves to indicate how the reaction between the hardening constituents of the water and the soap is progressing, for as this approaches completion the sound becomes softer, and when an excess of soap has been added the agitation is all but noiseless.

In the case of waters requiring more than 16 c.c. of soap solution for the 50 c.c. of water, it is necessary to take a smaller volume of the

Table of hardness in parts per 100,000, 50 *c.c. of water being used.*

water and dilute to 50 c.c. with boiled distilled water. The presence of magnesia salts is indicated in the soap test by the formation of a characteristic light curd, and also by the premature formation of a lather, which again disappears on the further addition of soap solution and shaking. If these signs are exhibited, only such a volume of water should be taken as, when diluted to 50 c.c., requires not more than 7 c.c. of the soap solution; indeed, it is a very good practice to invariably dilute waters so that not more than 7 or 8 c.c. of soap solution are required. In the presence of magnesia salts the results are always less accurate, and, unless great care is exercised, may become wide of the truth.

Permanent hardness. The permanent hardness is most conveniently determined by taking a small flask with a *very short neck* (the Erlenmeyer shape is very suitable), and adding the water to it until a definite weight (*e.g.* 250 grms.) has been made up. The water is then maintained in gentle ebullition for exactly half-an-hour, and, after cooling, the weight is again made up to the original by the addition of boiled distilled water, the soap titration being then performed on a measured portion of this, as described above.

Some analysts prefer to take a given volume of water and restore the volume after boiling, then removing the precipitated carbonates of lime and magnesia by passing through a dry filter.

The *standard solution of soap* is prepared as follows. A cake of Castile soap is scraped with a knife, and about 7 grms. of the shavings are dissolved in 500 c.c. of a mixture of 2 vols. of methylated spirit with 1 vol. of distilled water. Filter off the insoluble matter, and dilute the soap solution with half its volume of water. A portion of this solution is then further carefully diluted with a mixture of 2 vols. methylated spirit and 1 vol. water until 7·8 c.c. are required to form a permanent lather with a mixture of 25 c.c. of the standard calcium chloride solution (prepared by dissolving 0·2 grm. of Iceland spar in dilute hydrochloric acid, and, after driving off excess of acid on the water-bath, making up to 1000 c.c. with distilled water) and 25 c.c. of distilled water.

Poisonous metals. Of these the only ones which are of practical importance in water analysis are lead, zinc, copper, arsenic, and barium. As they are generally present in only very minute proportions, it is necessary to evaporate large volumes (5 litres and upwards) of water in order to obtain gravimetric determinations in the ordinary way; but the following special methods may be generally employed.

For *lead*, take 100 c.c. of the water, acidify with a few drops of acetic acid, and then add about 5 c.c. of a saturated solution of sulphuretted hydrogen. The colour produced is imitated by adding a known quantity of a standard solution of a lead salt to 100 c.c. of distilled water. Even such small proportions as 0·03 part Pb per 100,000 should be invariably recorded. (For the standard solution of lead, dissolve 0·1831 grm. crystallised normal lead acetate in 1000 c.c. distilled water; 1 c.c. = 0·0001 Pb.)

For *copper*, the same colorimetric method may be employed as for lead, using for comparison a solution of copper sulphate containing 0·0001 grm. Cu in 1 c.c. (0·3929 grm. crystallised copper sulphate per litre). In the absence of iron a very delicate colorimetric method may be employed, based upon the reaction between copper salts and potassium ferrocyanide, the water being acidified with hydrochloric acid, whilst in the presence of iron the blue coloration produced by ammonia may be used.

The presence of *zinc* is generally indicated by the gradual formation of a film of carbonate on the surface of the water when the latter is exposed to the air. Some of this film ignited on platinum foil should leave a residue, which is yellow when hot and white on cooling. The quantity of the zinc may be approximately determined, in the absence of other heavy metals, by acidifying 100 c.c. of the water with dilute hydrochloric acid, and then adding a solution of potassium ferrocyanide. The white turbidity produced is then compared with that obtained from a known quantity of a standard solution of a zinc salt (Snijders, Ber. 1878, 939).

Arsenic is best detected and estimated by Marsh's test; 500 c.c. of the water are rendered slightly alkaline with caustic soda or potash free from arsenic, and evaporated to dryness. The residue is extracted with strong hydrochloric acid, and the liquid introduced into a Marsh's apparatus. The gas is passed through a small U-tube containing pumice soaked in solution of lead acetate, and then through a piece of combustion tube constricted in the middle, where it is heated to redness. The passage of gas through the heated tube is continued for an hour, although nearly all the arsenic is liberated in 5 or 10 mins. The metallic ring formed is compared with a number of standard rings similarly obtained with known quantities of arsenic. A blank experiment must invariably be performed previously, to control the purity of the chemicals employed.

Barium may be detected and determined by concentrating a considerable volume of the water, acidifying with hydrochloric acid, and after filtering, if necessary, adding a solution of calcium sulphate. The barium sulphate precipitated is then collected and weighed in the ordinary manner.

Iron can generally be estimated colorimetrically by means of ferrocyanide or thiocyanate. Its determination is frequently of importance in waters used for industrial purposes.

In the ferrocyanide method, the water residue is dissolved in hydrochloric acid and diluted to 100 c.c. Of this 10 c.c. are transferred to a 100 c.c. cylinder; add 1 c.c. of strong nitric acid, dilute to 100 c.c., stir, and then add 1 c.c. of potassium ferrocyanide solution and mix well. The colour produced is compared with that obtained from a standard iron solution, but the same quantity of nitric acid must be present in each case (Sutton, Volum. Analys. 6th ed. 194; *v.* also Carter Bell, J. Soc. Chem. Ind. 8, 175).

In the thiocyanate method, two 100 c.c. cylinders are taken, and into each 5 c.c. of dilute hydrochloric acid (1 : 5) and 5 c.c. of dilute nitric acid (1 : 5), together with 15 c.c. of thiocyanate solution, are poured; then introduce a measured volume of the liquid to be tested into the one cylinder, and after filling up both cylinders to the mark with distilled water, imitate the red colour obtained with the liquid under examination by running in a standard solution of iron from a burette into the other cylinder. In this way one part of iron is said to be recognisable in fifty millions of water (Thompson, Chem. Soc. Trans. 1885, 493).

Determination of organic matter. A number of processes have been devised for the determination either of the whole or part of the organic substances present in water. Of those which lay claim to discovering the whole of these organic materials, none is entitled to any confidence, whilst even those which attempt to determine a part, or to indirectly obtain a comparative measure of the organic matter, are also open to objections on the score of accuracy. Only those methods more commonly in use by water analysts will be described here.

(1) ***Methods depending on the reduction of potassium permanganate.***

(*a*) *Kubel's process.* In this the reduction is effected in acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity and treated with 5 c.c. dilute sulphuric acid (1 : 3), and then with such a quantity of standard dilute permanganate (equivalent to centinormal oxalic acid) that the liquid is of a strong red colour. The mixture is then boiled for 10 mins., and the excess of permanganate added must be such that the colour is not discharged in this operation. 10 c.c. of centinormal oxalic acid are now added, and into the resulting colourless liquid standard permanganate is then run in until a faint red colour is obtained. The amount of oxygen consumed by the organic matter in the water can then be calculated.

(*b*) *Schulze's process.* In this the reduction is commenced in an alkaline and completed in an acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity, 0·5 c.c. caustic soda solution (1 : 2) are added, as well as 10–15 c.c. of standard dilute permanganate (equivalent to centinormal oxalic acid). The liquid is boiled for 10 mins., allowed to cool to 50° or 60°C. and then 5 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of centinormal oxalic acid are added, the liquid being shaken and gently warmed until the colour has quite disappeared. Then the standard dilute permanganate is run in until a faint red colour, remaining permanent for at least 5 mins., is obtained. The oxygen consumed by the organic matter of the water is then calculated.

(*c*) *Forchhammer process.* This resembles Kubel's method, inasmuch as the reduction of the permanganate is effected in an acid solution, but the temperature employed, instead of being defined, is that of the air of the laboratory.

Two flasks are carefully cleaned and into one 250 c.c. of the water, into the other 250 c.c. of distilled water, are introduced. To each 10 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of standard permanganate (containing 0·395 grm. per litre or 0·001 grm. available oxygen in 10 c.c.) are added, and the mixture is allowed to stand for three hours. At the end of this time the excess of permanganate remaining is determined by adding two drops of potassium iodide (1 : 10) to each flask, and then running in a standard solution of sodium thiosulphate (1 grm. per litre) until the whole of the free iodine is removed, a drop of clear starch solution being added at the close of the operation. The amount of permanganate destroyed in the blank experiment must of course be deducted from that destroyed in the case of the water, and from the difference the oxygen consumed by the organic matter of the water can be calculated (Tidy, Chem. Soc. Trans. 1879, 66).

In this country it is now almost the invariable custom of water analysts to allow the acid permanganate to act for 4 hours at 80°F. (26·7°C.); Thorpe (Metropolitan Water Reports, 1904) has also used 1 hour at 122°F. (50°C.), under which conditions a larger amount of oxygen is consumed.

It must be pointed out that in these several methods depending on the reduction of permanganate, the results are only comparative for the same kind of organic matter, a given weight of organic carbon in different kinds of water consuming different quantities of oxygen from permanganate under the same conditions. Thus it has been found that for surface waters, such as those of the rivers Thames and Lea, by multiplying the oxygen consumed in the Forchhammer process by the factor 2·38, the proportion of organic carbon (as determined by combustion) is approximately obtained, whilst in the case of deep well water the factor which must be employed is 5·8 (Woodland Toms).

Again, all these methods are affected by the presence of nitrites, ferrous salts, and larger quantities of ammonia compounds, all of which exercise a reducing action on permanganate. By determining the nitrous acid, a correction can be made for this, whilst the ferrous can generally be converted into ferric iron by shaking up the water several times in a half-filled bottle previously to the oxidation with permanganate; and the error due to ammonium salts is so small that it can generally be neglected (even one part NH_3 per 100,000 has no appreciable reducing effect) (Preusse and Tiemann, Ber. 12, 1906).

(2) *Determination of organic carbon by oxidation of organic matter with potassium dichromate and sulphuric acid* (Wolff, Degener, and Herzfeld). 500–1000 c.c. of the water are introduced into a capacious retort, the neck of which is drawn out and bent downwards and is connected with a Liebig's condenser. This arrangement enables the retort to be turned upwards and the condenser downwards, thus preventing any loss by spurting during distillation, which is carried on until 250–700 c.c. (according to the volume of water employed) have passed over. The distillate is submitted to Kubel's method (*v. supra*) to ascertain whether any volatile organic matters are present. Alkaline waters should be saturated with carbon dioxide, and acid waters carefully neutralised with sodium carbonate before the above distillation. The water remaining in the retort is evaporated down to 15 c.c. in a glass dish on a water-bath, the access of dust being carefully avoided. This concentrated liquid is introduced into a flask of 250–300 c.c. capacity, and the dish and retort are rinsed with 10 c.c. of dilute sulphuric acid (1 : 3), these rinsings being also added to the water in the flask. The decomposition of carbonates caused by the addition of this acid is completed by heating to 50°C. and shaking, and the evolved carbon dioxide completely displaced by air. After cooling the flask and its contents, 10 grms. of finely-powdered potassium dichromate are added, and the flask is then attached to the remainder of the apparatus. An india-rubber stopper with three holes is placed in the flask; through one hole passes a thermometer dipping into the liquid, through a second passes nearly to the bottom of the flask the tube of a bulb-funnel (A) provided with a stopcock, whilst through the third passes the bent tube of an inverted Liebig's condenser (B). The upper extremity of the condenser (B) is connected with two U-tubes (C and D) filled with fused calcium chloride, whilst between these is a third U-tube (E) containing coarsely-powdered antimony. Of these, C and D are intended to absorb the moisture passing the condenser, and the intermediate one, E, to retain any chlorine. Following on these tubes is a set of weighed potash-bulbs (F) for the absorption of carbon dioxide, and these bulbs are, of course, protected from ingress of air on the other side by means of a calcium chloride tube, which can be attached to an aspirator at the close of the experiment. The apparatus having been thus put together, 50–60 c.c. of diluted sulphuric acid (3 : 2) are gradually added through the stoppered funnel (A). During the first half-hour the temperature is kept at 50°–55°C., whilst during the second half-hour it is gradually raised to boiling, which is maintained from 5–10 mins. The aspirator is then attached, the air which enters by the funnel (A) having been previously freed from carbon dioxide by bubbling through caustic potash. The increase in weight of the potash bulbs (F) gives the weight of carbon dioxide evolved, from which the carbon itself can be calculated (Ber. 1886, 2618; Tiemann-Gärtner, Untersuch. d. Wassers, 247).

For a somewhat similar method of determining organic carbon in which permanganate is used instead of dichromate, *see* Blair, Organic Analysis of potable Waters, Churchill, 1891, 83. The method appears worthy of more extended trial.

(3) *Determination of organic carbon and nitrogen by combustion.* (*a*) *Frankland and Armstrong's process* (Chem. Soc. Trans. 6, 77). This method, which is unquestionably the most rational and exact, has been adopted to a comparatively limited extent by water analysts in consequence of the special apparatus and manipulative skill which it entails. The method will be only described in outline here, and for full particulars the reader is referred to Sutton's Volumetric Analysis, whilst for a critical survey of the methods employed in the organic analysis of water he should not fail to consult Mallet, Report of the United States National Board of Health, 1882.

The process is divisible into three parts: (1) the evaporation of the water, (2) the preparation and combustion of the residue thus obtained, and (3) the measurement of the gases evolved in the combustion.

For the *evaporation*, from 100 c.c. (in the case of sewage and highly-polluted waters) to 1000 c.c. (in the case of very pure waters) are measured into a clean flask, 20 c.c. of a saturated solution of sulphurous acid being added together with a drop of a solution of ferric chloride; the liquid is then rapidly boiled for a few seconds. This treatment secures the decomposition of carbonates, nitrates and nitrites, whilst any ammonia is fixed by the sulphurous acid, and this ammoniacal nitrogen, which has been previously determined, must be deducted from the total amount of nitrogen obtained in the combustion. The water is now rapidly cooled, and the evaporation commenced in an apparatus specially designed for the purpose. This consists of a nearly hemispherical glass dish about 4 ins. in diameter and without a lip. It is floated in a shallow copper basin heated below by a water-bath provided with constant feed, and on the flange of this copper basin there rests a truncated conical ring, constructed of lead or copper, and about 3 ins. in height, whilst upon a flange at the top of this again rests a tall glass shade about 12–18 ins. in height. The water for evaporation is placed in a flask which is provided with a delivery tube of special construction ground on to its neck, and which serves, when the flask is turned upside down, to maintain the water at a constant level in the glass dish in which the evaporation is proceeding, for this delivery tube is made to pass through a notch in the truncated conical metal ring, just beneath the glass shade which the latter supports, and delivers into the centre of the glass dish within. In the writer's laboratory, the evaporation of 500 c.c. of water is found to take from 10–12 hours. The evaporation should be continued until the residue is quite dry, and if the water contains only a small amount of total solids it is advisable to add a little ignited calcium phosphate to the dish before commencing the evaporation. In the analysis of sewage, or waters containing much ammonia and *no nitrates or nitrites*, it is advantageous to use 10 c.c. of a solution of metaphosphoric acid (1 : 10) instead of the sulphurous acid, as ammonium phosphate loses much less ammonia during evaporation than ammonium sulphite. A little ignited calcium phosphate should also be added to dry the residue in this case. But if there are no nitrates and nitrites and much ammonia, the more satisfactory, although more laborious, plan is to use a little ignited borax instead of the sulphurous or metaphosphoric acid. In this way the ammonia is completely dissipated on evaporation, and as no correction has, therefore, to be applied to the organic nitrogen found, the result is more correct. But as boric acid does not entirely decompose carbonates the accuracy of the organic carbon found by this method may be seriously affected, and it is advisable to make a separate determination of the carbon in a second experiment in which the sulphurous acid method is employed. Unless this method be adopted the results for organic nitrogen in the presence of much ammonia are nearly sure to be highly inaccurate.

If the water contains more than 0·5 part per 100,000 of nitrogen as nitrates and nitrites, the 20 c.c. of sulphurous acid employed above may not improbably prove insufficient for their complete destruction, and in the case of such waters the residue in the dish should be further treated with 10 c.c. of sulphurous acid, this evaporated off, and if the amount of nitric or nitrous nitrogen exceed 1 part per 100,000 this treatment of the residue with further quantities of sulphurous acid may be repeated twice or three times to secure complete destruction of the nitrates and nitrites.

The *preparation and combustion of the residue* thus obtained is effected by thoroughly mixing with the latter in the dish a small quantity of finely divided and carefully ignited copper oxide. This is then completely transferred a narrow piece of combustion tubing about 18 ins. long and sealed at one extremity. The dish is again rinsed with a little fine oxide, and this also transferred to the tube. Coarse and carefully ignited oxide of copper (preferably from wire) is then introduced to a depth of about 10 ins., whilst the fine oxide previously introduced will occupy about 2 ins. Upon the stratum of coarse oxide follows a copper gauze cylinder 3 ins. in length, and then another layer of coarse oxide about 1 in. long. The open extremity of the tube is now drawn out over the blowpipe, so that it can be connected with a Sprengel mercury pump. The tube is completely exhausted, and the combustion performed *in vacuo* in the ordinary way, the evolved gases being then drawn over by the pump and collected in a test tube filled with mercury and placed over the lower open extremity of the fall tube in the trough below.

The *volumetric measurement of the gases* (consisting of carbon dioxide, nitrogen, and possibly also nitric oxide and sulphur dioxide) collected as above is carried out in the Frankland gas apparatus, which admits of the measurement of very minute quantities of gas. Three measurements only are necessary. In the first place the gas is treated with a few drops of a saturated solution of potassium dichromate to absorb any sulphur dioxide that may be present. The volume of the gas is then accurately measured, after which it is treated with a few drops of strong caustic potash, which rapidly removes the carbon dioxide, after which the volume of the remaining gas is again carefully ascertained. The residual gas now consists of nitrogen, with possibly a little nitric oxide. It is mixed with a bubble of pure oxygen in order to convert any nitric oxide into nitrous and nitric acids, which are immediately absorbed by the caustic potash present, and then, on adding a drop or two of solution of pyrogallic acid, the excess of oxygen is absorbed and the remaining gas, which consists of nitrogen, is carefully measured. The diminution in volume effected by the caustic potash in the first instance obviously represents the carbon dioxide, whilst the final volume of residual gas, together with one-half of the contraction resulting from the addition of oxygen and pyrogallic acid, represent the total volume of nitrogen. From these volumes the weights of carbon and nitrogen respectively can be calculated. As already pointed out, if sulphurous or metaphosphoric acid has been used in the evaporation, and ammonia is present in the water, the ammoniacal nitrogen (subject to an empirical correction for loss of ammonia during evaporation) has to be subtracted from the total nitrogen found by combustion. A small correction (ascertained by blank experiments made from time to time with the reagents employed in the evaporation and combustion) has also to be applied to the carbon and nitrogen thus determined.

For *Dupré and Hake's method*, *see* Chem. Soc. Trans. 1879, 159.

In *Dittmar and Robinson's method* of determining organic carbon, the gases proceeding from the combustion tube are first passed through a U-tube containing a solution of chromic acid in 60 p.c. sulphuric acid to absorb moisture and sulphurous acid (the water is evaporated with sulphurous acid for the preparation of the residue), the carbon dioxide being absorbed in a weighed soda-lime tube (Chem. News, 1877, 36, 26). A method of determining organic nitrogen has also been devised by Dittmar and Robinson, and is described below.

(4) *Methods for determination of organic nitrogen only.* Of these the most common one in use is the well-known

(*a*) '*Albuminoid ammonia*' *process* of Wanklyn, Chapman, and Smith (Chem. Soc. Trans. 1867, 591), which does not yield the whole, but only very variable proportions, of the organic nitrogen in different nitrogenous organic substances, although in the case of some —such as leucine, aspartic acid, tyrosine, &c. —which frequently appear as decomposition products of albuminous matters, nearly the whole of the nitrogen is obtained as ammonia (Preusse and Tiemann, Ber. 12, 1906; Mallet, U. S. National Board of Health Report, 1882).

The method has already been described on p. 711.

(*b*) *Dittmar and Robinson's process.* In this process the residue, obtained in the same way as for the combustion process, is heated with fused caustic soda, or soda and baryta, in a copper or silver boat placed in a combustion tube in a current of hydrogen, the evolved ammonia being absorbed by very dilute hydrochloric acid, which is subsequently 'Nesslerised' (Chem. News, 1877, 36, 26). The results are accurate, and coincide with those obtained by the combustion process of Frankland and Armstrong.

(*c*) *Kjeldahl's process.* This well-known and now much-employed method for determining organic nitrogen was adapted for use in water analysis by Drown and Martin (Chem. News, 59, 272). It appears to give accurate results uninfluenced by the presence of nitrates and nitrites in such quantities as are found in ordinary waters, 500 c.c. of the water are placed in a round-bottomed flask of about 900 c.c. capacity; the volume is then reduced to about 200 c.c. by boiling, and to this, after cooling, add 10 c.c. of pure concentrated sulphuric acid. The mixture is then cautiously boiled, with the flask in an inclined position, until all the water has been driven off and the acid remains of a white or very pale-yellow colour. After removing the source of heat, add a little powdered permanganate until, on shaking, the liquid becomes green, showing that excess has been added. If a purple instead of a green colour appears, it shows that the whole of the water has not been driven off. When cool, 200 c.c. of water free from ammonia are added, care being taken to rinse round the neck of the flask, and thus wash in any acid which may be adhering there. 100 c.c. of sodium hydroxide solution are then added, and the mixture distilled with a Liebig's condenser. (The sodium hydroxide solution is prepared by dissolving 200 grms. of good caustic soda in 1250 c.c. of distilled water, adding 2 grms. potassium permanganate, and boiling down until the volume is rather less than 1000 c.c., making up to 1000 c.c. when cold.) The distillate is collected in a flask containing 50 c.c. of water free from ammonia, and 1 c.c. of dilute pure hydrochloric acid, and during the distillation of the first 50 c.c. the delivery tube of the condenser is made to dip into this acid liquid, whilst during the remainder of the distillation the flask is lowered so that the delivery tube is just above the liquid. The distillation is carried on until the whole of the ammonia has passed over, and the contents of the receiver are then 'Nesslerised' in the ordinary way. The most scrupulous care must be exercised to prevent access of ammonia from the air and reagents; a blank experiment should also be made for control.

Determination of dissolved oxygen. Much importance is, with very little reason, attributed by some analysts to this determination; it can, moreover, be rarely applied, as the samples must be collected with special precautions if the results are to have any value at all. The various processes in use have been examined by Kisch (Chem. Soc. Abstr. 1892, 98). *Reichardt's* method (Zeitsch. anal. Chem. 1872, 11, 271), as modified by Preusse and Tiemann (Ber. 1879, 12, 1768; Tiemann-Gärtner's Untersuch. d. Wassers, 278), consists in boiling a measured volume of water, and collecting the gases over a hot solution of caustic potash, the oxygen being then estimated either by explosion with hydrogen, or by absorption with potassium pyrogallate. In *Mohr's* method (Mohr's Titrirmethoden) the sample is mixed with an acid solution of ferrous sulphate of known strength, then with caustic soda to throw down ferrous hydroxide, and after remaining for a few hours (air, of course, being rigidly excluded), the precipitate is redissolved in sulphuric acid, and the remaining ferrous sulphate titrated with permanganate. In the *Schützenberger-Risler* process (Bull. Soc. chim. 1873, [ii.] 19, 152; 20, 145; Tiemann-Gärtner's Untersuch. d. Wassers, 277, 288; Catherine Williams and Ramsay, Chem. Soc. Trans. 1886, 760; Bernthsen, Ber. 13, 2277; Roscoe and Lunt, Chem. Soc. Trans. 1889, 552; Dupré, Analyst, 1885, 10, 156) the water is allowed to act on a solution of sodium hydrindigotin disulphonate, which is thereby converted into the blue compound, a standard solution of sodium hydrosulphite being then run in until the liquid is again colourless. In *Winkler's* process (Ber. 21, 2843) the water is mixed with a solution of manganous chloride, and then with potassium iodide and caustic potash; the precipitated manganous hydroxide absorbs the oxygen, passing into a higher state of oxidation. On adding hydrochloric acid the higher oxide of manganese gives rise to the liberation of an equivalent quantity of iodine, the amount of which is determined by titration with sodium thiosulphate. According to Kisch (*l.c.*), the results by the Reichardt-Preusse-Tiemann method are decidedly lower than those obtained by the Winkler process, which is in harmony with the experience of the writer. The results by Mohr's and Schützenberger's methods accord very well with those by Winkler; but Winkler's appears, on the whole, to be the most trustworthy, and the easiest to carry out. A modification of Winkler's method has been made by Rideal and Stewart (Analyst, 1901, 26, 141), and a more recent one reducing it to a colorimetric process by Rideal and Burgess (*ibid.* 1909, 34, 193).

A full description and discussion of the several methods will be found in Sutton's Volumetric Analysis.

The determination of dissolved oxygen has, in recent years, been much practised in connection with the rate at which dissolved oxygen is absorbed by sewage and effluents from sewage works. This matter is of importance as affording a measure of the readiness with which such liquids will remove the dissolved oxygen from a stream into which they are discharged. For Scudder's method, *see* Fowler's Sewage Works Analyses, or Sutton's Volumetric Analysis.

Determination of carbon dioxide. (1) The *total carbonic acid* is determined by completely precipitating as calcium carbonate with an excess of calcium hydroxide (a sufficient quantity of calcium chloride being added to decompose alkaline carbonates), then filtering off the precipitate, and determining the carbon dioxide in it in the usual way (Fresenius, Quant. An.; Tiemann-Gärtner, Die Untersuch. d. Wassers, 213). If the water is saturated with carbon dioxide under pressure, the above method must be preceded by Rochleder's process for estimating the gas which escapes on reducing the pressure to that of the atmosphere.

(2) The *free and semi-combined carbon dioxide* is determined by Pettenkofer's method, in which the water is treated with an excess of standard calcium hydroxide solution, and, after the precipitate has separated in a *crystalline* form, the clear liquid is decanted off, and the excess of lime ascertained in an aliquot part by titration with standard dilute oxalic acid, using phenolphthalein as indicator. If the water contains alkaline carbonates, sufficient neutral calcium chloride solution must be added to decompose them, whilst if there is a considerable proportion of magnesia salts, some ammonium chloride must also be added.

If the carbonic acid thus determined is subtracted from the total obtained according to (1), then the difference represents the combined carbonic acid. To this combined carbonic acid there corresponds, of course, an equal quantity of semi-combined, so that only any excess over and above this can be regarded as free carbonic acid. It must, however, be pointed out that the determination of total carbonic acid generally yields results which are below the truth by 1–1·5 units in 100,000 parts, in consequence of the solubility of normal calcium carbonate itself (*v.* Walker and Kay, J. Soc. Chem. Ind. 1912, 31, 1013.)

Determination of sulphuretted hydrogen. Colorimetrically with a solution of sodium nitroprusside, using for comparison a standard solution of sulphuretted hydrogen. The latter is standardised by taking a measured volume and adding an excess of decinormal sodium arsenite; shake well, and then acidify with hydrochloric acid. After the arsenious sulphide has completely subsided, dilute to 300 c.c., and filter through dry paper. Take 100 c.c. of the filtrate, remove acidity by means of solid sodium carbonate, add a drop of starch solution, and then run in decinormal iodine until a blue colour is obtained. This method may, of course, also be employed for the determination of the sulphuretted hydrogen in the water itself if present in sufficient quantity.

In using the colorimetric method, 300 c.c. of the water are treated with 5 c.c. sodium carbonate and 3 c.c. sodium hydroxide; allow the precipitate to subside for 1–2 hours, then decant or filter. To 250 c.c. of the filtrate in a colourless cylinder add 1 c.c. of sodium nitroprusside solution (4 grms. per litre), and for comparison take 245 c.c. distilled water, to which add 2 c.c. sodium hydroxide and as much of the standard solution of sulphuretted hydrogen as is required to produce precisely the same tint as is obtained with the water above. In this manner 0·1 part H_2S per 100,000 can be determined (Tiemann-Gärtner, Untersuch. d. Wassers, 232).

Sulphuretted hydrogen may also be accurately determined by means of centinormal iodine solution. 10 c.c. or other suitable volume of the latter are placed in a 500 c.c. flask, and the water added until the colour completely disappears; 5 c.c. of starch solution are then added, and centinormal iodine is run in until a blue colour is obtained, pure distilled water being added up to the 500 c.c. mark from a burette. On subtracting the sum of the volumes of iodine, starch solution, and distilled water added from 500 c.c., the volume of water which reacted with the iodine solution employed is ascertained. A correction should be made for the volume of iodine solution required to produce a blue colour.

BACTERIOLOGY OF WATER.

The great progress which has been made within recent years in our knowledge of infectious diseases, and of the processes dependent on bacterial life, renders it imperative that the subject of water supply should be considered from a bacteriological, as well as a chemical, point of view.

It has long been recognised that in making determinations of organic matter, ammonia, nitrates, &c., with a view to ascertaining the fitness or otherwise of water for drinking purposes, the concomitants of the living poisons of zymotic disease and not the morbific matters themselves, which were still more or less hypothetical entities, were being tested for, and that it was necessary that the living poisons themselves must be explored by biological, and not by purely chemical, methods.

Liquid and solid media.

The classical investigations on bacteria by Pasteur, Tyndall, Lister, Nägeli, Cohn, Fitz, Schloesing, Muntz, and others prior to 1880 were practically all made with liquid culture media only. Such culture media labour under several serious disadvantages:—

(1) Facility with which they become contaminated with bacteria and other organisms from the air and other surroundings;

(2) The competition which arises between the different microbes present may lead to the entire suppression of some through the overwhelming multiplication of others;

(3) The great difficulty of obtaining pure cultivations of specific micro-organisms.

The introduction of solid culture media by Koch at the beginning of the eighties, in the last century, led to great developments in bacteriology. An immense variety of investigations were now rendered possible which had long been awaiting attack. These new methods of bacteriological study were at once applied to the identification of the specific micro-organisms of numerous diseases, and to the investigation of the bacteria present, in *air*, *water*, *soil*, and all our other surroundings.

By means of *gelatin-plate-culture* it became possible to ascertain the number and the nature of most bacteria present in any material. Thus n the case of water the number and nature of the bacteria present in any sample could be determined, and by this means it was possible to ascertain the effect of any treatment or process of purification on the bacteria present n water. Thus it was applied by the writer in 1885 to the study of the removal of bacteria from water by artificial and natural *filtration*, by *subsidence*, and by *precipitation*.

The results obtained in investigations of this kind led to a great modification of the opinions which had previously been entertained with regard to the value of these processes in removing the zymotic dangers of water. Thus it was found that bacteria could be almost wholly removed from water by the process of sand filtration which had a comparatively insignificant effect on the organic matter and other ingredients discoverable by chemical analysis.

Similarly these methods of bacteriological nvestigation enabled such processes of water purification to be readily controlled. Thus if the safety of a water-supply depends on the efficiency with which the removal of bacteria by filtration s carried out, it is obvious that this efficiency should be continually controlled by bacterio-ogical examination, so that any defect in the working of the filters may be at once detected and rectified. The systematic control of water-works by bacteriological examination is now being very widely carried on with great benefit to the communities concerned.

With the discovery of the specific bacteria of cholera, of typhoid fever, and of many other diseases, attempts were naturally made to find hese specific pathogenic bacteria in contaminated water-supplies. The chance of such discovery by the ordinary method of plate-cultivation s, of course, hopelessly remote, because a single pathogenic organism must almost inevitably be accompanied in water by a host of non-pathogenic individuals, and amongst these multitudes of harmless forms the few harmful ones will under ordinary circumstances be overlooked, whilst, in the small quantities of water operated on, the pathogenic forms may be absent, although present in a larger bulk.

To surmount these difficulties, the natural device was to provide conditions which would be favourable to the particular pathogenic form being sought for and less favourable or even antagonistic to the multitude of non-pathogenic orms with which it would be accompanied. We may call the provision of such conditions he method of *enrichment or preferential culture*.

Such a method of enrichment was very satisactorily applied by Koch to the discovery of the *holera-bacillus* in the water of the Elbe at Hamburg during the epidemic of 1892. If 90 c.c. of he water under examination be incubated for 8 hours at 37° with 10 c.c. of a solution conaining peptone 10 p.c., and sodium chloride 0 p.c., cholera bacilli will be found in the thin urface pellicle, and from this cultures are made.

Typhoid fever is, of water-borne diseases, he most important in Western Europe. An normous amount of labour and ingenuity have been devoted in recent years to the discovery of the bacillus of this disease in water. That the problem is a very difficult one may be gathered from the fact that until recently *its detection even in the discharges of typhoid patients was very frequently abortive.*

The special difficulty attending the discovery of the typhoid bacillus depends on the circumstance that even in the intestine of the typhoid patient it is enormously outnumbered by other bacteria, and especially by the *Bacillus coli communis*, which, discovered by Escherich in 1886, has in recent years achieved the very greatest celebrity in the bacterial world.

Practically all conditions which are favourable to the typhoid bacillus are equally or even still more favourable to the *B. coli*, and for a long time all methods of favouring the typhoid bacillus at the expense of the *B. coli* proved futile. Much interest was, therefore, excited when in 1903 Roth announced that the *B. coli* was more disadvantageously affected than the typhoid bacillus by solutions of caffeine.

Experiments made by Kloumann[1] in 1904, however, showed that the differential effect on the two bacilli was only very slightly in favour of the typhoid bacillus.

A method of testing for typhoid bacilli in water and other liquids was elaborated by Hoffmann and Ficker in 1904; it was also based on the inhibitory action of caffeine and of crystal-violet on the *B. coli*. The method will be best understood by the following description of the manner in which it was successfully employed by Jaksch and Rau (1904) to detect typhoid bacilli in the drinking water supplied to Prague:—

900 c.c. water from a service tap were added to the *Hoffmann and Ficker culture-medium*, consisting of 10 grms. nutrose, 5 grms. caffeine, and 0·01 grm. crystal-violet, in 100 c.c. water.

The mixture was then incubated at 37° for 13 hours, when it was to be presumed that any typhoid bacilli originally present would have extensively multiplied. Loopfuls of this large cultivation were then withdrawn and spread on the surface of *Drigalski and Conradi Plates* (agar, meat extract, peptone, nutrose, lactose, sodium chloride, crystal violet and litmus), which were then incubated at 37° for 24 hours. On these plates the *B. coli* colonies are red (acid litmus) and non-transparent, whilst those of the typhoid bacillus are blue with a violet tinge, transparent, resembling dewdrops, and smaller than the *B. coli* colonies. In the Prague experiment these plates gave only a few red colonies, the majority being blue and transparent. The latter were sub-cultured, and, according to Jaksch and Rau, gave results in the most varied tests (including agglutination, toxicity, and immunisation) which were identical with those obtained with the true typhoid bacillus.

Other solid media which have proved of great value in distinguishing between coli-like and typhoid-like colonies are Loeffler's malachite-green agar, and McConkey's bile-salt-neutral-red agar, both of which will be referred to later.

By far the most extensive, interesting, and systematic search which has ever been made for the typhoid bacillus in natural waters is

---

[1] Kloumann, Centralbl. f. Bakteriologie, 1904, 36, 512.

that carried out by Houston in the waters of the three rivers—Thames, Lea, and New River—from which the greater part of the London water supply is obtained. As this investigation illustrates the most approved methods which are now available to the bacteriologist, it will be considered here in some detail.

Two hundred and ninety-four experiments in 8 series were made with 156 samples of raw river water (52 Thames, 52 Lea, and 52 New River) during the 12 months ended July 31, 1908. The total volume of water dealt with was 294 × 100 = 29,400 c.c. The total number of bacteria in this volume of water (as ascertained by gelatin-plate cultivation for 3 days at 20°–22°) was 135,687,500. The total number of colourless (or nearly colourless) colonies sub-cultured from the Drigalski or similar plates was 7329. These 7329 selected colonies form but a small fraction of the millions of bacteria which were excluded owing to the temperature of incubation, the composition of the media employed, and the fact of their appearing on the plate-cultures as coloured colonies.

The following tabular summary indicates the method adopted in this exhaustive investigation:—

Direct Plating on Solid Media.

- Series I. 100 c.c. of the sample of water were centrifuged and the resulting deposit spread over a number of plates consisting of *malachite-green* (1 *in* 5000), *saccharose, dulcite, salicin, neutral-red, bile-salt, peptone, lactose, agar*. The plates were incubated at 40°–42° for 24 hours, and the colourless colonies sub-cultured into special media, as described in the next table.
- Series II. Same as Series I, but the proportion of malachite-green was 1 in 10,000.
- Series III. Same as Series I, but the media used in the plates contained no malachite-green.
- Series IV. Same as Series I, but the proportion of malachite-green was 1 in 20,000, 1 in 40,000, and 1 in 80,000.

Primary Liquid Cultures followed by Plating on Solid Media.

- Series A. 100 c.c. of the sample of water were added to *bile-salt-glucose-peptone medium containing malachite-green* in proportion of 1 in 1000, 1 in 2000, 1 in 4000. This liquid was incubated at 40°–42° for 24 hours, and then plated on the same medium as was employed in Series I, 10 colourless colonies were in each case sub-cultured and tested as described.
- Series B. Same as Series A, but malachite-green in the liquid medium was in proportion of 1 in 8000, 1 in 16,000, 1 in 32,000. Subsequently plated on same medium as that used in Series II.
- Series C. Same as Series A, but the liquid culture medium consisted of meat-broth only without malachite-green or any other additions. Subsequently plated on same medium as that used in Series I.
- Series D. Same as Series C, but instead of cultivating 100 c.c. of water in one portion, 10 cultures of 10 c.c. each were made.

The following table shows the behaviour of 32 strains of the typhoid bacillus, on the one hand, and of the 7329 suspicious colonies isolated from the raw waters, on the other. *It will be seen that not one out of all these 7329 different microbes, although suspicious in certain features, gave reactions agreeing in their entirety with those of the typhoid bacillus.*

VERIFICATION TESTS FOR TYPHOID BACILLUS.

	Test 1	Test 2	Test 3	Test 4	Test 5	Test 6
Description of microbe.	Proskauer's and Capaldi's No. 2 medium[1] (with inner tube).	Lactose-saccharose-dulcite-salicin-medium (with inner tube).	Proskauer's and Capaldi's No. 1 medium[2] modified (with inner tube).	Glucose-neutral red broth cultures (with inner tube).	Peptone-water medium.	Gelatin sugar media:—galactose, glucose, lævulose, maltose, and mannite respectively.
RESULTS CHARACTERISTIC OF TYPHOID BACILLUS.						
32 strains of typhoid bacillus from a number of different laboratories.	Acid, no gas	No visible change. (No acid, no gas.)	No visible change. (No acid, no gas).	Purplish tint. (No gas, no fluorescence.)	No indole.	Acid, but no gas with all five sugars. No liquefaction.
RESULTS WHICH EXCLUDE, AS NOT TYPHOID BACILLUS, THE SUSPECTED MICROBES.						
7329 colourless (or nearly colourless) colonies, sub-cultured.	No acid, or acid and gas	Acid or gas-formation.	Acid or gas-formation, or decided growth.	Gas or fluorescence. (Absence of purplish tint.)	Indole.	Gas formation in one or all of the sugar media. (Liquefaction.)

From the very nature of this investigation—the search for a specific microbe in a natural water which at some period of its history is practically certain to have received this microbe in comparatively small numbers—it is impossible to make it really exhaustive. Houston has

---

[1] Solution of peptone and mannite.

[2] Solution of asparagine, mannite, glucose, galactose, lævulose, maltose, magnesium sulphate, sodium chloride, calcium chloride, potassium hydrogen phosphate, and litmus.

however, amplified his previous investigation in a very suggestive manner. Realising that the objection might be raised that the method adopted may not be capable of detecting a very small number of typhoid bacilli in the presence of a very large number of other microbes, he devised a mode of procedure which enabled him to affirm that in each particular sample of water examined there were *not more* than a certain definite number of typhoid bacilli in a given volume. The method adopted was this:—

Each sample of raw river water was divided into two equal portions of 500 c.c. (A and B). The A sample was inoculated with a very small number of typhoid bacilli. The B sample was not so infected, and was, therefore, normal raw river water. The subsequent procedure was exactly the same in each case, both samples A and B being treated exactly alike. The 500 c.c. of water were centrifuged and the resulting deposit spread over 16 plates prepared with solid medium of the following composition:

Agar, 2 grms.; peptone, 2 grms.; bile-salt, 0·5 grm.; lactose, saccharose, adonite, raffinose, and salicin, each 0·2 grm., made up with water to 100 c.c. and tinted with 0·4 c.c. of a 1 p.c. solution of neutral red. In some of the experiments malachite-green was added to the above, in the proportion of either 1 to 10,000, or 1 to 5000 of the medium.

Of the 24 experiments, 14 were carried out with raw Lea, and 10 with raw Thames, water. These waters contained on an average 62,688 bacteria per 1 c.c. (gelatin at 20°–22°, 3 days' incubation). The worst sample contained 760,000 and the best sample 1200 bacteria per 1 c.c. Thus in the 12 litres (500 c.c. × 24) of raw water (B samples) examined for typhoid bacilli there were 752,256,000 bacteria present.

The total number of colonies selected for study was 5451 from the infected A samples, and the same number (5451) from the non-infected B samples. The average number of typhoid bacilli artificially added to the A samples was 2·242 per 1 c.c. or 1121 per 500 c.c. The average number of typhoid bacilli isolated from the A samples was 14·54 per 500 c.c. of sample. It may be argued fairly, therefore, that if only $\frac{1}{14\cdot54}$ of the above number of typhoid bacilli had been present in the infected sample this microbe would still have been detected by the method of investigation adopted; but $\frac{1}{14\cdot54} \times 2\cdot242 = 0\cdot154$ typhoid bacillus per 1 c.c., or 1 typhoid bacillus in 6·5 c.c. would have been detected.

From the uninfected B samples, out of the 5451 colonies selected for special study, *one, and only one, consisted of bacteria which resembled the typhoid bacillus very closely.*

It will be instructive to record the observations which were made on submitting this typhoid-like microbe (*Lee W.* 694 ? *B. typhosus, Houston*) to the several tests used in the diagnosis of typhoid bacilli.

Characterisation of typhoid-like bacillus from raw river water (Lea W. 694 ? B. typhosus, Houston).

Morphology. A motile multiflagellate bacillus. The rods seemed shorter than in most strains of *B. typhosus.*

Gelatin and agar slope-cultures. Possibly the growth was slightly less filmy in character than that of the true *B. typhosus.*

Glucose-bile-salt agar-slope (neutral red). The streak somewhat brighter and cleaner red than in most strains of *B. typhosus.*

Lactose-bile-salt agar-slope (neutral red). Colourless streak.

Potato. No visible growth (5 days at 37°).

Nitrate-broth. Reduces nitrates to nitrites.

Peptone-water at 55°F. No visible growth after 5 days; on transferring tube to incubator at 37°C. growth occurred within 24 hours.

Indole test. No indole formation (5 days at 37°).

Liquid peptone (1 p.c.) *media* containing separately 1 p.c. of the substances stated and tinted with litmus. Sorbite and inosite are only used in 0·2 p.c. solution. Acid but no gas in sorbite, mannite, glucose, lævulose, galactose, and maltose respectively (2 days at 37°). No change in inulin, inosite, saccharose, salicin, adonite, lactose, dulcite, and raffinose respectively (5 days at 37°).

Gelatin glucose medium tinted with litmus. Acid but no gas formation.

Voges and Proskauer's reaction. Negative result, 5 days.

Gelatin. No liquefaction after one month at 20°.

Litmus milk. Slight acid but no coagulation (5 days at 37°).

Glucose-neutral-red-broth cultures. No gas, no fluorescence characteristic purplish tint.

Lactose-saccharose-dulcite-salicin-peptone medium tinted with litmus. No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 1 (*modified*). No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 2. Acid but no gas.

Agglutination experiments and tests for pathogenicity.

Anti-typhoid serum. Microscopically, 1 : 200 almost instantaneous clumping, 1 : 800 very fair clumping, 1 : 2000 little or none. *B. typhosus* tested with the same serum gave very similar results but appeared to be clumped slightly more rapidly and in slightly higher dilutions. The difference, however, if any, was not well marked.

Serum of an animal immunised with the suspected microbe (*Lea W.* 694 ? *B. typhosus, Houston*). Microscopically, 1 : 200 very rapid and satisfactory clumping; 1 : 2000 good, but not quite complete clumping within half an hour.

B. typhosus tested with the same serum gave very similar results, but was perhaps clumped a little more slowly and in slightly lower dilutions. The difference, however, if any, was not well marked. Microscopically, the titre limit was about 1 : 8000 (18 hours) and was practically the same for both microbes.

Pathogenicity. 2 c.c. of a broth-culture injected subcutaneously into a guinea-pig produced a swelling and illness with recovery. A guinea-pig intraperitoneally inoculated with 5 c.c. of a broth-culture died in less than 24 hours.

On the results of this laborious investigation, which had extended over more than two years, and which had been conducted with the most meticulous care and regardless of time and money, Dr. Houston very cautiously remarks: '*If this microbe had been isolated from a case of typhoid fever* (*or from a suspected case*) *I do not think any serious hesitation would have been felt in describing it as B. typhosus.*'

It would be impossible to produce more eloquent testimony than the above as to the enormous and almost prohibitive trouble which a systematic and conscientious search for the typhoid bacillus in a natural water entails.

Comparative unimportance of searching for the typhoid bacillus in water. The almost hopeless nature of the search for the typhoid bacillus in natural waters is of the less importance as the anxiety to detect this microbe in water is, for the most part, based upon an entire misconception of the objects of water examination. The object of a water examination is, in general, not to determine whether the particular sample of water contains typhoid bacilli and is, therefore, capable of carrying typhoid to the consumer, but to discover whether the water is likely *at any time* to contain such infective material.

Now any water which receives sewage matters must be regarded as a *possible* carrier of typhoid infection, for at any time these sewage matters may be derived from persons suffering from typhoid. Thus any sewage-contaminated water is a potential carrier of typhoid unless it has been subjected to conditions which would ensure the removal of the possibly present typhoid bacillus. Thus the all-important thing is to ascertain whether a given water has been contaminated with sewage, in what proportion such contamination has taken place, and whether the water since such contamination has been submitted to conditions which would remove or destroy typhoid bacilli should they have gained access with the sewage matters.

Firstly, as regards the detection of sewage contamination. Excremental contamination, if sufficient in amount, can be revealed with more or less certainty by chemical analysis, which can indeed even distinguish between whether such pollution is recent or remote in point of time, but in order to ascertain the fate of bacteria gaining access to water recourse must be had to biological methods. If there were bacteria absolutely characteristic of sewage, the determination of their presence would be sufficient to prove the danger of a water. Unfortunately we do not know of any bacteria which satisfy the condition of being *absolutely* characteristic of sewage, so we must be satisfied with a second best qualification for diagnostic purposes by those which are *very* characteristic of sewage.

The microbe which is most characteristic of the intestinal discharges of man and the higher animals is, as its name implies, the *B. coli communis*, and a great amount of time and ingenuity has been devoted to its accurate and expeditious discovery in water and other materials.

In identifying a particular organism, whether plant or animal, we depend on recognising in the individual a certain group of specific characters which are more or less arbitrary. The botanist at first tried to classify and distinguish bacteria by external appearances alone; he measured the length and breadth of these minute organisms; he counted the number of flagella with which some of them are provided; he was very careful to observe whether they were square or round at the ends, and so forth.

These morphological characters have, however, long been recognised as inadequate for purposes of identification, since organisms exhibiting the closest morphological similarity have been found to differ enormously in other respects.

After the introduction of Koch's methods much attention was directed to the macroscopic appearances to which the organisms give rise when grown on a variety of solid media, by which means microscopically similar bacteria can often be differentiated.

Some 20 years ago the writer commenced distinguishing bacteria, which were similar in form and in cultural appearances, by differences in the chemical changes which they could bring about in certain media. Thus he found that the capacity to reduce nitrates to nitrites was in some cases a valuable means of distinguishing between otherwise similar bacteria. This reduction of nitrates has been extensively used for diagnostic purposes, more especially by American bacteriologists. Somewhat later he devoted much attention to the fermentaion of carbohydrates, polyhydric alcohols, and hydroxyacids, by means of pure cultivations of micro-organisms, and showed how capricious is the power possessed by different bacteria in this respect. Thus perhaps one microbe will ferment glucose, mannite, and glycerol, but not dulcite or glyceric acid, another will ferment glucose, mannite and dulcite, &c.

This mode of differentiating between otherwise very similar forms of bacteria has been greatly extended within recent years. In the following table the classification of the Typhoid-coli group of bacteria into seven subgroups has been attempted :—

TYPHOID-COLI GROUP.

Sub-groups	Glucose	Acid gas	Lactose	Acid gas	Dulcite	Acid gas	Saccharose	Acid gas
I.								
B. *Typhosus* . . .	+	−	−	−	−	−	−	−
B. dysenteriæ . . .	+	−	−	−	−	−	−	−
B. fæcalisalcaligenes . .	−	−	−	−	−	−	−	−
II.								
B. enteritidis (Gaertner) .	+	+	−	−	+	+	−	−
B. paratyph . . .	+	+	−	−	+	+	−	−
B. paracoli	+	+	−	−	+	+	−	−
III.								
Bacillus from urine . .	+	+	−	−	−	−	+	+
IV.								
B. acidi lactici (Hueppe) .	+	+	+	+	−	−	−	−
V.								
B. coli (Escherich) . .	+	+	+	+	+	+	−	−
VI.								
B. pneumoniæ (Friedländer) .	+	+	+	+	+	+	+	+
VII.								
B. capsulatus (Pfeiffer) .	+	+	+	+	−	−	+	+
B. lactis aërogenes (Escherich)	+	+	+	+	−	−	+	+
B. cloacæ (Jordan) . .	+	+	+	+	−	−	+	+

There are, however, many bacteria which more or less simulate the characters of the typhoid bacillus on the one hand, and of the *B. coli* on the other; such forms exhibit almost every degree of approximation to one or other of these two types, from which they can only be distinguished by applying a number of tests. Such forms are designated as *atypical*, and what their relationship to the typical typhoid and coli bacteria may be is a matter of uncertainty. Possibly in some cases they may have been typical forms originally, but under the particular conditions to which they have been submitted they have lost some of their characters. Thus it is often found that the *B. coli*, on prolonged artificial culture, may lose either or both its indole-producing and milk-curdling properties

It is obvious that by increasing the number of biochemical tests many further variations of a given type of organism may be discovered, and, for the purpose of more precisely defining a particular microbe, bacteriologists have introduced biochemical tests involving the use of a variety of organic compounds—more especially carbohydrates, polyhydric alcohols, and glucosides. These tests generally consist in ascertaining whether an organism under investigation gives rise to acid or gas, or both, or neither, in a suitable nutritive medium containing one of these substances. The following list of substances employed in this manner will give some idea of the degree to which these biochemical tests have been complicated in recent years: adonite, asparagine, dextrin, dulcite, erythrite, galactose, glucose, glycerol, glycol, *iso*dulcite, lactose, lævulose, maltose, mannite, mannose, nutrose, raffinose, sucrose, salicin, sorbite, and starch. The above list by no means exhausts the number of organic substances which are acted on by bacteria, and by means of which, therefore, differences can be established.

Although such tests are extremely useful for the more precise definition of particular micro-organisms, they must be employed with discrimination, for as the writer long ago pointed out, these fermentations, as well as other characters of bacteria, are liable to be lost through conditions of environment, and he has also shown how in some cases they may be restored by resorting to particular methods of culture and training.

It is obvious that it would be impracticable to resort to such numerous tests in the ordinary bacteriological examination of water in which we are concerned with the detection of sewage or excremental contamination, unless some very great advantage should result from such multiplication of tests, and this is not the case at present.

Quantitative determination of B. coli in water. If we regard the *B. coli* provisionally as the best indicator of contamination with the living bacteria of animal refuse, we shall obviously view its presence with the more suspicion the larger the numbers in which it is discovered in a given volume of water.

The numerous methods which have from time to time been devised for detecting *B. coli* will be passed over, and only the one which in this country at any rate has superseded all others will be described.

An important departure in practical bacteriology was the introduction by McConkey and Hill ('Bile-salt broth. A simple test for fæcal contamination.' Thompson-Yates Laboratories Report, 1901, 4, [i.] 151) of a medium for the preferential culture of the *B. coli* and allied microbes from mixtures of micro-organisms. The essential ingredients of this medium are sodium taurocholate (bile-salt), 5 grms., glucose, 5 grms., peptone, 20 grms., water (tinted with litmus), 1000 c.c. Incubated in this liquid at 37°–42° bacteria of the *B. coli* group give acid and gas in 48 hours. Some bacteriologists use lactose instead of glucose, thus restricting the gas production to *B. coli* and its still closer allies. With this liquid medium in Durham fermentation-tubes cultivations of the water are made in the following quantities: 100, 10, 1, 0·1, 0·01, 0·001, 0·0001, 0·00001 c.c. The concentration of the medium should in all cases be approximately the same as that given above. In order, therefore, that the volumes of liquid incubated may not be inconveniently large, the 10 and 100 c.c. of water are introduced into correspondingly stronger McConkey media.

A positive reaction, *i.e.* the production of acid and gas, in any of these culture-tubes signifies that *at least one* coli-like microbe must have been introduced with the portion of water added. Thus, if acid and gas had been obtained, in a particular case, with all the tubes from 100 to 0·1 c.c., this would mean the '*presumptive*' presence of at least one *B. coli* in 0·1 c.c., and its absence in 0·01 c.c. and smaller volumes of water.[1]

In order to ascertain whether the 'presumptive' *B. coli* is typical or not, the tube containing the smallest portion of water which has given rise to acid and gas in the McConkey medium is plated on a solid medium of the following composition: Agar 20 grms., peptone 20 grms., sodium taurocholate (bile-salt) 5 grms., lactose 10 grms., neutral red (1 p.c. solution), 4 c.c., made up to 1000 c.c. with water. After 12 hours' incubation at 37°, the colonies will be distinctly visible, and those which are most likely to be *B. coli* will have a strong red colour owing to the acid produced by this microbe in the medium. Five of the most typical red colonies are separately inoculated into 5 glucose-litmus broth tubes, which are then incubated at 37°. Any of these 5 tubes which develop acid and gas are then each further inoculated into tubes of the following media which are then incubated at 37°:—

---

[1] There is one element of uncertainty connected with such tests made in liquid media which appears to be tacitly ignored by all bacteriologists who make use of them, and that is that the particular microbe sought for may in the process of cultivation in the liquid medium become hopelessly outnumbered or even suppressed by the much more abundant proliferation of some other microbe or microbes present in the mixture.

Thus the McConkey medium may be taken as specially favourable for the proliferation of bacteria of the *B. coli* type, but the water-bacteriologist is in general restricting his search to those bacteria which are sufficiently like typical *B. coli* as to produce acid *and* gas in the medium. Is it not possible that the bacteria capable of producing both acid and gas may be so greatly outnumbered by microbes not giving this reaction that the more typical *B. coli* forms may be so much kept in abeyance that no acid and gas reaction is obtained? Under these circumstances he would obviously draw the conclusion, and quite erroneously, that acid and gas producing microbes (and, therefore, *B. coli* amongst them) were absent. This is a matter which requires much further investigation before the conclusions as to *absence* of *B. coli* generally drawn can be justified.

(*a*) Neutral red broth to be examined for fluorescence.

(*b*) Litmus lactose-broth to be examined for *acid and gas.*

(*c*) Ordinary broth to be examined for *indole.*

(*d*) Litmus-milk to be examined for *acid and coagulation.*

(*e*) Gelatin to be examined for *non-liquefaction.*

The above glucose-tubes from which these inoculations have been made are also microscopically examined to see whether the microbe possesses the characteristic form and motility of the *B. coli.*

A microbe fulfilling these conditions has been designated by Houston as '*Flaginac*' *B. coli*, from Fl=fluorescence in neutral-red broth, ag=acid and gas in lactose, ín=indole in peptone broth, ac=acid and coagulation in litmus-milk.

The typical *B. coli* from human fæces gives these reactions, but, of course, it is possible to further differentiate between coli-bacteria by additional tests, such as fermentation of sucrose, dulcite, mannite, &c., but at present there would not appear to be any advantage in such multiplication of tests in the ordinary examination of water.

The following table summarises an interesting investigation made by Houston on the proportion of 'Flaginac' *B. coli* found amongst the coli-like microbes obtained from different sources:—

FLAGINAC B. COLI.

Source	Number of specimens of *B. coli* or coli-like microbes on which percentage is based	P.c. of flaginac *B. coli*
Milk . . .	343	61
Human fæces . .	101	85
Sewage . . .	several hundreds	65–85
Oysters . . .	464	43
Estuarial waters .	183	66
Water-cress . .	81	40
Washings of cress .	52	52
Water in which cress was grown . .	42	76
London filtered water	232	31

In the following table are recorded the results of some very suggestive pioneering experiments made by McConkey (1905), undertaken with the object of ascertaining whether there is any marked difference in the types of *B. coli* found in the excreta of man and some of the common domestic animals respectively. Should it be possible to establish such a difference, an important means of distinguishing between human and animal excrementitious contamination of water would be obtained.

B. COLI FROM HUMAN AND ANIMAL EXCRETA (MCCONKEY).

Group	Fermentation of		Number of lactose-fermenting Coli-form microbes isolated and experimented with			Results in percentages		
	Saccharose	Dulcite	Human	Animal[1]	Total	Human	Animal	Average

Sheep No. 2 . . .	10 to 100 millions	10 to 100 millions	10 to 100

Such an investigation would have to be enormously extended before results capable of being used for diagnostic purposes could be obtained.

An attack on the same important problem was also made by Dr. Wm. G. Savage (1904–5) in an extremely laborious investigation, which he has summarised in the foregoing table.

The absence of streptococci in the fæces of the pig is extremely remarkable.

It is convenient to classify waters tentatively according to the results of the examination for *B. coli*, thus :—

Classification of Water by B. Coli Test.

(1 c.c. of sewage is assumed to contain 100,000 *B. coli*.)

Class	Volume of water examined	*B. coli* per 1 c.c.	Pollution in sewage
	c.c.		per cent.
I .	— in 100	0	—
II .	+ in 100	0·01	0·00001
III .	+ in 10	0·1	0·0001
IV .	+ in 1	1	0·001
V .	+ in 0·1	10	0·01
VI .	+ in 0·01	100	0·1
VII .	+ in 0·001	1000	1
VIII .	+ in 0·0001	10,000	10
IX .	+ in 0·00001	100,000	100 (pure sewage)

This classification must not, however, be interpreted too rigidly, as it is based on the assumption that *B. coli* is always derived from fæces and that this microbe is incapable of multiplication under any circumstances after incorporation in what is known as 'sewage.'

In the two following tables are recorded the results of the ordinary bacteriological examination of a number of typical waters. The tables sufficiently explain themselves.

Storage of water. In 1886 (Water Purification, its Biological and Chemical Basis, Trans. Inst. Civil Engineers, 1886) the writer pointed out the great importance from a theoretical point of view of storage for the purification of surface waters. In 1892, again, he investigated the influence of storage on the bacteriological purity of the river waters abstracted for the supply of London, and showed that there is a most striking reduction in the number of suspended micro-organisms during storage in large reservoirs.[1]

The great importance of storage from the hygienic point of view was further manifest from the experiments made on the fate of pathogenic bacteria introduced into natural waters, and which showed that the duration of life of these bacteria under such conditions is generally very short.

In 1891–4 the writer had the opportunity of greatly extending his observations on this subject, as he was requested by a Committee of the Royal Society to make, in conjunction with the late Professor Marshall Ward, F.R.S., a special inquiry into the vitality of pathogenic bacteria in potable waters (*see* Proc. Roy. Soc.). The experiments were restricted to the study of the behaviour of the anthrax bacillus (and its spores), the typhoid bacillus, and the *B. coli communis*, and the potable waters employed were those of the Thames, Loch Katrine, and deep-well water from the chalk, these being fairly typical of the different kinds of water used for drinking purposes in this country. Experiments were made with these waters in their natural, and also in a sterilised, condition.

[1] Surface water from more or less cultivated land.

[2] Moorland water from Elan Valley, Wales.

The results obtained may be summarised as follows :—

(1) Unsterilised water infected with anthrax bacilli containing spores was still virulent after being kept for 7 months.

(2) Anthrax bacilli taken directly from an animal dead of anthrax, and, therefore, free from spores, died rapidly (mostly in 5 days) when introduced into unsterilised water kept at low temperatures (5° and 13° in these experiments), but when introduced into the same waters and kept at 19°, the bacilli formed spores, and the latter were still present in enormous numbers

even 42 days later, and doubtless for a much longer period still. This remarkable difference in behaviour is accounted for by the fact, previously discovered by Koch, that anthrax bacilli do not form spores below 16°.

The following results were obtained by introducing typhoid bacilli from one and the same cultivation and in the same numbers into each of the waters at one and the same time:—

Unsterilised water	Life of typhoid bacilli
Thames water (Oct. 19, 1893) 9°–12°	Between 9 and 13 days
Loch Katrine water (Oct. 19, 1893) 9°–12°	,, 19 ,, 33 ,,
Deep well water (Oct. 19, 1893) 9°–12°	,, 33 ,, 39 ,,
In two other separate experiments with unsterilised Thames water (May 11, 1893)	,, 25 ,, 34 ,,
and (Jan. 16, 1894) . .	,, 20 ,, 27 ,,

In all these experiments only 1 c.c. of water was examined for typhoid bacilli, and the method of search, the best known at the time, was that due to Parietti, in which the water is cultivated in a phenol-broth medium at 37°, which on becoming turbid is submitted to plate cultivation, the colonies obtained being then examined in detail for identification

It is particularly interesting to compare with the above results those obtained by Houston in a perfectly similar inquiry and making use of all the most modern developments of bacteriological technique. Dr. Houston made 18 experiments on raw Thames, Lea, and New River waters, infecting them with typhoid bacilli (the number added being in all but three experiments very large, *see* table below). The presence of the bacillus was tested for at weekly intervals in 1 c.c. by means of a medium containing *Agar-bile-salt-dulcite-lactose-saccharose-salicin-peptone-neutral-red-malachite-green*, and which is specially designed to favour the growth of this microbe whilst repressing that of most others. The results may be summarised in the following statement:—

In 3 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 1 week.

In 10 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 3 weeks.

In 16 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 4 weeks.

In 18 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 5 weeks.

Thus, notwithstanding the great advances made in the technique of testing for the typhoid bacillus, the results obtained by Houston are essentially similar to those obtained by the writer 15 years previously. Houston has, however, extended the investigation in an interesting manner by ascertaining the length of time required before even 100 c.c. of the infected water gave a negative result on being tested by the most modern methods for the presence of the typhoid bacillus. The whole of Houston's investigation (both for 1 c.c. and for 100 c.c. of water tested) is instructively summarised in the table below.

Description of water	Initial No. of typhoid bacilli in 1 c.c. of infected water	Number of typhoid bacilli in 1 c.c. of infected water after						Number of weeks required for destruction of typhoid bacillus in 100 c.c. of infected water
		1 week		2 weeks	3 weeks	4 weeks	5 weeks	
			(p.c. reduction)

New River (VI)	475,000	30	99·9	3	0	—	—	7

This table shows, on the one hand, that whilst in each case nearly all the typhoid bacilli are destroyed by a single week's residence in these raw river waters a few individuals persist for a much longer period of time. This illustrates in a very interesting and instructive manner a principle emphasised by the writer some 16 years before, 'that one of the factors determining the longevity of pathogenic bacteria placed in water, or for the matter of that placed in any unfavourable surroundings, is the absolute number in which they are present. In other words, amongst, for instance, 1000 bacteria taken from a given source there may be *some individuals* which will resist a particular adverse influence, whilst amongst 10 bacteria taken from the same source there may be *none* capable of resisting the adverse influence in question' (P. F. Frankland, Proc. Roy. Soc. 1894, 56, 486).

Before leaving the subject of the behaviour of the typhoid bacillus in water, mention must be made of some extremely interesting and ingenious experiments by the American bacteriologists, Jordan, Russel, and Zeit, in 1903. These investigators endeavoured to imitate natural conditions more closely than has been done in any other experiments by placing the typhoid-infected waters in permeable sacs made of celloidin and parchment, and then by submerging these in river, canal, or lake water, their contents were exposed to the influence of the dialysable substances present in the water under natural conditions.

Zeit experimented with Lake Michigan water and Chicago river water, the natural bacterial content of which varies between 68 and 2000 microbes per 1 c.c. in the case of the Lake, and between 80,000 and 1,500,000 microbes per 1 c.c. in that of the river water. Parallel experiments were made with infected water placed in ordinary bottles and in permeable sacs respectively. The typhoid bacilli introduced varied between 500 and 2,000,000 per 1 c.c. The destruction of the typhoid bacillus was taken as complete when negative results were obtained on cultivating 5 c.c. of the water, the death of the typhoid bacillus being generally confirmed by the subsequent cultivation, a few days later, of much larger volumes, sometimes as much as 800 c.c., of the water. Nine experiments were made with the Michigan Lake water, *the typhoid bacillus being never found after the eighth day.* Five experiments were made with the Chicago River water, *the typhoid bacillus being never found after the third day.*

Jordan experimented with the water of the Chicago Drainage Canal, which usually contains from 100,000 to 400,000 bacteria per 1 c.c. This water was infected with from 180 to 857,000 typhoid bacilli per 1 c.c. In these experiments, however, the maximum volume submitted to cultivation appears to have been only 1 c.c., and from negative results with even smaller volumes the death of the typhoid bacillus seems to have been concluded. Twenty-eight experiments were made in permeable sacs submerged in the canal, *the typhoid bacillus being never detected after the second day, excepting in one experiment in which it was still found on the tenth day.*

Russel's experiments were made with the Illinois River water, which contains from 1800 to 4000 bacteria per 1 c.c. This water was infected with 540 to 20,000 typhoid bacilli per 1 c.c. However, in these experiments, again, 1 c.c. appears to have been the maximum volume of water cultivated for the detection of the typhoid bacillus. Fourteen experiments were made in permeable sacs submerged in the Illinois River, *the typhoid bacillus being never found after the third day, excepting in one case in which it was detected on the ninth day.*

More recently, again, Houston has taken typhoid bacilli not from cultivations but from the human subject and introduced them into raw Thames water. He found that such bacilli perished very rapidly—much more quickly in fact than had been his experience with cultivated strains of the microbe.

The uncultivated typhoid bacteria were obtained from the urine of a 'typhoid carrier,' and on Aug. 9, 1910, the centrifugalised deposit (3·5 c.c.) from 389 c.c. of urine was added to 5000 c.c. of raw Thames water; the number of typhoid baccilli was determined as follows:—

At time of mixture, 770,000 typhoid bacilli per 1 c.c. of river water.

After 1 week, 4 typhoid bacilli per 1 c.c. of river water.

After 2 weeks, 0 typhoid bacilli in 100 c.c.

On the 24th day from the commencement of the experiment half-a-pint (about 284 c.c.) of the infected water was drunk, this quantity of water having *originally* contained 218,680,000 typhoid bacilli. Similar amounts were drunk with impunity on the 25th, 26th, 27th, and 28th days after the beginning of the experiment.

On Aug. 19, 1910, the experiment was repeated with a fresh sample of urine, the number of typhoid bacilli per 1 c.c. of river-water being 1650. A week later no typhoid bacilli could be found, and on the 23rd, 24th, 25th, 26th, and 27th day from the beginning half-a-pint of the infected water was drunk each day without any ill-effect (Sixth Research Report, Metrop. Water Board, Nov. 1910, p. 7).

If this drinking part of the experiment is to prove anything it would be necessary for Dr. Houston to follow it up by drinking a similar number of *fresh* typhoid bacilli from the same patient and contracting the disease, for without this last act we have no certainty that Dr. Houston is susceptible to this malady, and, therefore, a fit *corpus vile* on which to make this crucial test.

Vitality of the Spirillum of Asiatic cholera in potable water. Experiments were made by Houston with the cholera spirillum on exactly the same lines as those which he had previously adopted in the case of the typhoid bacillus in raw Thames, Lea, and New River water. The principal conclusions arrived at may be summarised as follows (4th Report on Research Work, Metrop. Water Board, June. 1909):—

'(1) Cholera vibrios die very rapidly in *raw* Thames, Lea, and New River water as the result of storage in the laboratory. At least 99·9 p.c. perished within one week, and in none of the experiments could any cholera vibrios (recognisable as such) be found even in 100 c.c. of water 3 weeks after its infection. In more than half the experiments the results were negative by the second week.

'(2) The isolation of cholera vibrios from *artificially* infected *raw* river water presents no insuperable difficulties even when the number artificially added is very small, both actually and relatively to the bacteria nominally present in the river water.

'(3) On the other hand, microbes liable (after careful study) to be mistaken for true cholera vibrios were not found in comparable, but non-infected, river water samples examined under precisely similar conditions.'

Thus the cholera vibrios are much more perishable in these raw river waters than are the typhoid bacilli under similar conditions.

The comparatively short duration of life of pathogenic bacteria when introduced into natural waters and more especially into surface waters, which these numerous and independent investigations establish, clearly show that the process of storage in large reservoirs must form a very important safeguard against the water-carriage of zymotic diseases. This safeguard, which is supplementary to and quite independent of that of filtration, has the great advantage of being under perfect control and much less liable to accidental disturbances than are most other methods of water-purification. It is, however, unfortunate that many reservoirs attached to water works have not been designed so as to secure the maximum advantages of storage, and their rearrangement with this object in view is generally a matter of great expense and sometimes impracticable. It is to be hoped that in future engineers will be more careful to arrange for such a circulation of the water that each particle of water entering shall remain as long as possible in the reservoir before passing out.

The influence of storage on the bacteriology of surface waters has recently been made the subject of very extended and interesting investigations by Houston in connection with the London water supply. There can be no doubt that adequate storage brings about the following beneficial changes:—

(1) Reduces the number of bacteria of all sorts.

(2) Reduces the number of bacteria capable of growing on agar at blood heat.

(3) Reduces the number of bacteria capable of growing in a bile-salt medium at blood heat.

(4) Reduces the number of coli-like microbes.

(5) Reduces the number of typical *B. coli.*

(6) Alters certain bacteriological ratios for river-waters, *e.g.* it reduces the number of typical *B. coli* to a proportionately greater extent than it reduces the number of bacteria of all sorts.

(7) If sufficiently prolonged, it devitalises the microbes of water-borne disease (*e.g.* the typhoid bacillus and the cholera vibrio).

(8) Reduces the amount of suspended matter.

(9) Reduces the amount of colour.

(10) Reduces the amount of ammoniacal nitrogen.

(11) Reduces the amount of oxygen absorbed from permanganate.

(12) Usually reduces the hardness and may reduce (or alter the quality of) the albuminoid nitrogen.

(13) Alters certain chemical ratios for river-waters; *e.g.* the colour results improve more than the results yielded by the permanganate test.

(14) Has a marked 'levelling' effect on the totality of water delivered to the filter-beds.

(15) Tends generally to lengthen the life of the filters (only under exceptional conditions is the contrary true).

(16) An adequately stored water is to be regarded as a 'safe' water, and the 'safety change' which has occurred in a stored water can be recognised by appropriate tests.

(17) The use of adequately stored waters renders any accidental breakdown in the filtering arrangements much less serious than might otherwise be the case.

The experimental basis for many of the above statements with regard to the benefits of storage will be found in the following table (Houston, Annual Report, March 31, 1910, p. 52):—

Fæcal streptococci in water. Attempts have been made to supplement the indications of fæcal contamination yielded by the presence of *B. coli*. The most recent and noteworthy of these is the examination of water for the presence of certain streptococci which are usually very abundant, sometimes even more abundant, in human fæces than is the *B. coli*. This matter has been engaging the attention of Dr. Houston since 1898, and he has recently (June, 1910) given a special account of the results, which he has obtained up to the present time.

At the outset it should be pointed out that these streptococci are not peculiar to human excreta, but are also abundantly present in those of the higher animals, many of Houston's experiments having been made with streptococci obtained from cow-dung. The study of these micro-organisms does not, therefore, at present put us in possession of that all important desideratum —a means of distinguishing between contamination due to the excrement of man and that which is due to the lower animals.

According to Houston, human fæces contain, roughly, 100,000 streptococci per 1 grm. On the other hand, in some stools streptococci are either absent or present in such small numbers relatively to those of other bacteria that search for them is useless. Their presence in water has hitherto been ascertained by spreading 1 c.c. of the water on a Drigalski-Conradi plate, on which medium, after incubation at 37°, the streptococci give rise to very minute colonies, which can then be sub-cultivated for determination of their biochemical characters.

Of 100 different cultures of streptococci obtained by Houston from sewage works fæces: (*a*) 100 produced acid in lactose and in raffinose media, and all of them clotted milk. (*b*) None reduced nitrates to nitrites. (*c*) Only four produced acid in a mannite medium. (*d*) 97 produced acid in a salicin medium. (*e*) 49 produced acid in a saccharose medium.

The grouping of these properties is best indicated by means of a convention similar to that employed in the case of *B. coli*, in which syllables are made to represent definite biochemical reactions, thus:—

la = acid in a *lac*tose medium.
ma = ,, ,, *man*nite ,,
mi = clot ,, *mi*lk ,,
ra = acid ,, *ra*ffinose ,,
sac = ,, ,, *sac*charose ,,
sal = ,, ,, *sal*icin ,,

The 100 streptococci examined may then be thus classified:—

la-mi-ra-sal	49
la-mi-ra-sac-sal	44
la-ma-mi-ra-sac-sal	4
la-mi-ra-sac	1
la-mi-ra	2

Thus 97 p.c. clotted milk, and produced acid in lactose, raffinose, and salicin media, and of these 48 produced acid and 49 no appreciable acidity in a saccharose medium.

During the year 1909 Houston examined the raw (unfiltered and unstored) Thames, Lea, and

New River waters for streptococci, employing 1 c.c. of each sample on Drigalski plates as above, with the following results :—

	No. of times streptococci were found in 1 c.c.
52 weekly samples of Thames water .	13
52 weekly samples of Lea water .	13
52 weekly samples of New River water	2

As regards the types of streptococci found in the above 28 samples of the 71 sub-cultures of streptococci examined the following combinations were found :—

	Thames	Lea	New River
La-ma-mi-ra-sac-sal.	1	2	0
La-ma-mi-sac-sal .	1	3	0
La-mi-ra-sac-sal .	9	17	0
La-ma-sac-sal .	0	1	0
La-ma-mi-sac .	0	3	0
La-mi-sac-sal . .	4	9	0
La-mi-ra-sac . .	2	10	0
La-sac-sal . .	0	1	2
La-mi-sal . .	0	1	0
La-mi-sac . .	2	0	0
La-ra-sac . .	0	3	0
Total	19	50	2

The above results are especially interesting as showing that the two impurer waters (Thames and Lea) contained streptococci much more frequently than the far purer water (New River), and further, that the streptococci actually discovered in the latter were of a type more remote from that of those which are usually discovered in fæces.

Bearing in mind that, on an average, upwards of 90 p.c. of the raw Thames and Lea samples, and about 50 p.c. of the raw New River samples contain typical *B. coli* in 1 c.c. or under, whilst in only 25 p.c. of the raw Thames and Lea samples, and in only 3·8 p.c. of the raw New River samples were streptococci found, it follows that the streptococci are a far less delicate index of contamination than the *B. coli*. The absence of streptococci in 1 c.c. of a water cannot, therefore, be regarded as any criterion of its purity. The relative scarcity of streptococci in waters which have undoubtedly received a considerable amount of sewage matters is accounted for by the fact, established by Houston, that streptococci very rapidly die off when placed in water. This circumstance points, of course, to the presence of streptococci serving as an indication of very recent contamination.

Recent bacteriological methods applied to other processes of water purification. From the evidence already brought forward it appears that confidence in the purification which can be effected by storage and sand-filtration, under favourable conditions, has been distinctly strengthened by the application of the more recent developments of bacteriological water examination—search for *B. coli* and other microbes more or less connected with sewage contamination.

Certain other processes of water-purification which are employed on the large scale may now be briefly considered.

Mechanical filters. The use of mechanical filters originated in America, and their employment in our own country is becoming more and more common. Such filters are in use at Bolton, Burnley, Heywood, Edinburgh, Crewe, Gloucester, Shrewsbury, and other places in Great Britain, whilst they have also been installed in India, Japan, and some of the colonies. Space does not permit the discussion of the relative merits of the two different processes of filtration. They each possess their advantages and disadvantages; they can each be made to yield good and bad results according to the manner in which they are employed. The following results may serve as an illustration of the very high degree of purification which *can* be secured by means of mechanical filters, which, in this instance, were employed to further purify a river water, which was being very imperfectly purified by some defective sand-filters.

Purification of River Water by Mechanical Filters.

	Number of Bacteria in 1 c.c.				*B. coli* (typical) in

Ditto after passing sand filters	130	405	2	2	+	+	0	0
Ditto after further passing mechanical filters . .	8	33	0	0	0	0	0	0

Clark's process of softening. Already in 1885 the writer showed that in softening water with lime, a very large proportion of the bacteria are carried down with the precipitated chalk, but that if the latter is allowed to stand in contact with the softened water bacteria again pass from the precipitate into the water. In the softening process this removal of bacteria may, under favourable conditions, amount to upwards of 90 p.c.

Recently the writer had occasion to deal with a chalk well water, which was causing anxiety in consequence of its frequently containing *B. coli* in rather small volumes. The most obvious and unobjectionable method of purification which suggested itself was softening with lime, inasmuch as the water contained plenty of calcium bicarbonate in solution. The following table shows the results obtained in a number of small scale experiments in which this water was treated with lime, and sometimes with aluminoferric, and in which the softened water was sometimes decanted, sometimes filtered through paper without disturbing the precipitate ('clear filtration' in the table), and sometimes filtered after deliberately disturbing the precipitate ('turbid filtration' in the table):—

PURIFICATION OF WATER BY LIME AND ALUMINOFERRIC.

	Gelatin		*B. coli* in				
	No. of bacteria per 1 c.c.	Days incubated at 20° C.	100 c.c.	50 c.c.	10 c.c.	1·0 c.c.	0·1 c.c.
Raw well water	10 259	2 7	+	+	+	0	0
Ditto after filtration through sterile paper	7 236	2 7	+	+	+	0	0
Ditto+lime water, filtered through sterile paper after 1 hour's subsidence	0 90	2 7	+	+	0	0	0
Ditto+lime water and aluminoferric, filtered after 1 hour	0 39	2 7	+	0	0	0	0
Ditto+lime water; clear filtration after 3 hours	1 74	2 7	+	0	0	0	0
Ditto+lime water and aluminoferric; clear filtration after 3 hours	1 44	2 7	+	+	0	0	0
Ditto+lime water; turbid filtration after 3 hours	0 41	2 7	+	+	0	0	0
Ditto+lime water and aluminoferric; turbid filtration after 3 hours	0 41	2 7	0	0	0	0	0
Ditto+lime water; clear filtration after 25 hours	3 96	2 6	+	+	+	0	0
Ditto+lime water and aluminoferric; clear filtration after 25 hours	0 14	2 6	+	0	0	0	0

A great many experiments were made in addition to those recorded above, but always with the same disappointing result, that notwithstanding a large percentage reduction in the total number of bacteria taking place, it was only in rare cases that the *B. coli* was banished from 100 c.c. of the water by the precipitation process. It must be remembered that the demands now commonly made on a purification process with regard to the removal of *B. coli* are much more stringent than with regard to the removal of bacteria in general. Thus, should an untreated water contain 1000 bacteria per 1 c.c., if by treatment the number were reduced to 50 per 1 c.c., this would represent a purification of 95 p.c., and the water would be regarded as quite satisfactory from the point of view of the total number of bacteria present. But, if an untreated water contained the *B. coli* in 0·1 c.c., and after treatment this microbe were not present in less than 10 c.c., this would signify a removal of 99 p.c. of the *B. coli* present in the original water. But so high is the standard of purity at present often demanded in respect to freedom from *B. coli*, that the water which had thus been purified to the extent of 99 p.c. might still be regarded as of a questionable degree of purity.

OZONE TREATMENT OF WATER.

[1] *B. coli* found absent even in 500 c.c.

Ozone treatment. The bactericidal properties of ozone have been long demonstrated,[1] but it is only in quite recent years that it has been used on a large scale for the sterilisation of town water-supplies. In France the drinking waters of the towns of Nice, Chartres, and Cosne are being subjected to ozone treatment, whilst a plant for the treatment of 10 million gallons of water will be shortly erected in connection with the Paris waterworks. In Germany there are installations at Paderborn, Schierstein, and Hermannstadt.

The writer has recently made experiments with ozone in connection with the practicability of purifying the chalk well-water to which reference has just been made above. The extraordinary efficacy of this agent will be apparent from the foregoing results obtained in experiments in which the impurity of the chalk well-water was enormously exaggerated by the addition of 4 p.c. of polluted canal-water.

Bleaching-powder treatment. The bactericidal action of hypochlorites, again, has been long known, and bleaching powder is one of the oldest and commonest of disinfectants. The

[1] Ohlmüller, Arbeiten a. d. Kaiserl. Gesundheitsamte, 1892, 229; van Ermengem, Ann. de l'Inst. Pasteur, 1895, 673; Ohlmüller and Prall, *loc. cit.* 1902, 417; Proskauer and Schüder, Zeitsch. Hygiene and Infectionskrankheiten, 41, 227, 243; 42, 293; Calmette, Ann. de l'Inst. Pasteur, 1899, 13, 344.

use of hypochlorites for the sterilisation of water-supplies was first brought into prominence in this country by Houston, who used 'Chloros' which is an electrolysed solution of common salt, for the treatment of the Lincoln water-supply during the memorable epidemic of typhoid which occurred in that city in 1904–5.[1]

The writer has recently had occasion to investigate the efficiency of the bleaching-powder treatment on a chalk well-water, the experiment being made with a large experimental plant.

From the results given on p. 734 it will be seen what a high degree of purification is obtained by this simple and inexpensive method of treatment, even when extremely small quantities of bleaching-powder are added to the water. Thus the only occasions on which *B. coli* was found even in 100 c.c. of the treated water was on the first day of each of the two series of experiments and thus when the apparatus had presumably not yet been completely washed out with treated water. On several occasions even 500 c.c. of treated water was examined for *B. coli*, and this microbe was on each such occasion found to be absent even in that large volume.

Similar results have been obtained by Sims Woodhead, Thresh, Hehner, Rideal, and others.

Treatment with ultra-violet light. The known bactericidal action of the ultra-violet rays has been applied by Victor Henri to the sterilisation of water on a large scale. The rays are supplied by a Cooper-Hewitt mercury lamp. The lamp is worked with 3 ampères at 220 volts, and is placed in the bend of a semi-circular trough through which the water is passed. At Marseilles the process has been tried with a plant yielding 130,000 gallons per 24 hours, and using 120 watts per 1000 gallons. The crude water always contained some *B. coli*, and the total number of bacteria varied between 30 and 300 per 1 c.c., whilst, in the treated water, *B. coli* was absent and the total number of bacteria was reduced to an average of 1 per 1 c.c. (Modern Methods of Water Purification, Don and Chisholm, London, 1911). *See* also W. Clemence, Engineering, Jan. 27 and Feb. 3, 1911.

Conclusions. During the 25 years that the systematic bacteriological examination of water has been practised an enormous amount of work has been carried out by a large number of investigators, but notwithstanding the immense multiplication of results it must be admitted that no very surprising novelties have been brought to light since the year 1895. By then all the salient features in the bacteriology of water had been mapped out, and the past 15 years have more especially been occupied in filling in countless details and in confirming over and over again what had already been broadly established.

Thus, already in the earlier period, the methods of bacteriology had been successfully applied to a determination of the value of the most varied processes of water purification natural and artificial, filtration, storage, precipitation, sedimentation, &c. It had been shown how such processes should, in the interests of public health, be continuously watched over and controlled by bacteriological examinations made at frequent intervals. Again, the vitality in water of the principal bacteria associated with water-borne zymotic disease had been investigated, and the results then obtained were substantially the same as those which have been arrived at by the most recent developments in bacteriological technique. In a word, these most recent developments in the methods of bacteriology have served to confirm and emphasise the conclusions which had been generally arrived at by the less perfect methods of the earlier period.

The all-important questions which the water-examiner has to answer are the same to-day as they have been all along: (*a*) has the water been contaminated with the excreta of man?; and (*b*) if such contamination has taken place, has the water in its subsequent history been subjected to conditions which would insure the destruction or removal of the pathogenic bacteria which may at any time be present in such human refuse?

To the first of these questions bacteriology cannot give a categorical answer even to-day, because we are not acquainted with any microbes which are absolutely characteristic of human excreta. The greatly increased facilities for the detection and quantitative determination of the *B. coli*, however, have undoubtedly placed us in a position to readily ascertain whether and to what extent a water has been contaminated with excremental matter irrespectively of whether the latter is of human or animal origin, but it is obvious that this will not, in general, carry us very far, inasmuch as practically all surface water *must* be more or less so contaminated.

To the second question a similarly qualified answer, again, can be readily given. If the water is free from *B. coli* in a large volume, it may safely be concluded that *a fortiori* it is free from the typhoid bacillus in a similar volume. But should the *B. coli* be found in a small volume, it does not follow that the water may at any time be liable to contain typhoid bacilli, because the discovery of the *B. coli* does not prove that the water has been contaminated by man at all.

Thus with regard to both questions, it is obvious that we are in a much stronger position in the matter of exculpating than in that of incriminating a water. However, the inference that a water free from *B. coli* in a large volume is, therefore, necessarily a safe one, requires a slight qualification in view of the remarkable and interesting revelations which have in recent years been made with regard to what are known as '*typhoid carriers*.' Some of these persons suffering from ambulatory typhoid discharge typhoid bacilli in the urine, and it is thus possible that water may actually become contaminated with typhoid bacilli without at the same time receiving any *B. coli*. Although this is not likely to be of frequent occurrence, still its possibility, especially in the case of men working in wells, filter-beds, and service reservoirs, should on no account be disregarded.

Certainly one of the most important advances made in bacteriology during recent years is the careful characterisation of bacteria by means of biochemical tests, and the isolation of particular types of bacteria from such mixtures as

---

[1] In that epidemic there were as many deaths (119) from typhoid in six months as had occurred from the same cause during the previous eighteen years.

are present in water by means of special culture-media, liquid and solid. However, until bacteriologists have agreed upon uniform tests for each particular microbe it is unavoidable that there should be much confusion and that the results obtained by different observers should be difficult to compare. Under these circumstances the interpretation of results by the individual observer is a matter of the greatest importance, and it is needless to say that unless the individual observer has a wide personal experience and a thorough knowledge of the factors affecting the purity of water-supplies of different kinds his interpretation of the results obtained will not only have little practical value but may easily lead to very serious mistakes.

Thus, whilst the outstanding achievement in bacteriological water examination during the past 15 years is the systematisation of tests for detecting the presence in water of specific bacteria, especially *B. coli*, Streptococci, and the spores of *B. enteritidis sporogenes, the different possible sources of these bacteria, and their different hygienic significance according to source* render any hard and fast application of standards based on the presence of these microbes impossible without liability to serious errors of judgment being committed.

Space has not permitted reference in detail to the spores of *B. enteritidis sporogenes*[1] as an index of fæcal contamination. The figures on p. 726 show how much less abundant in fæces are these spores than is the *B. coli communis*. They do not, therefore, form such a delicate test for sewage contamination as does the *B. coli*, and their final identification is much less certain. The water-bacteriologist should, however, not neglect a search for these spores, but should regard the evidence which their presence or absence affords as supplementary to that which is furnished by the *B. coli* results.

In conclusion a word may be said with regard to the relative value of the chemical and bacteriological examination of water. At the present time it is often supposed that the chemical has been entirely superseded by the bacteriological examination, and that the chemical analysis of drinking water can be dispensed with. In reality the two methods of examination supplement each other. In those cases in which the source and general characters of a water supply are well known, the variations in purity from day to day or from week to week can undoubtedly be more satisfactorily watched by means of bacteriological examination. On the other hand, it is often desired by means of a single examination to ascertain the fitness or otherwise of a water for domestic use, and in such cases the omission of a chemical analysis may lead to an entirely erroneous opinion being formed. The ingredients detected by chemical analysis—organic matter, ammonia, nitrates, chlorides, &c.—on which an opinion as to hygienic quality is based, are all much more permanent and uniform features in the composition of the water than are the amount and the nature of the bacterial life which it may contain. The chemical analysis will, therefore, if skilfully interpreted, enable a much better idea of the potability of the water to be obtained than would be possible from a single bacteriological examination.

There are so many factors and considerations which have to be taken into account if an opinion of any real value as to the hygienic quality of water is to be formed, that no knowledge or information which can be gained either by chemical, or by bacteriological examination, or by inspection of source, or by any other available means whatsoever should be neglected.

WAVELLITE. A mineral consisting of hydrous aluminium phosphate $3Al_2O_3{\cdot}2P_2O_5,12H_2O$, forming globular or stalactitic masses with an internal radiating structure. The colour is white, yellowish, or green; sp.gr. 2·32. The mineral usually occurs on the joint faces of slaty rock, and was first observed in the eighteenth century by Dr. W. Wavell in the slates at Filleigh near Barnstaple in Devonshire. Good specimens have also been found in Co. Cork. In larger amounts it occurs in Arkansas and Pennsylvania. At South Mountain in Pennsylvania it has been mined as a source of phosphorus, used locally for making matches. L. J. S.

WAX VARNISH *v.* Varnish.

WAXES, ANIMAL AND VEGETABLE. These waxes are a group of substances resembling beeswax in their physical properties, and are mixtures of compounds composed of the elements carbon, hydrogen, and oxygen. Waxes of mineral origin such as paraffin wax, ozokerite, ceresin, and montan wax are described elsewhere. The chief proximate constituents of the waxes are: (1) esters of fatty acids with alcohols containing a high number of carbon atoms; (2) esters of fatty acids with glycerol, thus palmitin and myristin seem to impart wax-like properties to some of the substances containing them; (3) free fatty acids; (4) free alcohols containing a large number of carbon atoms; (5) hydrocarbons. The formulæ assigned to the compounds with large molecules must be regarded as somewhat uncertain and may be altered by further investigations. Physically the waxes come in the series: (1) fixed oils; (2) soft fats; (3) tallow-like substances and solid fats; (4) waxes; and (5) resins. An explanation of the terms *saponification value*, *iodine value*, and *acid value* will be found in the article on Oils, fixed, and fats. Many of the waxes are difficult to saponify, and require special treatment to effect this. Descriptions of the more important and better-known waxes are given below. References: Schaedler, Technologie der Fette und Oele; Benedikt-Ulzer, Analyse der Fette und Wachsarten; Lewkowitsch, Chemical Technology and Analysis of Oils, Fats, and Waxes; Allen, Commercial Organic Analysis, vol. ii., Fixed Oils, Fats, and Waxes; Cowan, Waxcraft.

Arjun wax (*White insect wax of India*). About the year 1786 a wax produced by an insect was noticed in Madras, and it was thought that it might resemble the insect wax of China, but it appears to be different. The insect has been

---

[1] Klein. Local Government Board: Medical Officer's Reports, 1897–8, 1898–9, 1901–2; Klein and Houston, *ibid.* 1899–1900; Hewlett, Trans. Jenner Institute, Series II, 70; Journ. State Medicine, 1904, 12, 108.

named *Coccus ceriferus*, and also *Ceroplastes ceriferus*; it is found on the twigs of *Terminalia Arjuna* (Wright and Arn.) and several other trees; it is not, however, at all abundant. The wax occurs on the twigs in small mounds of a dull buff colour; its m.p. is given as from 55° to 63°, and its sp.gr. as 1·04 at 29°. It is moderately hard and brittle, and has a somewhat pleasant smell. It is partially soluble in cold alcohol, and almost completely soluble in boiling alcohol; it dissolves freely, but not entirely in benzene and in ether; it is only sparingly soluble in oil of turpentine and in carbon disulphide. In composition it corresponds to the formula $C_{13}H_{26}O$ (Pearson, Phil. Trans. 1794, 84, 383; Indian Museum Notes, 1891, 2, 91).

Balanophore wax is derived from the parenchymatous cells of *Langsdorffia hypogæa* (Mart.), a native of Brazil, and of *Balanophora* species (a native of Java and the neighbouring islands); which are parasitic plants some 5 or 6 cm. long, growing on the roots of other plants. These plants are so rich in wax that they can be set on fire and burn with a luminous flame, and torches can be made by coating wooden sticks with the plant made into a paste.

By boiling the plant the wax is procured as a greyish and yellowish mass. Ether extracts it from the plant, and as thus obtained it has the colour and consistence of natural beeswax; it melts at about 100°, has a sp.gr. of 0·995 at 15°, and is easily soluble in ether, and only very sparingly soluble in alcohol. The wax has the property of dissolving in cold sulphuric acid and being reprecipitated by water. It is a resinous wax, and also contains a glyceride (Schaedler).

Beeswax is produced by the common bee *Apis mellifica*, and also by some allied species; it is not collected from the flowers by the bee, but is the secretion of certain organs situated on the underside of the abdomen of the neuter or working bees, and is used by them in forming the cells of the honeycomb. They are said to consume about 10 lbs. of honey in order to secrete 1 lb. of wax. The honey is allowed to run out from the comb, which is then pressed to separate as much honey as possible. The adhering honey and other impurities are next removed by melting the mass in hot water; the melted wax floats on the surface, and is strained to remove dead bees and brood. The residue is put in layers with straw, and is pressed to obtain more wax, the straw acting as a filter; this product is known as 'press wax.' The mass then remaining is sometimes extracted with benzene to obtain still more wax, the product being 'extraction wax.' The 'extraction wax' is apt to be impure from the use of artificial comb, and also from substances being extracted from the dead bees and straw; further, wax compositions and adulterated beeswax are also sold under the name of 'extraction wax' (Hirschel, Chem. Zeit. 1904, 28, 212). A common practice is to pare off the capping of the honey cells and then place the comb in a centrifugal machine, which removes the honey and leaves the comb undamaged, so that it can be replaced in the hive to be refilled by the bees, and thus save the honey that they would use to produce fresh wax. In this system the capping only is melted down for wax.

Beeswax is yellow in colour and varies in tint, according to the materials employed by the bees and the care taken in its preparation; sometimes it is brownish, reddish, or greenish. It has a pleasant honey-like smell, which is made more apparent by warmth. When cold it is brittle; at ordinary temperatures it is tenacious; its fracture is dry and granular. The sp.gr. at 15° is from 0·958 to 0·975, that of melted wax at 98°–99° compared with water at 15·5° is 0·822. It softens when held in the hand, and melts at 62°–66°; it solidifies at 60·5°–63°. The chief components of beeswax are myricyl palmitate $(C_{30}H_{61})C_{16}H_{31}O_2$, free cerotic acid $C_{26}H_{52}O_2$, and hydrocarbons (Schwalb, Annalen, 1886, 235, 106). It is insoluble in water, cold alcohol dissolves very little, boiling alcohol dissolves a good deal, leaving an undissolved residue from which, however, something is dissolved every time the treatment with boiling alcohol is repeated. The soluble portion was called *cerin*, and the less soluble residue *myricin* by J. F. John (Chem. Tabellen der Pflanz. 1814, 42); he first separated the wax of *Myrica cordifolia* (Berg.), from Cape Colony, into a soluble and an insoluble portion, and then separated beeswax in the same way, and gave the products these names. The cerin and myricin from beeswax and from *M. cordifolia*, however, must not now be regarded as identical; the latter wax seems not to have been examined recently and probably would be found to resemble myrtle wax in its composition. Brodie (Phil. Trans. 1848, 147; 1849, 91) found a new acid free in the soluble part of beeswax, and named it *cerotic acid*; and in the myricin or insoluble part he found an ester of palmitic acid with a wax alcohol, which he called *melissin* (now called *myricyl* or *melissyl alcohol*). The dissolved substances are deposited when the alcohol cools. Beeswax is said to dissolve in about 300 parts of boiling alcohol, leaving only a small amount of yellowish-brown residue. Warm ether dissolves it readily, part being deposited on cooling. Buchner (Chem. Zeit. 1907, 31, 570) allowed beeswax to soak in ether at the ordinary temperature for some time, filtered the resulting homogeneous paste, and washed it with ether; after getting rid of the ether he obtained from the filtrate 30 p.c. of a fairly soft, deep yellow mass, and from the insoluble residue 70 p.c. of a bright brownish wax, considerably harder than the original wax. The soluble portion had an acid value of 40, and a saponification value of 83·8, whilst the insoluble portion had an acid value of 11·6, and a saponification value of 99·1; thus the cerotic acid and colouring matter dissolve in cold ether in higher proportion than the myricyl palmitate.

Other solvents are fixed oils, carbon disulphide, chloroform, and oil of turpentine. Cerotic acid is soluble in hot alcohol, but separates almost completely on cooling; its presence in beeswax probably increases the solubility of the myricin. Beeswax contains about 12–16 p.c. of free cerotic acid, but this probably includes some other acids. From 11 to 17·5 p.c. of hydrocarbons have been found in genuine samples of beeswax. Indian Ghedda wax contains less, only 8·6 p.c. having been found (Buchner, Chem. Zeit. 1905, 29, 79). Artificial comb containing added paraffin wax is sometimes used in the hives, and then the percentage of hydrocarbons in the wax is increased. Minor constituents and colouring matter are also present; the latter remains dissolved when the hot alcoholic solution cools. Berg. (Chem. Zeit. 1908, 32, 777) found at least 0·6 p.c. of cholesterol esters and probably considerably more, which are hard to saponify and have high saponification values; he separated also small quantities of various acids, one of them having the specific odour of beeswax. The acid value of yellow beeswax is from 17 to 23; the saponification value is from 88 to 107; and the iodine value is from 6 to 14, thus showing the presence of unsaturated compounds. Some varieties of beeswax vary in composition even more than appears above, especially those from China and India, the latter including that known as Ghedda wax (Buchner, Chem. Zeit. 1901, 25, 21, 39; 1905, 29, 33; 1906, 30, 528; Buchner and Fischer, Zeitsch. öff. Chem. 1913, 19, 147). Ghedda or East Indian wax has been examined by Lipp and Kuhn (J. pr. Chem. 1912, 86, 184), who found that it contains only one alcoholic radicle, namely ceryl, present chiefly as ester, thus differing from ordinary beeswax, which contains chiefly myricyl ester with only a little ceryl ester; the ester acids also differ from those of ordinary beeswax, but the hydrocarbons are the same, namely $C_{26}H_{54}$ and $C_{30}H_{62}$.

Indian beeswax is derived from three species of bees: *Apis dorsata*, *A. indica*, and *A. florea*, but chiefly from *A. dorsata* (*A. mellifica* does not occur there except as an importation). The wax from the combs of these three species is substantially of the same composition. It differs from European beeswax in having a lower acid value; in the case of 34 specimens from these 3 species the acid value ranged from 4·4 to 10·2, with an average of about 7, the saponification value from 75·6 to 130·5, and the Hübl iodine value from 4·8 to 11·4. Some Indian waxes of unknown origin gave higher acid values, and other values outside these limits. Turmeric is used to give a golden-yellow colour to the wax. Another kind of beeswax is produced in India from a small stingless bee known as the dammar bee, *Melipona* or *Trigona* species; this wax is of a blackish colour, and sticky consistency. In 8 specimens the acid value ranged from 16·1 to 22·9, the saponification value from 73·7 to 150, the iodine value from 30·2 to 49·6, and the m.p. from 66° to 76° (Hooper, Agricultural Ledger, 1904, 11, 73).

A wax called *Andaquies wax* is collected by the Indians in Colombia, especially by the Tamas tribe, which lives near the Rio Caqueta. It is probably the product of small *Melipona* bees. A sample was examined by Lewy (Ann. Chim. Phys. 1845, [iii.] 13, 453); after purifying it by treatment with boiling water he found that its m.p. was 77°, its sp.gr. at 0° was 0·917, and that it contained 81·66 p.c. of carbon and 13·55 p.c. of hydrogen. It is used locally for making candles for religious worship.

White beeswax. Yellow beeswax is not adapted to candle-making, as candles made from it burn badly and with a smoky flame. It is purified by repeatedly re-melting in hot water until it is no longer grey, and any remaining honey is removed. In doing this the grey underlayer is cut off, and re-melted with the raw wax. Dilute sulphuric acid is sometimes added to the water to diminish the tendency of the wax and water to form an emulsion.

The next step is to destroy the yellow colouring matter. Chlorine and many other bleaching agents attack the wax and make it more brittle and friable, and thus cause it to lose its softness, and tallow has to be added to restore it. Chlorine further forms chloro substitution products with the wax, and hydrogen chloride is liberated when the candle is burnt.

The best method of bleaching is to reduce the wax to thin strips or shavings so as to increase the surface as much as possible, and to expose it to moisture and sunlight. The melted wax is poured from a ladle into a square box of metal plate, in the bottom of which are several narrow slits. These slits are directly over a horizontal wooden roller revolving in a vessel filled with water which covers half the roller. The wax escapes from the slits in bands, which pass over the revolving roller and solidify in the water in the form of thin ribbons.

Another plan is to melt the wax in a rotating vessel of tinned copper provided with taps; from these the wax falls in drops or streams into ice-cold water. The grains or threads expose more surface, and the bleaching takes at least one-third less time, than when ribbons are used.

These ribbons, threads, or grains are removed from the water and spread on linen stretched over square wooden frames, and then exposed to the sun. Every day they are once or oftener sprinkled with water to keep them moist, and they are frequently turned over to expose fresh layers to the sun. After a longer or shorter period, depending on the intensity of the sunshine and the temperature, the bleaching is complete.

The wax is then once more melted in hot water, strained, and allowed to solidify in suitable shapes. The inner portion of the ribbon bleaches much more slowly than the outer surface, and the bleaching occupies 20–35 days or more. To accelerate the bleaching the partially bleached wax is re-melted and again made into ribbons so that new surfaces are exposed; this causes loss of from 2 to 10 p.c. Thread and granular wax rarely require re-melting. Wax from different sources bleaches with varying facility, and some cannot be bleached, so it is well first to try a sample on a small scale.

Since the sun-bleaching is probably due to the formation and action of either ozone or hydrogen peroxide, the action can be aided by melting together from 1 to 1½ parts of rectified oil of turpentine, free from resin, with 8 parts of yellow wax, and then making into ribbons, and proceeding as above; this reduces the time some 6 or 8 days, at the end of which the smell of turpentine will have disappeared. Sometimes a few per cent. of tallow are added to the wax to hasten the bleaching.

Wax bleachers frequently make additions to the wax—such as argol, alum, white arsenic—which, however, seem to have no great value. They are removed on re-melting the wax with water; or else additions of tallow, vegetable waxes, stearic acid, &c., are made to increase the whiteness of the wax after bleaching.

Wax in threads and grains can be bleached by immersion in hydrogen peroxide, and also by treatment with sodium hypochlorite, or dilute chromic acid or a mixture of potassium dichromate and sulphuric acid, but the products are not suitable for some purposes. Animal charcoal can also be used to decolorise it.

White wax is comparatively hard and brittle, with a splintery fracture, translucent at the edges; its solubility in the various media, its proximate and ultimate composition, are nearly the same as those of yellow wax, but the physical properties and chemical values are somewhat altered by the process of bleaching.

Beeswax, both white and yellow, is liable to adulteration. The substances used are: water; powders such as yellow ochre, clay, brickdust, kaolin, gypsum, barium sulphate, litharge, sulphur, pea flour, starch and flour (but small quantities of starch and flour may occur in genuine wax that has been rolled or pressed, as the rollers or presses are dusted with flour to prevent the wax from sticking); carbon compounds such as tallow, wool fat, spermaceti, insect wax, stearin, stearic acid, resin, paraffin wax, ceresin, ozokerite, and various plant waxes. Methods of examining wax for adulterants will be found in: Lewkowitsch's Chemical Technology and Analysis of Oils, Fats and Waxes, 1909; Allen's Commercial Organic Analysis, vol. ii. 1910; Foods and Food Adulterants, U.S. Dept. Agric., Chem. Div., Bulletin No. 13, pt. vi. 1892; (this contains a very full bibliography, which is abstracted in J. Soc. Chem. Ind. 1892, 11, 756); and in various original papers.

Candelilla wax is obtained from plants growing in great quantities in northern Mexico and the southern parts of the United States; attention was called to the wax on these plants by Sanders in 1905. The analytical results published about it vary widely, and samples of wax called by this name possibly come from different plants, and may also vary with the age of the plants and the time of year at which they were gathered; the mode of preparation, and the presence of water in the wax may also account for some variations. *Euphorbia cerifera* (Alcocer), *E. antisyphilitica* (Zucc.), and *Pedilanthus Pavonis* (Boiss.) have been given as the plants from which the wax was obtained.

The wax occurs as an excretion covering all parts of the plant except the roots; it can be obtained by boiling the plant with water and skimming off the layer of melted wax; the pieces of plant must be kept from rising by wrapping them in wire cloth or by tying them in bundles and weighting these down. Another plan is to subject them to live steam, which melts off the wax, which can be easily separated from the condensed water. It can be purified by re-melting and straining or filtering through animal charcoal in steam-jacketed iron filters. The yield is from 2½ to 5 p.c. of the dry plant. The wax varies in colour from light greenish-yellow to almost chocolate-black; it can be bleached sufficiently to compare with carnaüba wax. It is harder and more brittle than beeswax, but not so hard nor so brittle as carnaüba wax; at first sight it appears more like a resin than a wax.

The following are some of the analytical values recorded: m.p. 66°–80°; sp.gr. 0·9820–0·9856 at 15°/15°; refractive index at 85° 1·4545–1·4626; acid value 12·4–19·0; saponification value 35·0–86·5; Reichert-Meissl value 0·53–7·69; iodine value 14·0–20·4; unsaponifiable matter 76·7–77·3 p.c.; hydrocarbons 42·5–59·7 p.c. Hydrocarbons with formulæ near to that of hentriacontane $C_{31}H_{64}$ seem to be present. The winter wax is thought to have the highest melting-point, density, acidity, and proportion of hydrocarbons. Sanders (Chem. Soc. Proc. 1911, 27, 250) states that a sample of the wax prepared in January from plants collected in Coahuila was greenish-white, and contained a considerable proportion of water. When freed from this it was dark brown, and gave the following values: m.p. 67·5°; sp.gr. 0·9850; acid value 14·39; saponification value 46·76; iodine value (Hübl) 16·60; unsaponifiable matter 77·00 p.c.; and hydrocarbons 48·60 p.c. He states that it contained hentriacontane and myricyl alcohol. Olsson-Seffer (Imp. Inst. Bull, 1909, 7, 411) and other analysts give some values which do not fall within the limits mentioned above.

The wax is soluble in oil of turpentine, chloroform, ether, benzene, carbon disulphide, and acetone when hot; it dissolves partially in boiling alcohol, but the greater part separates on cooling. A mixture of 3 parts of absolute alcohol and 2 parts of 90 p.c. benzene was found to be an excellent solvent for it when hot. It can be used for making varnishes, insulating materials, shoe polishes, floor polishes, dental moulding compositions, sealing wax, lithographic inks, waterproof papers, lacquers for metals, and also to raise the melting-point of cheaper waxes for the manufacture of candles and matches. Several factories are engaged in preparing it in Mexico, and it is coming into European commerce. Further references are: Sanders, Anal. Inst. Med. Nac. Mexico, 1905, 7, 498; La Candelilla, pubd. by Instituto Medico Nacional, Mexico, 1910; Hare and Bjerregaard, J. Ind. and Engin. Chem. 1910, 2, 203; Fraps and Rather, *ibid.* 454; Niederstadt, Analyst, 1911, 36, 598; and Chem. Zeit. 1911, 35, 1190; Imp. Inst. Bull. 1912, 10, 128.

Cape berry wax. Samples of this wax have been shown at exhibitions in London, and it is capable of being collected in quantities in Cape Colony, but it has not yet come into any extensive use. It is probably derived from one of the species of *Myrica* growing in South Africa, which include *M. quercifolia* (Linn.), *M. cordifolia* (Linn.), and *M. serrata* (Lam.); it is similar to myrtle berry wax in its general characters and in its physical and chemical properties, which were found to be: sp.gr. 0·874 at 99°; m.p. 40·5°; m.p. of the fatty acids 47·5°; mean molecular weight of the fatty acids 236·1; acid value 4·1; saponification value 211·1; iodine value 1·1. It yields a hard white soap, but does not seem to be suitable for candle making (Imp. Inst. Bull. 1906, 4, 300). The results of another examination are: sp.gr. 0·9893; m.p. 49°; refractive index at 80° 1·4364; acid value 2·5; saponification value 212·3; iodine value 2·03; unsaponifiable matter 2·51 p.c.; fatty acids 89·7 p.c.; m.p. of mixed fatty acids 48·5°; solidifying-point of these 46·5°; mean molecular weight of these 241·4; it was described as South African berry wax, and was pale greenish-grey with a granular fracture; when melted it formed a greenish-brown muddy liquid, and it was filtered before examination (Cocking, Chem. and Drug. 1908, 73, 74).

Carnaüba or **carnahuba wax** is derived from the carnaüba palm, *Copernicia cerifera* (Mart.) (*Corypha cerifera*, Linn.), which grows in Brazil, especially in the provinces of Ceara, Rio Grande do Norte, and Piauhy. The trunk is 25–35 ft. high with a crown of leaves at the top. The young leaves of about 3 ft. long have a coating of wax on both the upper and under sides, which appears homogeneous to the naked eye. The wax layer is thicker on the upper side, and comes off in scales; on the lower side it is thinner and more adherent. The harvesting extends over the six dry months of the year, and the leaves are cut twice a month, about eight leaves being cut from a palm at a time, those leaves that have reached a certain stage of development being taken, leaving the very young leaves to develop later. If the leaves are allowed to become too old the wax is easily detached, and is lost before the leaves are brought to the ground. The leaves are spread out to dry, and are then slit up with a knife and beaten over a cloth to detach the wax, which comes off in scales or as a greyish-white powder. A little water is added to the powder, and it is melted and poured into moulds, in which it solidifies in cakes of about 2 kilos. About 850 leaves give 16 kilos. of wax; about 1·8 kilos. of wax, valued at 1*s.* 6*d.*, are obtained from one palm. On poor land 1200 leaves, and on good land only 500 leaves are required to give the 16 kilos. In some estimates, however, the yields are not so good as these.

In the year 1908 the exports of carnaüba wax from Brazil amounted to 2,592,027 kilos., with a value including cost, insurance, and freight of £242,243; in 1907 the exports were 2,778,801 kilos. with a value of £418,600.

Raw carnaüba wax is of a dirty yellowish or greenish colour, amorphous, hard, brittle, and easy to powder. In its outward appearance it is compact, but penetrated with very many air spaces; it is tasteless, and smells, when fresh, somewhat like fresh hay—*i.e.* of coumarin; later it becomes inodorous. It is purified by remelting, and has then a greenish-yellow or straw-yellow colour. The m.p. is variously given as from 83°–86°, and an old specimen melted at 90°–91°. In preparing bleached carnaüba wax, a certain amount of paraffin wax is added, such wax consequently has a lower melting-point. The wax, especially when fresh, on melting diffuses a slight odour, which is not unpleasant; on distillation it gives a paraffin-like product. The sp.gr. is 0·990–0·999 at 15°. The acid value is from 0·3 to 8·0; saponification value 78–88·3; and iodine value 7–13·5.

The composition has been very fully examined by Stürcke (Annalen, 1884, 223, 283); he found that the principal constituent is the myricyl ester of cerotic acid ($C_{27}H_{53}O_2{\cdot}C_{30}H_{61}$), or as the free acid was not crystalline, it may perhaps be the ester of an isomeride closely resembling cerotic acid; that it contains a considerable quantity of free myricyl alcohol $C_{30}H_{61}OH$; and that minor constituents isolated after saponification, are: (1) a hydrocarbon with m.p. 59°–59·5°; (2) an alcohol $C_{26}H_{53}{\cdot}CH_2OH$ with m.p. 76°; (3) a dihydric alcohol $C_{23}H_{46}(CH_2OH)_2$ with m.p. 103·5–103·8°; (4) an acid $C_{23}H_{47}{\cdot}CO_2H$ with m.p. 72·5°, isomeric with lignoceric acid; and (5) the lactone $C_{19}H_{38}{<}{\genfrac{}{}{0pt}{}{CH_2}{CO}}{>}O$ with m.p. 103·5°.

When the wax is extracted with boiling alcohol the myricyl alcohol dissolves together with a small amount of the myricyl ester, and these constituents separate when the alcohol cools; if the extraction is continued the later extracts remove small quantities of the ester, which is only very slightly soluble in boiling alcohol, the last extracts containing less than a gram per litre. The wax is not easily saponified; Berg (Chem. Zeit. 1909, 33, 885) recommends the use of xylene as a solvent for this purpose.

Carnaüba wax when mixed with paraffin, ceresin, beeswax, &c., increases their hardness and gives a peculiar lustre; it also raises their melting-points. It is used for making hard candles, leather polishes, and certain varnishes. It is bleached by melting and filtering through animal charcoal, but some paraffin wax is added to facilitate the process, and this lowers the melting-point of the bleached wax. Another use of the wax is for making Edison's phonograph cylinders.

Cochin China wax (*Cay Cay fat, Irvingia butter*). This is obtained from the fruit of the Cay Cay tree, *Irvingia Oliveri* (Pierre), a forest tree reaching the height of 100 ft., and growing widely in the east of Cochin China. The fruit is the size of a lemon, the endocarp has the size and shape of an almond with its outer covering. and the kernel, too, resembles in size and shape that of the almond. The fruits are ripe in July. and fall to the ground; they are gathered into heaps by the natives, and left for two months to allow the soft outer parts to decompose; they are then carried to the houses and dried in the sun. They are opened with a strong knife, and the kernels are removed, dried in the sun, and pounded in a mortar. The pulp is placed in a vessel having a bottom of plaited material; this is fixed above water in another vessel, and the water is heated, but not to boiling. When the pulp has become a sticky paste it is wrapped in a mat of rice straw, and submitted to pressure in a crude press, the operations being repeated several times, and the melted wax is either allowed to solidify in moulds or else is cast into candles in bamboo tubes. In the laboratory the dry kernels extracted with carbon disulphide gave 52 p.c. of wax. The wax is of a greyish-yellow colour, and is unctuous to the touch. The purified wax softens at 37°, melts at 38°, and solidifies at 34° (Vignoli, Le Cay Cay, Thèse présentée à l'Ecole Superieure de Pharmacie de Montpellier, 1886).

Bontoux (Les Matières Grasses, 1908, 1276; J. Soc. Chem. Ind. 1909, 28, 429) found that 100 dry seeds weighed 360 grms. and gave 78 p.c. of shells and 22 p.c. of kernels. The latter, on extraction with light petroleum, gave 60·45 p.c. of wax. The wax had the consistency and texture of beeswax, and was more brittle, with the same conchoidal fracture; its sp.gr. at 40° compared with water at 40° was 0·913; it melted at 39·7° in a capillary tube, and solidified at 31°; its acid value was 0·86; saponification value 235·3; unsaponifiable matter 0·42 p.c.; iodine value 6·7; Reichert-Meissl value 0·62. The insoluble fatty acids, together with the unsaponifiable matter were 94·0 p.c., their m.p. was 38·8°; solidifying point (titer test) 36·6°; neutralisation value 250·2; and mean molecular weight 224. Two samples of the wax of native origin had nearly the same values, but the acid values were 23·5 and 34·9, which, however, are not excessive, and they contained 0·16 p.c. and 0·19 p.c. of unsaponifiable matter. Bontoux prepared methyl esters, and concluded that the wax was mainly composed of myristin 60–65 p.c., laurin 30–35 p.c., and about 5 p.c. of olein. The wax gives a hard white soap. The production in Indo-China has declined, owing to the introduction of petroleum. A Cay Cay wax is also obtained from the fruit of the tree *Irvingia malayana* (Oliver), which grows in Cambodia. Other references are: Heckel, Annales de l'Institut colonial de Marseille, 1893; Apoth. Zeit. 1898, 169; Crevost, Les arbres à suif de l'Indochine, Hanoi, 1902; Bulletin économique de l'Indochine, Hanoi, 1902.

Cow tree wax (*Milk tree wax*). In the north of Venezuela, in the neighbourhood of Caracas and of Lake Maracaibo, and in the valley of Caucagua, there grows a tree (*Brosimum Galactodendron*) called *Palo de vaca* or *Arbol de leche*, which yields a thick milk when incisions are made in its trunk; this is drunk like milk by the inhabitants. This milk, when heated, forms a skin, and if this is removed and evaporation continued, an oily liquid is obtained, together with a fibrous mass. The oily liquid when it has solidified, is a yellowish-white, hard translucent wax; it begins to melt at 40°, and is completely melted at 60°. It is insoluble in water, but is easily dissolved by essential oils. It dissolves in boiling alcohol and separates on cooling; it is saponifiable by caustic potash. It can be used like beeswax for making candles. Humboldt, Ann. Chim. Phys. 1817, 7, 182; Boussingault and Mariano de Rivero, *ibid.* 1823, 23, 219; Marchand, J. pr. Chem. 1840, [i.] 21, 43.

Fig tree wax (*Gondang* or *Kondang* or *Getah wax, Java* or *Sumatra wax*). This wax is obtained in Java from the milky juice which runs from incisions made in the bark of the gondang, a wild fig tree (*Ficus variegata*, Blume. = *F. ceriflua*, Jungh. = *F. subracemosa*, Blume.). The juice is boiled with water until the wax separates. It forms a fairly hard cake, cream coloured within, turning brown in the air; it has a conchoidal fracture and can be powdered, but not readily. The crude wax melts at about 60° to a very viscous mass, which, on cooling, remains viscous for a long time, and from which an aqueous liquid separates. The sp.gr. of the wax after melting is 1·015 at 15°. It softens at 55°, and is only completely melted at 73°. It is soluble in benzene, chloroform, carbon disulphide, oil of turpentine, light petroleum, and boiling ether. Boiling alcohol dissolves it slowly, and the greater part separates on cooling. Cold alcohol keeps in solution a little over 5 p.c. of the wax. By means of boiling alcohol over 70 p.c. of white crystalline purified wax can be obtained, melting at 61°, insoluble in cold alcohol, but soluble in boiling alcohol. Greshoff and Sack (Rec. trav. chim. 1901, 20, 68), by analyses and saponification of the wax thus purified, obtained results suggesting that it is an ester $C_{30}H_{52}O_2$ of an alcohol $C_{17}H_{28}O$ (ficoceryl alcohol), with m.p. 198°, and of an acid $C_{13}H_{26}O_2$ (ficoceric acid), with a m.p. 57°, this ester is probably associated with some accessory substance; they also think the original wax contains some free ficoceryl alcohol.

Vogl (Lotos, pubd. at Prag, 1872, 22, 54) describes Sumatra wax or Getah Lahoe coming from the same tree. Kessel (Ber. 1878, 11, 2112) assigns formulæ to components of the wax which differ from the above.

Insect wax. This is also called *Chinese wax*, *Chinese tree wax*, *Vegetable spermaceti*, and sometimes, but incorrectly, *Japanese wax*; it must not be confused with Japan wax. It is the secretion of an insect *Coccus pela* (Westwood), *Coccus ceriferus* (Fabr.). The industry of its production is peculiar, in that the insects are bred for the purpose of producing eggs in one district, and these eggs are then transported to another district where the insects are reared to produce wax. The Chien-Chang valley in the prefecture of Ning Yuan Fu (Long. 102° 26′, Lat. 27° 54′) in the Sze Chuan province of China is the great breeding-ground of the wax insect; it is about 5000 ft. above sea-level. Here the insects are reared on the *Ligustrum lucidum* (Ait.) or large-leaved privet. In March, when the trees were seen by Mr. Hosie, he found numerous brown pea-shaped excrescences attached to the bark of the boughs and twigs. The larger of these were readily detachable, and when opened presented either a whity-brown pulpy mass or a crowd of minute animals like flour, whose movements were just perceptible to the naked eye. From 2 to 3 months later these had developed in each case into a swarm of brown creatures, each provided with six legs and a pair of antennæ; each of these was a wax insect. Two hundred miles to the north-east of the Chien-Chang valley, and separated from it by a series of mountain ranges, is the prefecture of Kia-ting-fu (Long. 104°, Lat. 29° 34′), also called Chia-ting-fu, containing the district of Omi and the valley of the Ya river, the headquarters of the wax-producing industry. The scales produced in the Chien-Chang valley are ready for removal by the end of April, and are then full of eggs; they are made up into paper packets, each weighing about 16 oz. Sixty of these packets make a load, and are conveyed by coolies from the Chien-Chang valley to the town of Hung Ya in the Kia-ting-fu prefecture for sale to the farmers. In May thousands of coolies are engaged in the traffic. They travel only at night, in order to avoid the high temperature of the day, which would tend to the rapid development of the insects and their escape from the scales. At the stopping places the packets are opened out in cool places; but in spite of this, each packet is found to have lost on an average an ounce in transit. A pound of scales laid down in Kia-ting-fu, in years of plenty, costs about half a crown; in bad years the price is doubled. In favourable years a pound of scales will produce 4–5 lbs. of wax. In the plain around Kia-ting-fu the plots of ground are thickly edged with stumps of *Fraxinus chinensis* (Roxb.), a species of ash varying from 3 or 4 to 12 ft. high, with numerous sprouts rising from their gnarled heads, and resembling at a distance pollard willows. On the arrival of the scales they are made up into small packets enclosed in a leaf of the wood-oil tree. The edges of the leaf are tied together with a rice straw, by which the packet is suspended close under the branches of this ash. A few rough holes are drilled in the leaf with a blunt needle, so that the insects may find their way through to the branches. On emerging from the scales the insects creep rapidly up to the leaves, among which they remain for a period of 13 days. They then descend to the branches, on the underside of which they take up their position, and commence to deposit the wax. This first appears as an under-coating on the sides of the boughs and twigs, and resembles quinine sulphate or a covering of snow. It gradually spreads over the whole branch, and attains, after 3 months, a thickness of about a quarter of an inch. After the lapse of 100 days the deposit is complete, the branches are lopped off, and as much of the wax as possible is removed by hand. This is placed in an iron pot of boiling water, and the wax on rising to the surface is skimmed off and placed in a round mould, whence it emerges as the insect wax of commerce. Where it is found impossible to remove the wax by hand, the twigs and branches are thrown into the pot, so that this wax is darker and inferior. The insects which have sunk to the bottom of the pot are placed in a bag and squeezed of the last drop of wax, and are then thrown to the pigs. Not only the *Fraxinus chinensis*, but also the *Ligustrum lucidum* is used in the final wax-producing stage of the industry. The wax is used for coating the exterior of animal and vegetable tallow candles, as it serves to hold in the more fusible tallow when the candle is burning; a little is also mixed with the tallow; it is employed to give a gloss to paper, for coating pills, and as a polish for furniture and jade-ware (Nature, 1891, 43, 291; Wilson, Chemi and Druggist, 1906, 68, 143).

Insect wax is white and crystalline, resembling spermaceti in appearance, but it i harder and more fibrous; it is brittle, and a 15° can be powdered. Its sp.gr. is 0·970 at 15 (0·926 at 15°, Gehe and Co., Zeitsch. anal. Chem 1895, 34, 765) and 0·809–0·811 at 98°–99°; m.p 80°–83°; saponification value 80–93; iodine valu 1·4. It is only very slightly soluble in alcoho and ether, but is readily soluble in naphtha from which it can be crystallised. Brodie (Phil. Trans. 1848, 159) saponified the wax by melting it with potash, and obtained an alcoho and an acid; the alcohol he named *cerotin*, and to it he assigned the formula $C_{27}H_{56}O$, it is now called *ceryl alcohol*; the acid he considered to be the same as the cerotic acid he had obtained from beeswax, to which he had assigned the formula $C_{27}H_{54}O_2$; the wax he regarded as ceryl cerotate, the ester of this alcohol and acid. Brodie's formulæ cannot be regarded as certain. Marie (J. Chem. Soc. 1897, 72, i. 318) proposes $C_{26}H_{52}O_2$ or $C_{25}H_{50}O_2$ for the cerotic acid of beeswax; and Henriques (*ibid.* 460) regards ceryl alcohol and cerotic acid from insect wax as $C_{28}H_{54}O$ and $C_{26}H_{52}O_2$, and it is stated that the identity of the cerotic acids from insect wax and from beeswax is not quite certain. Other substances besides ceryl cerotate are probably present.

Japan wax (*Japan tallow, Sumach wax*). This must not be confused with insect wax, which is sometimes called *Japanese wax*. Japan wax is one of the most important of the vegetable waxes, large quantities being exported from Japan: it is obtained from the berries of *Rhus succedanea* (Linn.), and of *R. vernicifera*, both of which grow in Japan and China; it is also said to be obtained from *R. sylvestris*, which grows in Japan. The wax is obtained in various ways. In *R. succedanea* the wax lies between the kernel and the outer skin of the berries; the meal obtained by crushing or grinding the berries is steamed and pressed, Perilla oil being often added in the course of the pressing in order to obtain a larger yield of the wax; such addition renders the wax softer and raises its iodine value. Another method is to boil the meal with water and remove the wax which rises to the surface. Occasionally the wax is obtained by extraction with solvents. The wax is purified by remelting, filtering, and bleaching in flakes, and is finally cast into cakes for export.

The wax is pale yellow and hard, with an even or conchoidal fracture; it becomes yellow or brown on keeping, and acquires a white powdery surface; it melts at 50°–56°, but if it has only recently solidified, the melting-point is considerably lower; it solidifies at about 41°, the temperature rising to 48° or 49° as it solidifies. It becomes transparent 10°–12° below its melting-point, which should be remembered in taking its melting-point. The sp.gr. is 0·975–0·993 at 15°; at 98°–99° it is 0·875–0·877, compared with water at 15·5°. Wax that has recently solidified has a lower density than that which has been kept for some time (Kleinstück, Chem. Zeit. 1890, 14, 1303). The saponification value is 214–237·5, and the iodine value is 4·2–15. The fatty acids obtained from it melt at 54°–62°. The unsaponifiable matter is 1·1–1·6 p.c. It dissolves in boiling alcohol, but nearly all separates on cooling. It is liable to adulteration with water and starch. It is used for making polishes and also for currying leather.

The wax consists chiefly of palmitin with some free palmitic acid. Its composition has been investigated by Eberhardt (Inaug. Diss. Strassburg, 1888), and by Geitel and van der Want (J. pr. Chem. 1900, [ii.] 61, 151); the latter found in the cakes they used acid values of 21·7–32·6, saponification values of 217·5–237·5, and iodine values 8·3–8·5. In one sample by saponification they obtained 5·96 p.c. of soluble and 90·62 p.c. of insoluble, fatty acids. By saponifying a large quantity they obtained glycerol and insoluble fatty acids, which contained a little oleic acid, and which were chiefly palmitic acid, and also contained an acid which they called *japanic acid*, melting at 117·7°–117·9° with a suggested formula $C_{20}H_{40}(CO_2H)_2$; they think it probable that this acid occurs in the wax as a mixed glyceride of palmitic and japanic acids. Schaal (Ber. 1907, 40, 4784) did not find the acid $C_{20}H_{40}(CO_2H)_2$ in the liberated fatty acids, but found small quantities of the acids $C_{19}H_{38}(CO_2H)_2$, $C_{18}H_{36}(CO_2H)_2$, and $C_{17}H_{34}(CO_2H)_2$, *v.* also JAPAN WAX, Vol. III. 187.

Mexican myrica wax (*Mexican myrtle wax*). This wax is obtained by the Indians in Mexico from the fruit of *Myrica jalapensis*, and is sold in Mexico city, where it is used for making candles. The tree is known locally as 'arbol de la cera,' and occurs in Vera Cruz, sometimes in dense thickets covering considerable areas. The wax forms a greenish-white layer on the outer surface of the fruit, and is obtained by boiling the fruit in water and skimming off the floating melted wax; it is refined by melting and straining. On examination it gave the following values, which resemble those of Cape berry wax: sp.gr. 0·8763 at 99°; m.p. 43·2°; acid value 4·07; saponification value 214·5; iodine value 2·38. It is considered that it would be suitable for making candles and soap (Olsson-Seffer, Bull. Imp. Inst. 1909, 7, 410).

Myrtle berry wax (*Myrtle wax*, *Laurel wax*, *Bayberry tallow*) is obtained from the wax myrtle, *Myrica cerifera* (Linn.), a shrub growing on peaty soil in North America, and common along the North Atlantic sea coast. The fruit is brown or blackish and the size of a pea; it secretes the wax and becomes covered with a snow-white crust, penetrated by brown or black points of the skin, so that the wax can only be got off as a powder and not in coherent pieces.

Wax is also got from other Myricaceæ, namely *M. caracasana* (Humb. and Bonpl.) in South America, especially in Columbia and Venezuela, and *M. aethiopica* (Linn.) in Abyssinia. *See* also *Cape berry wax* and *Mexican myrica wax* above.

To obtain the wax the berries are boiled with water, and the fatty mass that floats on the surface is skimmed off and poured into flat dishes; the yield of wax is from 20 to 25 p.c., and a bush yields from 10 to 15 kilos. of berries. The wax which comes from the United States has a deep green colour, probably due to chlorophyll; this colour is bleached to a grey-yellowish tint by exposure to light and air for several years, but the change extends only a few millimetres below the surface.

The statements as to its composition are not concordant. Smith and Wade (J. Amer. Chem. Soc. 1903, 25, 629), however, examined the wax, preparing it by extracting the berries with light petroleum, and concluded that it was mainly palmitin (glyceryl tripalmitate) with some lower glyceride and a small amount of free acid; they obtained pure palmitin by crystallising four times from light petroleum. The berries they used were picked in September, and the extraction and examination were made in November. The values they record are: sp.gr. 0·9806 at 22°/15·5°, and 0·878 at 99°/15·5°; refractive index at 80° 1·4363; acid value 30·7; saponification value 217; iodine value (Hübl) 3·9; Reichert-Meissl number 0·5. From these they inferred the absence of oleic and volatile acids. They also concluded that no stearin was present. The m.p. in this sample was 48°, as determined by Allen's method (vol. ii. pt. i. 34), and the solidifying-point was 45°; but it was found that the melting-point rises considerably on keeping the wax. A redetermination in March of the m.p. gave it as 52·5°, a rise of 4·5° in 4 months. A specimen of wax about 4 years old melted at 57° and solidified at 58·3°. Wax from berries obtained in August and extracted in March melted at 55·4°.

Some other observers have found the acid value to be only about 4. It is inferior to beeswax in ductility and plasticity; mixed with beeswax it can be employed for making candles; these are said to give a pleasant smell when extinguished. It could probably be used for soap making. Chittenden and Smith (Amer. Chem. J. 1884, 6, 217) employed this wax as a source for preparing pure palmitic acid.

Ocuba wax is obtained from the fruit of a shrub *Myristica ocuba* (Humb. and Bonp.), growing in the Para province of Brazil. It grows well in marshy places, and is found in abundance along the banks of the Amazon river. The fruit encloses a nut covered with a thick skin. The skin extracted by water gives a fine red colour (Ocuba red); after washing with water the nuts are thrown in heaps, crushed to a paste, and boiled, when the wax separates and floats on the surface. The crude wax resembles beeswax, and by purification can be obtained white and suitable for candle-making. 100 kilos. of the seeds give 20–22 kilos. of wax. The product is said to be a mixture of wax, fat, and resin, to melt at 40°, and to have a sp.gr. of 0·920 at 15°; it is only slightly soluble in cold alcohol, but is completely soluble in boiling alcohol and ether (Chem. Revue über die Fett- und Harz- Industrie, 1901, 8, 213).

Palm tree wax is the product of a palm tree *Ceroxylon andicolum* (Humb. and Bonpl.), which grows on the Andes in Columbia at altitudes of 7900–9700 ft.; it attains a height of 160 ft., and the trunk is coated with the wax, which gives it a white and marble-like appearance. The wax is obtained by cutting down the tree and scraping off the coating, which is then boiled with water; the wax is thus softened and floats on the surface, and impurities are removed. One tree is said to yield 25 lbs. The wax is made into balls and dried in the sun. Candles are made from it by the addition of a little tallow, and are sold in Carthago. That which is obtained from the Indians is yellowish-white, porous, and friable. When melted it is dark yellow, slightly translucent and fragile like resin. It is partly wax and partly resin, and melts at a temperature a little above that of boiling water; it becomes strongly electric by friction. It is readily soluble in hot alcohol; on cooling the solution becomes a white congealed mass. By using large quantities of alcohol and allowing the solution to cool the waxy part separates and the more soluble resin remains in solution; by repeating this operation several times the wax can be separated from the resin and from a small amount of a bitter substance. Ether also dissolves it, and by evaporation feathery crystals can be obtained. The purified wax melts below the temperature of boiling water, and then resembles beeswax, whilst the resinous matter melts above this temperature (Boussingault, Ann. Chim. Phys. 1825, 29, 330; 1835, 59, 19; Seemann, Pop. Hist. of the Palms, 1856, 222).

Bonastre (J. Pharm. Chim. 1828, 14, 349) obtained purified wax by repeated extractions with cold alcohol, and then dissolving the residue in boiling alcohol and filtering. When cold the solution became thick and opaque, like an aqueous starch solution; on standing for some months crystals appeared. On removing the alcohol white silky crystals were obtained; when dried and ground in a mortar it gave luminous sparks. He named this purified wax *ceroxyline* or *cerosiline*. Lewy (Ann. Chim. Phys. 1845, [iii] 13, 447) found that the wax purified from the resin melted at 72°, and contained carbon 80·73 p.c., and hydrogen 13·30 p.c. Teschemacher (Mem. and Procs. Chem. Soc. 1845, 25) also describes this wax.

Peat wax. Waxy substances are obtained when peat is extracted with suitable solvents. By means of benzene or toluene from 1 to 8 parts of crude wax have been obtained from 100 parts of the dry material of samples from different sources. This crude wax was found to contain sulphur, usually amounting to less than 1 p.c. of the wax, but in one case reaching 10·5 p.c. The crude wax consisted of some resinous matter, but principally of a mixture of ester and free acid. The acid or acids obtained by the saponification of the crude wax corresponded in composition to a fatty acid containing about 22 carbon atoms; the alcohols thus obtained appeared to contain about the same number. No trace of glycerides was found (Kraemer and Spilker, Ber. 1902, 35, 1212). A process was patented in 1903 by Bouchaud-Praceiq (Fr. Pat. 338736) for extracting peat, lignite, &c., with alcohol or ethyl esters, &c., and recovering the wax from the solvent. The wax is said to be hard and to resemble beeswax, and to have a higher melting-point and a sp.gr. above 1·000 (J. Soc. Chem. Ind. 1904, 23, 710).

Zaloziecki and Hausmann (Zeitsch. angew. Chem. 1907, 20, 1141), by extracting peat with alcohol, obtained a dark yellow or brown waxy substance, but the yield was only 10 grms. from some kilograms. It had no sharp melting-point, melting between 80° and 96°; it dissolved very easily in amyl alcohol, and less readily in ethyl and methyl alcohols. In ethyl ether or benzene it dissolved only partially, giving a dark green liquid and leaving a brown insoluble residue. By saponifying the substance soluble in ethyl ether an alcohol was obtained, melting between 124° and 130°, and having a composition and molecular weight corresponding to $C_{20}H_{40}O_4$, and also an acid which began to soften at 145° and melted at 184°, having a composition and molecular weight corresponding to $C_{18}H_{25}O_5$. The part insoluble in ether gave on saponification an alcohol having the same melting-point, composition and molecular weight as the other alcohol, but differing a little in its behaviour, and also an acid which had not melted when 260° was reached, and which had a composition and molecular weight corresponding to $C_{21}H_{25}O_7$. Small quantities of other substances appeared also to be present in the wax, and the above substances are very possibly mixtures.

Pisang wax. This wax occurs as an excretion on the leaves of a species of *Musa*, which grows wild in Java, especially in the uncultivated regions of Tjilatjap and Koeningan. *Pisang* is the Malay name for the banana. The natives obtain the wax by scraping the leaves, throwing the scrapings into boiling water, and then collecting the melted wax. It is said that one stem bears on the average seven leaves (a leaf may be as much as 6 ft. in length), and that 100 leaves yield ½ kilo. of wax. The cakes of wax are white, cream, or slightly greenish in colour, and slightly transparent; the wax is hard with a coarsely granular or crystalline fracture and is very friable. It has been examined by Greshoff and Sack (Rec. trav. chim. 1901, 20, 65), who record the following: sp.gr. 0·963–0·970 at 15°; m.p. 79°–81°; acid value 2–3; it is very hard to saponify, and the saponification value found was 109. Boiling alcohol dissolves very little (about 1 p.c.), and on cooling only retains 0·2 p.c. It is easily soluble in boiling oil of turpentine, amyl alcohol, or carbon disulphide. At 15° petroleum, ether, acetone, and oil of turpentine retain 1 p.c. or less; chloroform and carbon disulphide retain less than 2 p.c. On the basis of ultimate analyses of the wax, freed from the part soluble in boiling alcohol, and of the acid and alcohol obtained by saponification, the authors propose provisionally the formula $C_{37}H_{74}O_2$ for the wax, regarding it as an ester formed from $C_{24}H_{48}O_2$ *pisangceric acid*, and $C_{13}H_{28}O$ *pisangceryl alcohol*. The acid melts at 71°, and the alcohol at 78°.

Raphia wax. The raphia palm, *Raphia pedunculata* (Beauv.) or *Ruffia*, which grows in Madagascar, furnishes the fibrous material used by gardeners and known as 'bass'; this is the epidermis of the upper side of the palm leaf. The dull under surface is coated with a whitish layer or bloom, which can be easily rubbed off. After the bass is removed large quantities of the residues are available as a source of the wax. They are spread out to dry on cloths in the open air, but must be sheltered from the wind as the light waxy matter is easily blown away. After drying for 2–4 days a white coating is apparent on the under surfaces of the leaves; this is detached as a powder by shaking or rubbing the leaves between the hands. The powder is collected, freed from foreign matter by sifting, and then put into boiling water when the wax melts and floats on the surface, and earthy impurities settle to the bottom. The melted wax is separated and allowed to solidify. It is yellow to dark brown in colour, and rather harder and more brittle than beeswax. In an experimental trial it was found that ten leaves of medium size (3½–4½ metres in length) weighed 104·5 kilos. and yielded 0·75 p.c. of wax; the yield in practice, however, would be less than this.

Raphia wax in its physical properties resembles carnaüba wax but differs chemically; it seems likely to be applicable to the manufacture of candles, polishes, &c., if it can be produced at a sufficiently low cost.

Two specimens were found to have the following properties: m.p. 82°, 83°; sp.gr. 0·836, 0·832 at 99°/15·5°; acid value 4·9, 6·5; saponification value 51·3, 50·3; iodine value 7·7, 10·7 (Bull. Imp. Inst. 1908, 6, 380). It is only slightly soluble in alcohol, ether, acetone, chloroform, light petroleum, and carbon disulphide. It dissolves, but not completely, in boiling alcohol, and separates on cooling. It appears to be mostly composed of an alcohol or mixture of alcohols having a composition corresponding to $C_{20}H_{42}O$, but differing from arachic alcohol (Compt. rend. 1905, 141, 1251; 1907, 144, 594).

Spermaceti occurs in special cavities in the head of the sperm whale or cachalot, *Physeter macrocephalus* (Linn.), and also in the blubber; it is held in solution by the sperm oil at the temperature of the whale's body. It also occurs in the bottle-nose whale *Balaena rostrata*, and in some other cetaceans, but not in the oil of the whalebone whales. The spermaceti from *Balaena rostrata* has a slightly higher melting-point than that from the sperm whale. The great bulk of the head of the sperm whale consists of dense cellular tissue infiltrated with spermaceti, this is surmounted by the 'case' which holds nearly a ton of very fine oil and spermaceti known as 'head matter.' When removed this head matter is full of spermaceti crystals. The blubber surrounds the whole body in a layer about 18 ins. thick; it is 'tried down,' that is heated to separate the oil from the tissue; on cooling the oil deposits thick scales of spermaceti and becomes semi-solid. The 'trying down' is sometimes done on the ship and sometimes at the factories. At the latter the semi-solid mass undergoes several filtrations and pressings to separate the oil from the spermaceti, which is melted and cast into moulds once or twice during the series of pressings. Finally, the wax is warmed and agitated with a little caustic potash solution to remove the last traces of colour and to neutralise traces of acid, and is cast into blocks forming an almost blue-white glistening semi-crystalline solid (Field, Soc. Arts. Cantor Lectures, 1883). It is said that for some purposes it is best not to free it entirely from the sperm oil.

The sp.gr. at ordinary temperatures is about 0·945, but values as divergent as 0·905 and 0·960 have been given, owing probably to irregularities caused by the crystalline structure. The sp.gr. of melted spermaceti at 98°–99° is from 0·808 to 0·816 as compared with water at 15° (Kebler, Amer. J. Pharm. 1897, 69, 104). The m.p. is from 41° to 49°, but by repeated purifications it reaches 53·5°. The acid value is from 0 to 1·8; saponification value from 120·6 to 134·6; the iodine value of highly purified spermaceti is 0, but values up to 9·3 (by Wijs' method) have been found, caused, no doubt, by the presence of sperm oil (Dunlop, J. Soc. Chem. Ind. 1908, 27, 63). It is insoluble in water; cold alcohol dissolves little except the adhering oil, it is soluble in boiling alcohol, ether, chloroform, carbon disulphide; it separates in a crystalline form from its solution in hot alcohol or ether.

Spermaceti is mainly composed of cetyl palmitate $(C_{16}H_{33})C_{16}H_{31}O_2$. It was examined by Chevreul in 1814, and the purified substance was named by him *cétine*; in 1818 he described the alcohol obtained by its saponification (now known as *cetyl alcohol*) under the name *ethal*, formed from the first syllables of ether and alcohol (Recherches, Chim. sur les Corps Gras. 1889, 148). The acid with which the cetyl alcohol $C_{16}H_{33}OH$ is combined was found later to be palmitic acid. Although spermaceti has a crystalline appearance, it contains compounds other than cetyl palmitate. Heintz (Pogg. Ann. 1854, 92, 609, 93, 536) believes that it yields on saponification stearic, palmitic, myristic, and lauric acids, and the alcohols $C_{18}H_{38}O$, $C_{16}H_{34}O$, $C_{14}H_{30}O$, and $C_{12}H_{26}O$; he named the first, third, and fourth of these *stethal*, *methal*, and *lethal* in analogy to Chevreul's *ethal*. These very probably exist in the spermaceti as esters of the corresponding acids. He also found another liquid substance in the products of saponification.

Spermaceti is used for making candles which burn brightly and in pharmacy for making ointments. For candle-making the addition of a few per cent. of beeswax or paraffin is advantageous to remove the brittleness of the spermaceti. Sperm candles of prescribed composition and properties were formerly used as the standard for measuring the illuminating power of different lights (Young, J. Soc. Chem. Ind. 1891, 10, 185; Met. Gas Referees, *ibid.* 1894, 13, 65); but now a pentane lamp is used, representing ten standard candles.

Sugar cane wax. A waxy substance is produced by the sugar cane, and is noticeable on the rind of some varieties, especially near the nodes; it is most abundant on the violet cane. It was first described by Avequin (Ann. Chim. Phys. 1840, [ii.] 75, 218), who named it *cérosie*. Cold alcohol removes some colouring matter, chlorophyll probably, but does not dissolve the wax. The purified wax can be obtained by removing the portion soluble in cold alcohol, then dissolving in boiling alcohol, cooling, pressing, driving off the alcohol, and melting. It is dull yellow, hard, and can be powdered; it is insoluble in water, cold alcohol and cold ether; hot ether dissolves it to some slight extent, and deposits it on cooling in small crystalline grains; boiling alcohol dissolves it completely, and the solution on cooling becomes semi-solid, just as does an alcoholic soap solution. It melts at 82° and solidifies at 80°, and its sp.gr. is 0·961 at 10°. When made into a taper it burns with a fine white flame like wax or spermaceti.

Analyses of the wax were made by Dumas (*ibid.* 222) and Lewy (*ibid.* 1845, [iii.] 13, 451) who assigned formulæ to it on the supposition that it was a single compound, but from Wijnberg's experiments (Het Rietwas en de Mogelijkheid zijner Technische Winning, 1909; J. Soc. Chem. Ind. 1909, 28, 991) the wax appears to contain about 45 p.c. of myricyl alcohol $C_{30}H_{62}O$, and also a substance with a composition corresponding to $C_{33}H_{68}O$, which is neither an ester nor a primary alcohol, since it yields no hydrogen when heated with soda lime. Prinsen Geerligs (Arch. v. d. Java-Suikerindustrie, 1893, 1, 67) also examined the wax.

In the manufacture of cane sugar the juice is purified by treatment with lime and heating; the resulting muddy precipitate is filtered off and forms a waste product. Wijnberg proposes to extract the wax from this by the use of benzine or other solvents and utilise it (Fr. Pat. 397843, 1908). He finds that the extract from fresh mud contains a large proportion of fatty matters besides the wax, but that in mud which has been kept for some time the fatty matters undergo a kind of fermentation, and are decomposed and a product is obtained approximating more closely to the wax got by scraping the cane. It is stated that extraction of the wax has been undertaken in Java. The subject is treated of very fully in Wijnberg's book mentioned above. H. H. R.

WEED KILLERS. The best weed killer for the purpose of the agriculturist is generally the hoe in some form or other, aided by the sun and wind. To permit of the ready discrimination, by mechanical means, between the crop and the accompanying weeds is one of the most important advantages of regular drilling or planting. It is only in a few cases that the farmer can derive much advantage from the application of chemical methods of destroying weeds, since, as a rule, any means which will destroy weeds, will render the soil, for a time at least, unfitted for the growth of any plant.

For destroying *all* vegetation, *e.g.* for keeping garden paths free from weeds, any general plant poison may be used. Of these there are many; indeed any soluble salt, applied in strong solution, will kill plants by producing plasmolysis. In practice, strong solutions of common salt, 10 p.c., *i.e.* 1 lb. per gallon; dilute sulphuric acid (1 part in 25 to 30 of water); dilute solution of phenol (about 1 oz. commercial carbolic acid to a gallon of water); of sodium arsenite (about 1·5 p.c. solution); or of calcium sulphide (made by boiling 1 part of sulphur with 50 parts of water and 10 parts of quicklime) are often used, the liquid being simply applied to the surface of the walks from a watering pot, which should be well painted on the inside. Sulphides, thiocyanates, and sulphites act as effective plant poisons, and to their presence the poisonous action of fresh 'gas lime' is largely due. Many metallic salts act as plant poisons, even in excessively dilute solution. According to Coupin (Compt. rend. 1901, 645) the weakest solutions of the various salts which had an injurious effect upon the growth of the roots of the seedlings of wheat, contained 1 part of the anhydrous salt and the following parts of distilled water:—

Copper sulphate . .	700,000,000
Mercuric chloride . .	30,000,000
Cadmium chloride .	10,000,000
Silver nitrate . .	1,000,000
Zinc sulphate . .	40,000
Lithium chloride . .	12,000
Calcium iodide . .	10,000
Barium nitrate . .	4,200
Borax	1,000
Manganese chloride .	1,000
Calcium bromide . .	400
Calcium chloride . .	260

The extreme dilution of the copper sulphate which can produce a poisonous effect, *when applied in solution to the roots*, is remarkable. In the presence of soil, however, many of these substances, including copper sulphate, are converted into insoluble and harmless compounds.

But the use of these plant poisons in agricultural practice is limited, owing to the difficulty of restricting their action to the weeds. In some countries, where a particular weed has become a scourge, recourse to these drastic measures is sometimes made, *e.g.* prickly pear in Cape Colony has been destroyed in many districts by the use of sodium arsenite, or of solutions of arsenical sheep dips, 1 or 2 p.c. solution of the former being sprayed over the uprooted trees, which then die and can afterwards be burnt.

Of more importance to the farmer is the *differential* or *selective* poisoning of weeds, by the use of solutions which, while destroying certain weeds, produce no injurious effect upon the crop itself. The best known of such methods is in the destruction of charlock or wild mustard (*Sinapis arvensis* [Linn.] or *Brassica Sinapistrum* [Boiss.]). The method, due to an accidental observation by Girard in France, in 1897, is to spray the barley or oat field infested with the charlock in the spring, when the charlock plants are about 2 or 3 ins. high, with from 40 to 70 gallons per acre of a 3 p.c. solution of crystallised copper sulphate, best on a still, dry, dull day. Unless rain soon follows the spraying, in which case the result is spoiled, it will be found that the charlock plants quickly blacken and die, while the barley or oats and clover (if that be also present) are uninjured. In addition to charlock, known in various districts as 'ketlock,' 'wild mustard,' 'yellow flower,' and in Ireland as 'preshaugh,' other cruciferous weeds, of which 'runches' (*Raphanus raphanistrum*) is the most important, can be killed by the same treatment. Ferrous sulphate in 10 or 12 p.c. solution may be substituted for the copper sulphate, but according to experience in Ireland (Leaflet No 6. Dept. of Agric. and Tech. Instruction for Ireland. 1901) is not so efficient. Cereals, clovers (and most other *leguminosæ*) are uninjured by the treatment, but docks and thistles, although not usually killed, are seriously checked in growth.

Various explanations of this differential action of copper and iron sulphate solutions have been offered. Girard ascribed it to the solution being retained by the rough and more or less horizontal leaves of the charlock, while the smooth erect leaves of the cereals would permit of the solution running off. Against this is the fact that other plants with horizontal leaves, *e.g.* clovers, suffer little damage. Another possible explanation is that interaction between the metal of the copper or iron sulphate and the sulphur compounds which are characteristic of the *cruciferæ*, may take place and lead to the destruction of the plant.

A third and probable theory is that the cell walls of the leaves of charlock are thinner or weaker than those of cereals, and more readily permit of plasmolysis being set up, when they are brought into contact with saline solutions applied to the exterior of the leaves. This view receives some support from the fact, observed by Heinrich (Jahresb. fur Agricultur-Chemie, 1901, 351), that 15 or 20 p.c. solutions of sodium nitrate, ammonium sulphate, or potassium chloride—substances which cannot exert any chemical toxic effect—are also effective in destroying charlock. Moreover, the importance of a dull, still, dry day for the spraying, which is always shown in field trials, is in accordance with this explanation, for under such conditions, the droplets of the solution, deposited on the leaves of the plant, would retain their original concentration for a longer period than on windy or sunny days when evaporation would be hastened.

The experience of the Irish Department of Agriculture is that from 50 to 70 gallons per acre of a 3 p.c. solution of copper sulphate, under favourable conditions of weather, is the most effective spray for destroying charlock in cereal crops, and that even when the weed has come into flower, it can be successfully destroyed by this treatment, whilst the cereals and clover are uninjured.

A certain amount of indirect 'weed' killing can be achieved by suitable manuring; thus the growth of grasses is favoured at the expense of admixed leguminous plants, by repeated applications of nitrogenous manures, whilst the opposite effect is produced by application of calcareous, phosphatic, and potash manures with avoidance of nitrogenous ones. But this method is of limited application, and is rarely of service to the farmer. It may, however, be used in the adjustment of the relative proportions of grasses and clovers in a lawn. But for the destruction of the more important and troublesome weeds of the farm and garden reliance has chiefly to be placed upon the mechanical methods of cultivating the soil at the most suitable season. H. I.

WEISSENFELS LIGNITE RESINS *v.* Resins.

WEISSGILTIGERZ or **WEISSGÜLTIGERZ** *v.* Freibergite.

WELD is the dried herbaceous plant known as the *Roseda luteola* formerly cultivated to a considerable extent in France, Germany, and Austria. Its cultivation in this country has nearly ceased, because not only is the quantity of colouring matter present very small, but the carriage of the plant, owing to its bulky nature, is extremely expensive. A special interest, however, attaches to weld, for it is said to be the oldest European dyestuff known, and was used by the Gauls and other nations dwelling north of the Alps in the time of Julius Cæsar.

The plant attains a height of about 3 feet, is pale brown in colour, and is sold in sheaves like straw. The colouring matter is disseminated throughout the entire plant, but the greater quantity occurs in the upper extremity and the seeds.

Luteolin, the main colouring matter of weld, was examined by Chevreul (J. Chim. Med. 6, 157; Annalen, 82, 53), who obtained it in a crude condition; its isolation in a state of chemical purity was first achieved by Moldenhauer (Annalen, 100, 180), who assigned to it the formula $C_{20}H_{14}O_6$. It was subsequently investigated by Schützenberger and Paraf (Bull. Soc. chim. 1861, [i.] 18), who proposed the formula $C_{12}H_8O_5$ and purified it in a somewhat novel manner which is worthy of mention. Weld was exhausted with alcohol, the extract evaporated, and treated with water, which threw down a dirty greenish precipitate. This was collected, introduced with a little water into a sealed tube and heated to 250°. On cooling the sides of the tube were found to be coated with golden-yellow needles of luteolin, and the impurities had collected at the bottom of the tube to form a resinous cake.

Hlaziwetz suggested that luteolin had the formula $C_{15}H_{10}O_6$, and was isomeric with the *paradiscetin*, which he obtained during the fusion of quercetin with alkali (Annalen, 112, 107).

For the preparation of luteolin in quantity Perkin (Chem. Soc. Trans. 1896, 69, 206, 799) employs weld extract.

300 grms. of the extract dissolved in 3 litres of water is treated with 100 c.c. of hydrochloric acid (33 p.c.), and the mixture is digested at the boiling temperature for some hours. A quantity of a black resinous substance separates, which is collected while hot, and the filtrate, which contains the colouring matter, is allowed to stand for 12 hours. A brown precipitate of impure luteolin is slowly deposited, and is collected, washed, and dissolved in a little hot alcohol. On pouring this solution into ether, the main bulk of the impurity is precipitated, and the ethereal liquid on evaporation yields a yellow residue, which is crystallised from dilute alcohol. The product in addition to luteolin contains apigenin (Chem. Soc. Trans. 1900, 77, 1315), and the latter can only be removed with certainty by the following method. The mixture dissolved in boiling glacial acetic acid is treated with a few drops of strong hydrochloric acid; this causes the almost immediate separation of luteolin as hydrochloride, whereas the apigenin remains in solution. The hydrochloride is collected, decomposed by water, and the luteolin crystallised from dilute alcohol.

Luteolin $C_{15}H_{10}O_6$ crystallises in yellow needles or leaflets, m.p. 327°–329° (Perkin), 327° (Kostanecki, Różycki and Tambor, Ber. 1900, 33, 3410), soluble in alkaline solutions with a yellow coloration. With alcoholic lead acetate it gives a bright yellow precipitate, and with alcoholic ferric chloride a green solution.

Luteolin sulphate $C_{15}H_{10}O_6{\cdot}H_2SO_4$, orange-red needles; *luteolin hydriodide* $C_{15}H_{10}O_6{\cdot}HI$, orange prisms; *luteolin hydrobromide*

$$C_{15}H_{10}O_6{\cdot}HBr,H_2O,$$

ochre needles; and *luteolin hydrochloride*

$$C_{15}H_{10}O_6{\cdot}HCl,H_2O$$

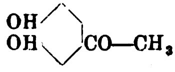
(Perkin, *l.c.*) are readily prepared by the action of the acids on luteolin in the presence of boiling acetic acid. By treatment with water these compounds are quantitatively decomposed into luteolin and the acid.

Monopotassium luteolin $C_{15}H_9O_6K$, fine yellow needles, from luteolin by means of alcoholic potassium acetate, is decomposed by boiling water with separation of luteolin. The *sodium* compound $C_{30}H_{19}O_{12}Na$ behaves similarly.

Tetra-acetyl luteolin $C_{15}H_6O_6(C_2H_3O)_4$, Perkin, also Herzig (Ber. 1896, 29, 1013), colourless needles, melts at 221°–223° (P.), 225°–227° (H.). *Tetrabenzoyl luteolin* $C_{15}H_6O_6(C_7H_5O)_4$, colourless needles, melts at 200°–201° (P.).

Dibromluteolin $C_{15}H_8Br_2O_6$, yellow needles, melts at 305°.

By the action of nitric acid on luteolin Rochleder (Zeitsch. Chem. 1886, 602) obtained oxalic acid, and with fused alkali *protocatechuic acid* and *phloroglucinol*. Digested with boiling 50 p.c. potassium hydroxide solution, phloroglucinol and *acetylcatechol* are produced (Perkin and Horsfall, Chem. Soc. Trans. 1900, 77, 1322).



When methylated in the usual manner luteolin behaves somewhat peculiarly, for it yields, in addition to luteolin trimethyl ether, also methyl luteolin trimethyl ether (P. and H.).

Luteolin trimethyl ether $C_{15}H_7O_3(OCH_3)_3$, lemon-yellow needles, m.p. 161°–163°, forms a *monoacetyl* derivative $C_{15}H_6O_3(C_2H_3O)(OCH_3)_3$, colourless prisms, m.p. 156°–158°, and with alcoholic potash gives a bright yellow crystalline salt, which is decomposed by water.

On hydrolysis with alcoholic potash at 170° the trimethyl ether gives *veratric acid*, and *phloroglucinol monomethyl ether*, which was isolated in the form of *disazobenzene phloroglucinol monomethyl ether*, orange needles, m.p. 251°–252°.

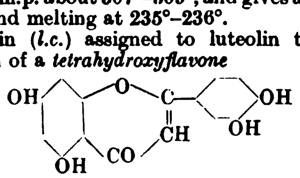
Methyl luteolin trimethyl ether

$$C_{16}H_9O_3(OCH_3)_3,$$

melts at 191°–192°, and the *monacetyl derivative* $C_{16}H_8O_3(OCH_3)_3(C_2H_3O)$ at 175°–176°. By means of alcoholic potash *veratric acid* and *methyl phloroglucinol methyl ether* (identified as *disazobenzene methyl phloroglucinol monomethyl ether*, orange-red needles, m.p. 198°–201°) are produced.

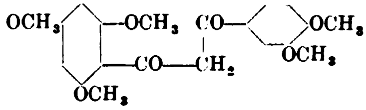
By digestion with boiling hydriodic acid *methyl luteolin* $C_{16}H_{12}O_6$, yellow leaflets, is formed, m.p. about 307°–309°, and gives an acetyl compound melting at 235°–236°.

Perkin (*l.c.*) assigned to luteolin the constitution of a *tetrahydroxyflavone*



and the more recent synthesis of this colouring matter by v. Kostanecki, Różycki and Tambor (*l.c.*) has indicated that this formula is correct.

When *phloracetophenone trimethyl ether* is condensed with *ethyl veratrate* it gives 2 : 4 : 6 : 3′ : 4′ *pentamethoxybenzoylacetophenone*,



and this by long digestion with boiling hydriodic acid (sp.gr. 1·96) is converted into luteolin.

When air is aspirated through alkaline solutions of luteolin (and also those of chrysin and apigenin), oxidation does not occur. This property, according to Perkin (*l.c.*), distinguishes the colouring matters of the flavone from those of the flavonol class, which are readily oxidised by this treatment.

It has already been stated that weld contains a second colouring matter *Apigenin*, *v.* PARSLEY.

Dyeing properties of weld. The importance of weld as a dyestuff in silk and wool dyeing has greatly diminished in consequence of its low colouring power compared with quercitron bark, flavin, and old fustic. This in one respect is unfortunate, because of all the natural yellow colouring matters, it yields the purest and fastest shades. In conjunction with aluminium and tin mordants it gives very bright pure lemon-yellow colours, and these do not change to an olive or reddish tint as is the case with other vegetable yellows. With chromium and iron mordants weld gives yellowish and greenish olives respectively. For yellow, wool and silk are mordanted with alum and tartar in the usual manner and dyed subsequently in a decoction of weld with the addition of chalk to the dye-bath. Weld alumina yellow is to some extent still employed for certain army cloths and braid in this country. For silk dyeing, weld extract is manufactured in small quantity, and is used for the production of yellow and olive colours.

WHALE OIL is obtained from the blubber of various species of the genus *Balaena*, viz. *Balaena mysticetus*, Greenland or 'right' whale (northern whale oil); *Balaena australis* (southern whale oil); *Balaenoptera longimana*, *Balaenoptera musculus* (common rorqual, the largest of all known animals), *Balaenoptera borealis* (northern or Rudolphi's rorqual; finback oil, finner-whale oil, humpback oil); *Neobalaena marginata* (Australian whale); *Rhachianectes glauca*, Cope (Japan). Other cetaceans, the zoological species of which have not been determined yet, or which are identical with the foregoing species, are known as bowhead whale, Californian grey whale, orca or killer whale, beluga or white whale; these are chiefly caught by American whalers in the Northern Pacific. The northern whale oil is the 'train oil' of commerce proper; but this name has become a generic name, and has been extended to all other 'blubber oils' included in this group and even to fish oils (*see* OILS, FIXED, AND FATS).

The blubber of whales caught in the northern seas of Europe was, in the early days of the whaling industry, 'tried' on board the whalers; but in consequence of the low yield, and also of the low quality of oil thus obtained, the whales are now brought into the 'trying' stations situated in Finmarken, on the Lofotes, Faro, Shetland, Hebrides, and in Iceland.

To a large extent the American whalers still 'try' the blubber on board ship and deliver the crude oil into the refineries of New Bedford, Mass., on the east coast, and of San Francisco on the west coast. In British Columbia the most modern methods (*see* below) are now in vogue.

During recent years a very extensive whale oil industry has sprung up in the whaling grounds adjacent to the South African coast, especially to that of Natal. The whale, killed by a gun shot, is blown up with air so as to float the carcase, which is brought immediately into the trying stations, when the whale is hoisted on to a working platform where the blubber is stripped clean from flesh, and care is taken to leave as little flesh as possible on the blubber. The latter is then cut into strips, which are thrown into chopping machines, whence the comminuted mass is immediately delivered into melting-pans, and 'boiled' with steam. Five different qualities of whale oil are produced. The best quality is the oil which first runs off the blubber at the lowest temperature, known in commerce as 'Whale Oil No. 0'; it is of a pale-yellow colour, and has but a faintly fishy smell. This oil contains a very small quantity of free fatty acids. The best brands are 'water-white,' and are free from volatile fatty acids. On further boiling, the second quality—'Whale Oil No. 1'—runs off; it is a little darker in colour, although still pale yellow. Its fishy smell is more pronounced than the oil of the first running.

These two qualities of oil are stored in large vessels, whereby they become clarified whilst depositing 'stearine,' which is filtered off, pressed in hydraulic presses, and sold as 'whale tallow,' 'whale stearine,' for soap-making.

The residual mass in the boiling pans, together with the flesh of the whale, is cut up into strips or fairly large lumps, and is 'tried down' in a digester under a pressure of 40–50 lbs. The oil classed as 'No. 2 oil' is thus obtained. This oil has a brown colour and a strongly developed fishy smell; its proportion of free fatty acids is considerably higher than in 'oil No. 1.' In some stations 'whale oil No. 2' is made from the blubber residues only, and does not contain any oil from the flesh. Hence it represents a superior article to the 'No. 2 oil.'

The bones are worked up in the same manner, and yield a still inferior quality of oil. Such oil ('whale oil No. 3') is darker still, has a more strongly developed odour, and a high percentage of free fatty acids. 'Whale bone oil' of commerce is, however, not exclusively made from the bones, except in those cases where the product is sold under guarantee as 'bone oil.'

All these operations are carried out with the greatest rapidity and precision simulating the routine of the Chicago packing houses which have served as a prototype to the arrangement of a modern whaling station.

In the old whaling stations where the carcase cannot be handled so expeditiously, the oil remains for a longer or shorter time in contact with the flesh, which rapidly undergoes putrefactive changes. The oil suffers in consequence and becomes dark, and is more objectionable as regards smell and free fatty acids than the preceding qualities. This oil is known in the trade as 'carcase oil,' 'whale oil No. 4.'

The residue remaining after the removal of the oil is worked up for manure, 'whale guano.'

This process is carried out in Newfoundland (at Balena) Pacific coast, and South Africa, where the Government has established several new plants. The carcasses of the whale are there completely used up in the manufacture of oil, 'stearine,' bone meal or bones, and other articles of commerce.

If the whale is landed in a perfectly fresh state, cattle meat can be prepared from the fresh meat, as is being done in Iceland and in the Faro Islands, and in South Africa. Some fresh meat is also consumed by the inhabitants locally (Iceland and Faro Islands).

The 'right whale' oil is of better quality than the 'southern whale' oil. The 'finner whale' oil is of still lower quality. Hence the finner whale was formerly neglected by the whalers, but at present even this kind of whale is eagerly pursued by them along the coasts of Norway and Newfoundland, as also to a smaller extent on the Asiatic coast of Russia, and the coast of Japan. For the chemical characteristics of whale oil, *see* OILS, FIXED, AND FATS.

The chemical composition of the whale oil fatty acids has not yet been established satisfactorily. The deposited 'stearine' consists to a large extent of palmitin. The iodine value of a sample of pressed cake examined in the author's laboratory was 37·9. Volatile fatty acids are absent; the high Reichert values recorded by earlier observers are undoubtedly due to the specimens examined having been highly rancid. The liquid fatty acids are characterised by the occurrence of clupanodonic acid, of which about 10 p.c. can be isolated from whale oil in the form of its octobromide.

Whale oil is not infrequently adulterated with rosin oil, the detection of which is simple. More difficult is the detection of admixed seal oil, on account of the great similarity of the two oils; at present this is practically impossible by chemical means; taste alone permits the recognition of seal oil.

The 'water-white' and 'pale' brands of whale oil are used as burning oil, and very extensively in soap-making. The lower qualities are employed for leather-dressing.

Whale oil is also used as a batching oil for jute, for tempering steel, and as a lubricant for screw-cutting machines. J. L.

WHEEL ORE *v.* BOURNONITE.

WHETSLATES *v.* WHETSTONE.

WHETSTONE. Some of the finest whetstones for sharpening edged tools, such as the 'Arkansas stones,' are made from *novaculite*, a rock so called from *novacula*, a razor. The sharpening quality is said to be due to the presence of disseminated crystalline silica, or, in some varieties, to minute crystals of garnet or rutile. The rock is so hard that it has to be cut with diamond dust. Some of the pure white novaculite seems to be a silicious deposit from hot springs, whilst other varieties are altered schistose rocks of fine grain. The so-called 'Hindostan whetstone' is worked in the State of Indiana, whilst the stone known as 'chocolate whetstone' is a mica-schist from New Hampshire. The famous 'German razor hones' are formed of a fine-grained argillaceous rock, occurring in slate near Ratisbon. The Scotch 'snake stone' or 'Water-of-Ayr stone' is used for rubbing down the surfaces of other stones and of copper-plates. 'Tam o' Shanter hones' are employed as ordinary whetstones. Coarse whetstones, used chiefly for scythes, have been worked for many years near Blackdown in Devonshire, and are known as 'Devonshire batts.' They are made from silicious concretions embedded in sand, probably of Upper Greensand age. Somewhat similar scythe stones have been worked at Penzlewood near Stourton in Wiltshire.

(H. B. Woodward, Geol. Eng. 1887; Renard, Mem. Ac. R. Belgique; Rep. Geol. Surv. Arkansas, 1890, vol. 3, Whetsones, by L. S. Griswold; G. P. Merrill, The Non-Metallic Minerals, 2nd ed. New York, 1910); *v.* OILSTONE.

WHISKEY. The term 'whiskey,' applied to the national beverage of Scotland and Ireland, only came into common use in the latter part of the eighteenth century, and is derived from the Celtic 'uisque-beatha' or 'usquebaugh,' meaning 'water of life,' no doubt in reference to its stimulating properties. A similar signification is seen in the terms applied to strong alcoholic liquors in other countries, as 'aqua vitæ,' and 'eau de vie.' Burns employs the three terms 'aqua vitæ,' 'usequbæ,' and 'whiskey' synonymously.

The introduction of the manufacture of alcohol into Europe is, as the word suggests, due to the Arabs, but in the grape-growing countries of the south, the spirit is naturally produced chiefly from wine, and in the north, from different kinds of grain, the different materials used giving rise to the distinctive flavours characteristic of the spirits of different countries.

In Scotland the manufacture of whiskey was a subject for legislation as early as the sixteenth century, and extracts from the statutes show that 'aqua vitæ' was not the exclusive product of malted barley, but that unmalted grain was also used in the early days of spirit distillation in Scotland, and this has been the practice in Ireland up to the present day.

In 1805, during the Napoleonic wars, and owing no doubt to the possibility of a shortage in the supply of grain for food, the use of grain for the manufacture of spirits was prohibited throughout the United Kingdom.

In both Scotland and Ireland the pot-still was used prior to the invention of the patent continuous still by Aeneas Coffey in 1831, since when the patent still has been increasingly employed for the manufacture of spirit from a mixture of malt and unmalted grain, and known locally as 'whiskey.' About two-thirds of the potable spirit made in Scotland and Ireland at the present time is of this description. The spirit produced from other materials as molasses, rice, starch, potatos, dates, currants, &c., is almost invariably distilled from a 'patent still,' and is used chiefly for industrial purposes. This applies particularly to the spirit made in the English distilleries (about eight in number), where patent stills are almost exclusively employed. When *malt only* is used the whiskey is produced in Scotland chiefly, and in Ireland exclusively, from pot-stills. In Scotland there are 150 distilleries, 137 of which use pot-stills only; 10, patent-stills; and 3, both pot and patent-stills. In Ireland, out of 27 distilleries, 18 use pot-stills only; 2, patent-stills only; and 7, both pot- and patent-stills.

The different characters of the various kinds of whiskey are due to the presence of small amounts of secondary products, sometimes referred to as 'impurities' or 'by-products' (as esters, higher alcohols, &c.), rarely exceeding in the aggregate one-half p.c. of the ethylic alcohol present, but sufficient to impart a distinctive flavour and aroma to the spirit.

These differences in character depend mainly upon (*a*) the kind and relative proportions of the materials used in the wash; (*b*) the methods of mashing and fermentation employed; and (*c*) the type of still used and the manner in which it is worked.

For the processes of mashing, fermentation, and distillation employed in the manufacture of ordinary alcohol, and for a description and diagram of Coffey's patent still, *see* article ALCOHOL.

This is known as 'silent' or neutral spirit, but grain spirit, distilled from patent stills, when intended for potable purposes, is not so highly rectified as to be deprived of its 'whiskey' character.

In the manufacture of pot-still whiskey in Scotland, barley-malt is practically the only material employed in the mash, whilst in the Irish pot-still distilleries the mash consists of a mixture of barley-malt with unmalted barley or other grain. The proportions vary with a view to securing particular flavours in the whiskey, but a typical mash consists of about four-fifths barley (malted and unmalted), and one-fifth of wheat, oats, and rye, the proportions decreasing in the order of enumeration. Maize is generally excluded from the pot-still whiskies.

Besides the formation of sugar by the action of diastase during the mashing process, other substances, the exact nature of which is not thoroughly understood, are obtained in solution, from which the secondary constituents of the finished whiskey are both directly and indirectly derived. According to Bell (Select Committee of the House of Commons on British and Foreign Spirits, 1890–1) some of the essential oils naturally existing in the malt and grain, and the empyreumatic and creosotic bodies with which the malt becomes impregnated during the process of drying over peat, anthracite, or coke fires, pass through the operations in a more or less chemically unchanged condition, thus imparting distinctive characters to the whiskey, particularly when the ordinary pot-still is employed for the distillation.

Similarly during the process of fermentation, the conversion of the sugar into ethyl alcohol is accompanied by other chemical changes resulting in the formation of substances which also influence the flavour of the finished whiskey. Of these the principal are the higher alcohols, which have been shown by Ehrlich and others to be due to the splitting up of certain nitrogenous substances (amino acids) produced by the peptonising action of the malt in the mashing process. The ultimate result is affected by the special nature of the yeast, the temperature at which it works, and the time occupied in fermentation.

The simplest form of pot-stills employed in Scotland are heated by direct fire, and have no special means of rectification. The long neck of the still, however, although originally designed simply to prevent particles of the boiling mash being mechanically carried over by frothing or spraying, incidentally has the further important practical use of effecting considerable rectification.

The pot-stills sometimes have their rectifying power increased by means of perforated plates placed transversely in the neck of the still, or by the use of 'purifiers,' pipes or circular vessels cooled by water and fitted between the neck of the still and the condenser.

Some stills are heated by means of steam-jackets or coils instead of direct fire, and this difference in the method of heating is said to have an important influence on the flavour of the whiskey. Certain empyreumatic bodies are thought to be generated by the open fire method, but according to Bell, Schidrowitz, and Thorpe, these are more probably derived from the peat or coke used for heating the malt kilns.

In the manufacture of Scotch whiskey, two distillations only are usually made, first from the 'wash still' from which the whole of the volatile constituents are collected as 'low wines'; and second, from the 'low wines still,' the distillate from which is collected in three fractions, viz. (1) 'foreshots,' (2) clean spirit or 'whiskey,' and (3) 'feints.' The first and third fractions are added to the low wines of the next distilling period, and so on throughout the distilling season, the residue left in the wash still ('pot ale'), and that in the low-wines still ('spent lees') being run to waste.

The whiskey is generally run off at a strength of 11–25 overproof, but in the Lowlands, where a third distillation or 'rectification' is generally made, the strength of the whiskey distillate is from 40 to 45 overproof.

In Ireland the pot-stills are generally much larger than in Scotland, having sometimes a capacity of 20,000 gallons. The head of the still is shorter, and the still for low wines and feints is provided with a 'lyne arm,' or long pipe which passes through a tub of water, the liquid thus condensed between the head of the still and the worm being conveyed by a 'return pipe' to the body of the still. By this means a considerable degree of rectification is effected.

Three distillations are the rule for Irish pot-still whiskey, and the fractions are more numerous than in the manufacture of Scotch whiskey, consisting of strong low wines, weak low wines, strong feints, and weak feints. The middle or 'whiskey' fraction is also run off at a higher strength than in the Scotch process, viz. from 24 to 30 overproof.

The point at which the collection of foreshots is stopped and that of whiskey commenced, as well as that at which the running of whiskey ceases and the collection of feints begins, is determined by the judgment and experience of the distiller, but various simple devices are employed for testing the distillate at different stages, as glass floats or hydrometers, specific gravity beads, and samplers for testing the distillate by dilution with water and observing whether the mixture is opalescent or clear.

Scotch whiskeys may be divided into the following five principal classes: (1) Highland malts; (2) Lowland malts; (3) Campbeltowns; (4) Islays; all made from malt in pot stills; and (5) grains, a name given to patent-still whiskeys. *Irish whiskeys* have no corresponding classification, all the 'self' or non-blended whiskeys being sold under distinctive names.

The secondary products, and therefore the character of the spirit, are considerably affected by the strength at which the whiskey is run off. Some of these products (especially esters) suffer partial decomposition in both the mash and low wines stills, whilst others, of higher boiling-point, remain in the stills and are run to waste with the pot ale and spirit lees. More than two-thirds of the secondary products are lost in this manner, only from 10 to 30 p.c. passing into the finished whiskey. (For the recovery and utilisation of the esters left in still residues, *see* art. RUM.)

It has not yet been found possible to trace any definite relationship between the commercial characteristics of various pot-still whiskeys, and their composition as ascertained by analysis, for the reason that the secondary constituents are not individually identified by chemical analysis, but are assessed in groups consisting of members of the same family though in varying proportions, *e.g. acids, aldehydes, esters*, and *higher alcohols*.

There is some reason to believe, from the researches of Guareschi and Mosso (on behalf of the Italian Government), Vaughan of Michigan University, and Husz of Sweden, that other bodies may be present due to decomposition of albuminous matter in the grain and having alkaloidal properties. They are alleged to be largely accountable for the deleterious effects of spirit drinking, but, if present, they occur in such minute quantities as to elude identification hitherto.

Husz attributed the unusually deleterious character of the spirits drunk in Sweden in a certain year to the use of unsound grain, and Lombroso has shown that an alkaloid having an action like strychnine is generated in decaying maize. Lauder Brunton, whilst attributing much of the harmful effects of new spirit to furfural, also supports the theory that these effects may be partly due to the presence in minute quantities of alkaloidal bodies, especially in potato spirit.

Schidrowitz has determined the percentage of nitrogen in new pot-still whiskies with the results shown below, but failed to detect the least trace of substances giving alkaloidal reactions. The nitrogen is calculated as NH_3, and expressed as grams per 100 litres of absolute alcohol—

Highland malts	0·09–0·19
Lowland malts	0·11–0·30
Campbeltowns (malt) . .	0·08–0·14
Grains	0·03–0·14
American rye whiskies (matured)	0·26–0·39

No definite evidence was, however, obtained by the Royal Commission on Whiskey, &c., that the deleterious effects attributed to the consumption of spirits are directly due to the presence of poisonous secondary products, and the bulk of the medical evidence was to the effect that the actual amount of the secondary products is so small compared with that of the ethyl alcohol, that the physiological effects produced by them must also be extremely small in comparison with those due to the ethyl alcohol itself. It would appear to follow, therefore, that whiskey derived either from pot or patent still has much the same toxic effect if taken in the same quantity and at the same alcoholic strength.

At the same time, since many substances are known to produce marked effects on the digestive system merely as a result of the sensation produced by their *flavour*, this plays an important part from a dietetic point of view, and the more agreeable flavour of a mature whiskey may exert a favourable mental effect which promotes the activity of the digestive processes, whilst the unpalatable flavour of new 'silent' or neutral spirits may tend to interfere with digestion apart from the direct effect due to the alcohol itself.

The methods usually employed for the estimation of the different groups of secondary constituents are given in detail in the Minutes of Evidence taken by the Royal Commission on Whiskey and other Potable Spirits, 1908–9, vol. ii. App. Q, xii. Thorpe; *see* also vol. i. App. F. Schidrowitz.

The following tables give the results of analyses of various kinds of whiskey by Schidrowitz, Tatlock, and Thorpe, expressed in all cases as parts by weight in 100,000 parts by volume of absolute alcohol (*e.g.* grams per 100 litres).

Schidrowitz and Kaye's results of analyses of 100 samples of the principal classes of *Scotch pot-still whiskey* are summarised in the following table, showing the minima, maxima, and averages—

Results of analyses of 5 samples of spirits made in Germany and sold as cheap whiskey in Hong Kong are given on p. 754.

Samples A and B consisted of 'silent' spirit, with an admixture of pot-still whiskey for the purpose of imparting the genuine flavour of whiskey. They are very similar to what is usually sold as 'whiskey' in public houses in England. Samples C, D, and E consisted of highly rectified 'silent' spirit coloured and flavoured to imitate whiskey. The fusel-oil impurities were much less than is usually found in genuine Scotch and Irish pot-still whiskeys of high commercial quality, whilst furfural and other aldehydes were practically absent, and there was no evidence that these spirits contained anything of a deleterious nature apart from the alcohol itself.

'Pot-still' and 'patent-still' spirits (Thorpe, Royal Comm. on Whiskey and other Potable Spirits, App. Q, vi., vii., viii.). An examination

Total secondary constituents .	367·2	381·9	45·9	44·4	43·8	176·1

of the tables, pp. 755, 756, giving the results of the analyses of a number of representative samples of both kinds of spirits shows very clearly the broad distinction between the 'pot-still' and 'patent-still' spirit.

There is always a much larger amount of the secondary constituents in the 'pot-still' spirit. Speaking generally, the percentage of every one of the secondary constituents usually determined is greater in the 'pot' than in the 'patent' spirit, but the most marked differences are in the 'higher alcohols' and 'furfural.' 'Patent' spirit contains no furfural when new, although after storage in wooden casks it is sometimes found to contain traces of this substance, but always in much smaller amount than in 'pot-still' spirit, in which it is never absent. The low percentage of the 'higher alcohols,' and the absence of all but mere traces of furfural render it a comparatively easy matter to distinguish 'patent' from 'pot-still' spirit. But the variations in the amounts of the secondary constituents in both classes of spirits renders it less easy to estimate the exact proportion of each kind of spirit present in mixtures. Comparing the 'pot-still' spirits among themselves, it will be observed that there are considerable variations in both the total amount and in each constituent of the secondary bodies. The Scotch whiskeys generally show a somewhat less total amount than the Irish, and the Speyside, Banffshire, and Highland samples have a rather smaller amount than the Islay and Campbeltown samples. The latter, as well as most of the Irish samples, are mainly 'blending' as distinguished from 'self' whiskeys.

The differences between new and old 'pot-still' whiskeys, so far as shown by analysis, are mainly in the increased amounts of the volatile acids and aldehydes, and to a less extent of the esters found in the old spirit when stored in wooden casks. The higher alcohols and furfural appear to remain very much the same. Any changes that occur in 'patent' spirit are of a similar kind.

'Pot-still' whiskey is almost always stored in sherry casks, or in other well-seasoned wooden casks that have formerly contained similar spirit. A large proportion of the increases in the secondary constituents which occur in spirit stored in such casks takes place in the first few months, and is due to a process of extraction of these products absorbed in the wood of the casks from former spirits. This absorption is to some extent selective. The ethyl alcohol slowly diffuses through the wood of the cask and passes into the air, leaving some of the esters and higher alcohols behind in the wood, which thus becomes more or less charged with the secondary constituents, according to the length of time and other circumstances attending the storage of spirit in the warehouse.

Probably also, especially when the casks are empty, there is some production of acids, aldehydes, and esters by the slow oxidation of alcohols in the wood of the casks.

A comparison of the ordinary 'patent' spirits with British and foreign spirits of high strength which are not usually stored in wooden casks, but in metal drums or vats, shows that the latter spirits contain still less of the secondary constituents, and that the slight changes which occur in ordinary patent spirits do not take place in these high strength spirits. These spirits are used mainly for technical and industrial purposes, and are often of very great purity, although made from molasses, potatos, and beetroot sugar residues, or other materials not employed for making spirits intended for consumption in this country.

Maturation or *ageing*. In addition to the changes above referred to in the secondary constituents due to storing in casks, there are other changes due to the presence of substances not included in the ordinary analysis of spirits, but which have much to do with the difference in flavour of new and old whiskeys. Thorpe, for example, found indications of pyridine bases, allyl alcohol, and allyl aldehyde derived from the peat used as fuel in malting, and acrolein, due either to the fat in the wash extracted from the grain or possibly from the soap which is occasionally added to the contents of the still to prevent frothing. Schidrowitz found in new pot-still whiskey distinct evidence of the presence of pyrrole, phenolic bodies, an alkaline substance (probably an ammonium salt), sulphuretted hydrogen, sulphurous acid, and a trace of nitriles. All of these are readily changed on exposure to air and moisture, as in storage in casks. The pyrrole probably resinifies, the phenols interact with aldehydes, acids, and alcohols, forming condensation products; the sulphuretted hydrogen and sulphurous acid would readily oxidise, and the nitriles (if present) rapidly condense or be transformed into acids. None of these substances was found in mature spirit.

Numerous processes have been suggested for the artificial ageing or maturing of whiskey. These are, for the most part, oxidation processes, as by treatment with charcoal, or (as in Carroll's process) by passing the spirit vapour mixed with air, and superheated to 300°F. through a pipe enclosed in a steam jacket also heated to 300°F. Hewitt's method, which is a de-aldehyding process, consists of the addition of phenylhydrazine-sulphonate of sodium or calcium to the low wines still, by which means the aldehydes, including furfural, are held back, and the amount of these passing into the distillate considerably reduced. The effect of all these processes is to remove the harsh flavour of new spirits and impart the softer character of mature whiskey, thus accelerating the time when the spirit becomes ready for consumption as a beverage, but without necessarily imparting to it the true characteristic flavour of whiskey which has been matured by long storage.

The changes in the secondary products due to storage of whiskey in wooden casks and bottles are shown by Thorpe in Appendix Q, ix., x., xi. The results show that there is a well-marked increase in each of the secondary constituents during the first six months' storage. After 9–12 months the higher alcohols and furfural remain practically constant, and the increases in the other constituents were very slow. After about 18 months the differences were within the limits of experimental error. Practically no change occurs in spirits stored in glass bottles.

Crampton and Tolman (J. Amer. Chem. Soc. 1908, 30, 98) examined the spirit stored in casks by sampling annually for a period of 8 years, and found an increase in the higher alcohols due to the fact that the wood was less pervious to these than to ethyl alcohol and water. The other secondary constituents increased rapidly for 3 or 4 years, and then only very slowly. An increase of furfural was probably due to the charred wood of the interior of the casks. It

was found also that water passed through the wood of the cask more rapidly than the ethyl alcohol, thus giving rise to an *increase in strength*. This is unusual and was no doubt due to the exceptionally warm and strongly ventilated place of storage.

American whiskey. The United States Pharmacopœia prescribes the following requirements for whiskey. It should be at least 2 years old; its sp.gr. should lie between 0·930 and 0·970; its alcoholic content should be not less than 44 p.c., nor more than 55 p.c. by weight; its residue not more than 0·25 p.c.; the residue from 100 c.c., which should be neither sweet nor spicy, should dissolve in 10 c.c. of cold water, and this solution should be coloured only a pale green when treated with a drop of very dilute ferric chloride solution (a deeper colour would indicate more than traces of tannin). In evaporating the liquor on the water-bath for the residue, the last traces volatilised should have an agreeable odour free from harshness, indicative of the absence of fusel oil. Its reaction should be slightly acid, but not more than 1·2 c.c. of deci-normal alkali should be required to neutralise 100 c.c. of the liquor using phenolphthalein as indicator.

Rye whiskey is made in the United States and Canada from rye and malt only. *Bourbon whiskey* (so-called from Bourbon County, Kentucky, where it was originally made) is prepared from a mixture consisting of 50–60 p.c. maize, 10 p.c. malt, and the remainder rye.

The following table gives the results of analysis of Bourbon and rye whiskeys by Schidrowitz:—

Results of analyses of 188 samples of new and old Bourbon and rye whiskey examined in the laboratory of the United States Department of Agriculture (Wiley) are shown on next page.

Imitation whiskey is sometimes prepared from strong neutral or 'silent' spirit diluted to the proper strength and flavoured with certain essential oils or artificial fruit essences, as oil of wintergreen, œnanthic and pelargonic esters, and coloured with caramel. Prune juice is sometimes added to give 'body' to this mixture.

Fleischman quotes the following as a recipe for a low grade 'blended whiskey': spirits, 32 gallons; water, 16 gallons; caramel, 4 oz.; beading oil, 1 oz. 'Beading oil' (so-called from its use in producing an artificial bead on cheap liquors) is prepared by mixing 48 oz. of sweet oil of almonds with 8 oz. of commercial sulphuric acid, neutralising with ammonia, adding double the volume of proof spirit, and distilling the mixture (The Art of Blending and Compounding Liquors and Wines, New York, 1885).

Adulteration of whiskey. Under the Sale of Food and Drugs Act, whiskey (like brandy and rum) may not be sold below a strength of 25 p.c. under proof unless the fact of dilution is notified,

and the great majority of prosecutions under the Act for the adulteration of whiskey are on account of dilution with water below the legal limit of strength. For the method of calculating the degree of dilution, *see* art. Brandy.

Sometimes a neutral or 'silent' spirit made from substances other than grain (as potatos, beet-sugar residues, &c.) is mixed with sufficient genuine whiskey to give it a more or less whiskey character, and such adulteration is best detected by expert tasting ('degustation') combined with a determination of the secondary constituents and a comparison of the relations which they bear to each other.

Amongst the various substances alleged to have been used for the grosser forms of adulteration may be mentioned creosote, fusel oil, methylated spirit, sulphuric acid, and salt. Traces of copper, tin, and lead have been found as accidental impurities derived from the stills and other apparatus employed.

In consequence of representations made as to the deleterious character of the whiskey sold in public-houses in the poorer class districts of the larger towns in England, Scotland, and Ireland, and at fairs and markets, particularly in the west of Ireland, an investigation into the matter was made a few years ago by the Excise Authorities. Nearly 100 samples were taken from all parts of the United Kingdom and analysed in the Government Laboratory, but, apart from the fact that most of these consisted mainly of plain patent-still spirit, no evidence of the presence of the deleterious adulterants above referred to could be found.

The results of analyses (showing the maxima, minima, and averages) are summarised in the following table (Thorpe):—

	Volatile acid	Aldehydes	Esters	Higher alcohols	Furfural	Total
England (38 samples)—						
Maximum	25·1	22·5	127·9	310·5	1·9	370·7

Average	8·2	11·1	47·8	232·0	1·2	300·3

There is no legal definition of 'whiskey' in the United Kingdom, but numerous suggestions were made by witnesses before the Select Committee on British and Foreign Spirits in 1890–1, and the Royal Commission on Whiskey and other Potable Spirits in 1908–9, differing essentially in principle and depending chiefly upon the point of view of the witness.

The strictest definition suggested was that 'whiskey' should be manufactured in a pot still exclusively and from certain prescribed materials grown in the country, as malted barley alone in the case of 'Scotch' whiskey, and malted barley with unmalted grain (barley, wheat, oats, or rye) in the case of 'Irish' whiskey.

Others would admit patent-still spirit,

restricting, however, the materials to cereal grains (including maize), and the saccharifying agent to the diastase of malt, whilst in a few cases the extreme view was held that no restriction should be imposed either on the materials used or the process of distillation.

Since much of the barley used in both Scotland and Ireland is of *foreign* growth, the definition of Scotch and Irish whiskey cannot well exclude the use of foreign grain, and therefore maize (which came into use in 1846 immediately after the repeal of the Corn Laws) is not excluded in the manufacture of 'whiskey.'

With respect to the blending of patent-still spirit made from grain with pot-still spirit, it was held that since whiskey (consisting as it does of alcohol and water, with certain by-products derived from malt and grain) does not cease to be whiskey when diluted with water, so the addition of patent-still spirit, also made from grain, does not remove the mixture out of the category of 'whiskey.'

After full consideration of all the evidence the Royal Commission of 1908–9 arrived at the following conclusions and definitions:—

(1) That the term 'whiskey' having been recognised in the past as applicable to a potable spirit manufactured from (*a*) malt, or (*b*) malted and unmalted barley or other cereals, the application of the term 'whiskey' should not be denied to the product manufactured from such materials.

(2) That no restrictions should be placed upon the processes of, or apparatus used in, the distillation of any spirit to which the term 'whiskey' may be applied as a trade description.

(3) *Definition.* 'Whiskey' is a spirit obtained by distillation from a mash of cereal grains saccharified by the diastase of malt; that 'Scotch whiskey' is whiskey, as above defined, distilled in Scotland; and that 'Irish whiskey' is whiskey, as above defined, distilled in Ireland.

WIIKITE. A rare mineral consisting of tantalic and titanic acids, zirconia, silica, cerium, and yttrium earths, thoria, uranic oxide, ferrous oxide, &c., and of interest in containing scandium (Sc_2O_3, 1·17 p.c.) in relatively large amount. It is a black, brown, or yellow, amorphous mineral resembling euxenite or yttrotantalite in appearance, and has been found, together with monazite, in a felspar quarry at Impilaks, Lake Lagoda, Finland. It supplied the material for Crookes's work on scandium (Proc. Roy. Soc. 1908, A, 80, 516; Phil. Trans. 1908, A, 209, 15). Orthite from the same locality has also been found to contain 0·8–1·0 p.c. of scandia (R. J. Heyen, Sitz-Ber. Akad. Berlin, 1911, 379). More recently (Dec. 1911) a mineral containing scandium as an essential constituent has been described (*v.* THORTVEITITE).

L. J. S.

WILLEMITE. A mineral consisting of zinc orthosilicate Zn_2SiO_4, crystallising in the rhombohedral system (with parallel-faced hemihedrism). It is abundant at Franklin Furnace, and Sterling Hill in New Jersey, where it is mined, together with zincite and franklinite, as an ore of zinc (ZnO, 73 p.c.). At a few other localities it is of sparing occurrence. It varies considerably in colour, being yellowish, apple-green, flesh-red, &c.; the lustre is vitreous to resinous; sp.gr. 4·0–4·1. *Troostite* is a variety containing up to 10 p.c. of MnO replacing the zinc oxide. When struck with a hammer or when exposed to the emanations of a radium salt, the mineral displays a brilliant green phosphorescence.

WINE. Wine, strictly speaking, is the fermented juice of the fruit of *Vitis vinifera.* The term *British wines* is applied to beverages made after the manner of wine from substances other than the juice of fresh grapes.

The vine is cultivated for the manufacture of wine in the middle and south of Europe, the northern and southern extremities of Africa, some of the western parts of Asia, the islands of the Atlantic, portions of America—from the Potomac in the north to the centre of Mexico in the south—in California, and in Australia. The number of varieties is very large; but experience shows that the vines employed in particular districts should either be indigenous to those districts or be improved varieties of the indigenous strain. Thus, European vines when tried in America were but partially successful; whilst, on the other hand, American vines transplanted to the Gironde degenerated and yielded no potable wine. The vine grows on chalky, silicious, aluminous, and magnesian soil, best along the borders of rivers, and on ground which, though not itself soaked with water, can constantly attract it from the subsoil.

Vintage and vinification. The methods of procedure vary with the character of the wine —*i.e.* whether white or red wine is to be produced. The practice as regards the period of ripeness at which the grape is gathered varies considerably; thus, in the case of champagne, where the greatest attainable paleness is desired, the grapes are gathered before the point of fullest maturity, whereas the wines of Burgundy are vintaged when the grapes produce the deepest colour. Wines from imperfectly-ripened grapes require longer time to mature after manufacture, and, theoretically speaking, the grapes should hang until excessive dryness or danger of frost threatens; but other and conventional considerations, such as colour, have to be taken into account. In exceptional instances, as in the Sauterne district, those berries only are cut out of the bunch which have attained the desired point of ripeness; but the common practice is to gather all the grapes carried by the vines, the vintagers either separating immature and spoiled berries as they proceed, or carrying the whole bulk to a kind of specialist, who performs this part of the labour. Whichever course may be taken, the selected fruit is carried to the press house, and the question then arises whether the stalks are to be removed or pressed with the grapes. In the case of white wines the almost universal practice is to leave the grapes upon the stalks, for the reason that the resulting liquor is almost at once separated from the marc, and before the astringent principle of the stalks can be communicated to it, whereas red wines must be allowed to remain upon the marc for some time, and the stalks are removed. The commonest mode of separation is to cause the grapes to pass through a series of sieves, by which the stalks are retained. The grapes are now crushed, either by being trodden underfoot in vats or by being passed through machines furnished with grooved rollers, the one thing to be avoided in either case being the bruising of the seeds and stalks if these have not been removed. The next process is pressing. The machines employed for this purpose were formerly boxes, so made that the must was expelled through apertures by superincumbent pressure exerted by a screw; but latterly centrifugal machines have been employed, with a saving of labour and time. In white wines the must is separated as much as possible from the marc before pressing; whilst in the preparation of champagne the grapes are not crushed at all previous to being placed in the press. In the case of red wines the colour is obtained by allowing the juice from the crushing to ferment, after which it is stirred with the grape husks, whereby the requisite amount of colouring matter ('*œnolin*' or '*œnocyanin*') is dissolved. So much of the must as can be drawn off by taps is run off by that means, and the marc is pressed; the two portions of the must are then added together. The proportion of must depends upon whether the stalks are removed or not; in the former case it is about 95–97 p.c. of the whole, in the latter it may only be 70 p.c.

The following is a summary of analyses by König of a large number of musts of different origin :—

	Specific gravity	Water p.c.	Nitrogenous matter	Sugar	Acid	Other non-nitrogenous matter	Ash
Minimum .	1·0690	51·53	0·11	12·89	0·20	1·68	0·20
Maximum	1·2075	82·10	0·57	35·45	1·18	11·62	0·63
Average .	1·1024	74·49	0·28	19·71	0·64	4·48	0·40

Fermentation.—The natural fermentation of grape juice is due to the action of a yeast (*Saccharomyces Ellipsoideus*) existing on the skin of the grape. White wines are generally fermented at a temperature of 10° or 12° in barrels with only the bunghole open for the escape of carbon dioxide. Red wines are ordinarily fermented in vats open at the top, on account of the bulk caused by the retention of the husks and the necessity of stirring, an operation variously performed during or at the completed period of fermentation, according to the district. The higher the temperature the sooner the fermentation is finished; at low temperatures a moderate fermentation takes place, which becomes more violent as the liquid becomes warmer, and reaches a maximum at 27°. By the employment of high temperatures a must rich in sugar can be converted into a wine feebly alcoholic, sweet, and yet having tasting properties. Medium musts are best fermented at from 20° to 24°, and this temperature is reached when the fermentation begins at 15°. When fermentation is completed—*i.e.* after 10 to 14 days—the liquor has become clear, the yeast cells and other suspended matters are deposited at the bottom of the vessel, and the 'young' wine is racked off and allowed to rest for some weeks.

The young wine slowly loses its sugar by after-fermentation, and albuminous substances, colouring matters, together with the acid potassium tartrate, and calcium tartrate, separate out, forming a crust known as *argol* or *argal* (*q.v.*; also TARTARIC ACID). It is then racked again into clean casks (which are often 'sulphured' before use), fined, if necessary, with isinglass or white of egg, and occasionally with dried blood or with potassium ferrocyanide. When clear it is racked again and sometimes pasteurised before being bottled or stored in casks to mature.

Influence of the 'marc' on wine. By allowing the skins and stones of ripe grapes to remain in contact with the must, the resulting wine is said to improve in bouquet, &c., and is less liable to become stale and ropy. In order to redden wine with the skins of black grapes the temperature of the wine should be between 15° and 17°. Bad grapes impart to white and red wines a brown colour. Such wines soon become turbid. Bad grapes and mildewed skins, as well as bad casks and puncheons, precipitate the red colouring matter, so that the wine becomes pale. The following are some of the cases in which the treatment of wine with 'marc' has been successful:—Wine which is muddy and cannot be clarified by the ordinary fining agents; wine in which a fining agent has been used which failed to sink to the bottom; wine which has become weak and flat; wine which is assuming or has assumed a black colour; wine having a barrel taste or a by-taste; wine which is 'corked'; wine remaining after casking off; and wine which is obtained by pressing the lees. In cases where the fermentation of new wine has been checked suddenly, the addition of marc prevents the separation of yeast (J. Nessler, Chem. Zentr. 1882, 265; Chem. Soc. Abstr. 1882, 1014).

Composition. Wine contains alcohols, glycerol, acids, salts, extractive matter, and those principles which give to it its particular colour, special flavour, smell, or bloom (*bouquet, Blume*). Whilst some of the constituents can be accurately isolated and described, others can only be detected by the smell.

The principal alcohol is ethyl alcohol. In rare instances some butyl alcohol, and in others amyl alcohol, together with ethylene glycol and *iso*butyl glycol (Henniger) are present. The quantity of alcohol in natural wines from grapes varies from 6 to 12 p.c. by weight, or from 13 to 26 p.c. proof spirit, but these limits are extended in exceptional cases. The quantity of glycerol is usually from 7 to 14 p.c., of the alcohol present.

The principal acids present are tartaric, malic, and tannic acids, due to the original grape juice, and carbonic, formic, acetic, and succinic acids, as products of fermentation.

These greatly aid in the preservation of the wine by preventing the formation of fungi. Traces of propionic, butyric, and œnanthic acids also occur in wine, together with acetaldehyde and possibly some of its homologues. Salicylic and boric acids have also been found as natural constituents of wine. As regards the origin of the fixed vegetable acids of wine, H. Brunner points out (Chem. Zentr. 1877, 4) that malic, succinic, glycollic, and oxalic acids—which are found in unripe grapes, together with tartaric acid—may either be formed by direct building up of the molecules in the plant, or their formation may be partly direct and partly indirect.

It can be demonstrated in the laboratory that the first reduction products of carbonic acid are formic and oxalic acids, and that, from the latter, we can (by the action of hydrogen) pass successively through glyoxylic, tartaric, and malic, to succinic acid, and all these acids have been found in the grape in its various stages of growth. The principal reactions may be represented as follows :—

$$2CH_2O_3+H_2=C_2H_2O_4+2H_2O;$$

Carbonic acid. Oxalic acid.

$$C_2H_2O_4+H_2=C_2H_2O_3+H_2O;$$

Glyoxylic acid.

$$2C_2H_2O_3+H_2=C_4H_6O_6;$$

Tartaric acid.

$$C_4H_6O_6+H_2=C_4H_6O_5+H_2O;$$

Malic acid.

$$C_4H_6O_5+H_2=C_4H_6O_4+H_2O.$$

Succinic acid.

Tartaric acid occurs mainly as the dextro-variety; lævo-tartaric acid is only of comparatively infrequent occurrence. If tartaric acid is not found—as, for example, in certain samples of sherry—its absence is probably due to its removal by 'plastering,' to which reference is made later on. The amount of free acid in sound wine, reckoned as tartaric acid, varies between 0·3 and 0·7 p.c. (inclusive of volatile acid, which should not exceed 0·15 p.c.); a greater amount than this imparts sourness to the wine.

The characteristic smell of wine is said to be due to œnanthic and other esters. These esters probably confer the bouquets which distinguish one vintage from another. Among them are acetopropyl, butyl, amyl, capryl, butyro-ethyl, caprylo-ethyl, capro-ethyl and pelargo-ethyl, and the tartaric esters.

According to Jacquemin (Compt. rend. 110, 1140), the characteristic bouquets of wines are due to the special characters of the yeast used in each district. One and the same must fermented with the yeast obtained from several different districts gave wines having the bouquet characteristic of the district from which the particular yeast had come.

Babo states that the bouquet of the wine from Riesling grapes is produced by the action of frost; wines from other grapes also possess a like bouquet if the grapes are frozen. Rommer (Bull. Soc. chim. [iii.] 2, 297) fermented the juice of an inferior grape and of hot-house grapes respectively with yeast cultures obtained from the Champagne, Côte d'Or, and Baxy districts, and found that in each case the wines had the bouquet of those from which the yeast has been derived. Certain of the odoriferous principles are no doubt in the nature of essential oils, which have not hitherto been isolated owing to their small amount and extremely unstable character under the influence of heat and air. In order to retain the bouquet, wines should be bottled as soon as they have attained their maximum bouquet.

According to Berthelot, the amount of the esters in wine is, after a certain time, a constant quantity independent of the nature of the alcohols and acids, but a function only of their relative amount: If A be the percentage weight of alcohol in the mixture, a the amount of alcohol equivalent to the total free acid contained in one litre of wine, on the assumption that it is acetic acid (46 alcohol=60 acetic acid), y the proportion p.c. of a present as ester in one litre of wine when the alcoholic strength of the wine is A, and x be the amount of alcohol present in the compound ethers of one litre of wine; then

$$y=1{\cdot}17A+2{\cdot}8$$
$$x=\frac{y\times a}{100}$$

The alcohols other than ethyl alcohol present are left out of the account, but as they are insignificant in amount the error is trifling. This formula affords a mode of judging of the age and genuineness of wines, except in the case of very young wines, or wines which have been recently fortified, the esters in these cases being less than that required by the formula. The maximum esterification is reached in from 4 to 6 years. The alcohol obtained by the decomposition of all the esters rarely exceeds 0·06 p.c. of the wine. (For Thudichum and Dupré's method, *v. l.c.* 203.)

Sugar in wine. The sugars occurring in must and in wine are dextrose and lævulose. Cane sugar is never naturally present in must, but it is sometimes added, as in the case of champagne, but even then it is rapidly transformed into invert sugar. Glycerol is formed as a by-product of the growth of yeast during the process of fermentation, and is accompanied (amongst other changes) by the decomposition of sugar. For every 100 parts of sugar which disappear, from 3 to 4 parts of glycerol are produced. After complete fermentation the sugar seldom reaches 0·5 p.c., but when fermentation is arrested by the addition of alcohol, as in the liqueur wines of France and Spain made from dried grapes, and the sweet wines of Hungary, the sugar may be as much as 20 p.c. or more. In some wines—as *e.g.* Sauternes and sweet Rhine wines—sugar occurs in the form of inositol.

The colouring matters in wine are due to two sources. In white wines—which range from an almost colourless liquid, as champagne, to the deep yellow sherry—the colour is derived from the oxidation of the so-called extractives contained in the juice, which, as was before explained, is separated from the husks as quickly as possible. The grapes of some of the best red wines yield an almost colourless juice if pressed before fermentation, and it is only by the joint action of alcohol and acid upon the husks, stalks, and seeds during fermentation, that the red colour is extracted from the marc. Mulder separated the colouring matter contained in red wines by means of lead acetate, and found it to consist of a substance which was bluish-black in colour and amorphous in structure. It is only sparingly soluble in alcohol, insoluble in water, ether, chloroform, carbon disulphide, oil of turpentine, oil of olives; but soluble in solution of tartaric acid or cream of tartar, and in alcohol containing a trace of acetic acid, the saturated solution showing a blue colour; more acetic acid turns the solution red. It is soluble also in alcohol containing tartaric acid, exhibiting a red colour, but neither of these acids renders it soluble in ether or chloroform. The colour of wine, consequently, depends both upon the amount of colouring matter and the amount of free acid contained in it, as the violet colour becomes redder in proportion to the quantity of free acid acting upon the blue colouring matter.

The colouring matter precipitated by hydrochloric acid—in which it is deposited slowly at the ordinary temperature, but more rapidly on boiling—has been examined by Terreil (Bull. Soc. chim. [ii.] 44, 2). The precipitate always contains a substance resembling ulmic acid, from which the colouring principle may be dissolved out by alcohol. Thus obtained it forms brittle varnish-like scales, insoluble in water and ether, but readily soluble in alcohol, forming a brownish-red solution with a slightly yellow tinge. Acids change this colour to an intense red, while alkalis give a green colouration, which changes rapidly to a brownish-yellow on exposure to the air (*cf.* O. Griessmayer, Dingl. poly. J. 123, 531; Chem. Soc. Trans. 1887, 368).

The colouring matter of red wines (*œnolin* or *œnocyanin*) may be estimated with sufficient accuracy for technical purposes by the method of Cari Mantrand (Bull. Soc. chim. 1906, [iii.] 35, 1017), by precipitating with lead acetate, decomposing the precipitate with sulphuric acid, filtering, and weighing the residue from an evaporated portion of the filtrate. The œnocyanin may be concentrated and preserved in glycerol for use in confectionery, &c. The maximum amount found was 17·2 grms. per litre in Algerian wine.

Some additional colour is imparted to white wine by the tannin extracted from the oak casks during maturing. On the other hand, the natural colouring matter of red wine is reduced by the operation of fining as well as on ageing.

Caramel is frequently used to colour white wines (*e.g.* brown sherry), and occasionally boiled must is added either to the juice before fermentation or to the finished wine. (For foreign colouring matters, *see* below.)

Tannin is derived from the grape skins and stalks, the juice itself being practically free. It is sometimes added, however, to champagne and other white wines to prevent 'scuddiness' or turbidity. The natural tannin of grapes is decomposed by acids or by fermentation into glucose and an acid which is not gallic acid.

The *albuminous substances* in the grape, which set up the ferment, ought by that action to be removed in the yeast when the fermentation is properly carried out, and should not exceed 4 parts per 1000 of wine, unless the latter has been 'fined.' The albuminous matter is also reduced by 'plastering,' and in *old* wines it is thrown out together with tannin and colouring matter. In imperfectly fermented wines a certain amount remains, and, in the case of white wines, may again render them liable to fresh fermentation. In red wines this danger is obviated by the presence of the tannin of the husks, which preserves the albuminous matter from change.

The small quantity of *ammonia* which is present in grape juice, or is formed during fermentation out of albuminous substances, is, for the most part, precipitated during fermentation as magnesium-ammonium phosphate; a small amount, however, remains, and in some wines is accompanied by minute traces of trimethylamine.

Under the term '*extractives*,' some chemists include all matters other than water, alcohol, and volatile acids; others only those substances which are not volatile up to 100° or 110°. The latter would, however, exclude glycerol, which is properly included amongst the extractives. The composition of certain constituents of the extract which contribute to the smell and taste of the wine is still very obscure. The extractives are, of course, abnormally increased by plastering and addition of sugar (*v. infra*).

The *mineral constituents* of wine, as found in the ash, are potash, soda, and lime as phosphates, chlorides, carbonates, and sulphates, traces of iron, magnesia, and silica, and occasionally alumina, lithia, and manganese. In pure natural wines the ash rarely exceeds 0·3 p.c., but may be much higher in wines which have been plastered, or to which alkalis have been added to reduce their acidity.

As regards the amount of *alcohol*, a very comprehensive set of tables, embracing the results of the examination of 133 wines, is given by Thudichum and Dupré (Treatise on the Origin, Nature, and Varieties of Wine, 128–304), from which the following *resumé* is compiled:—

	Strength of wines in degree of proof spirit
German wines, 35 samples . .	16·2–26·3
French wines, 22 samples . .	18·0–37·2
Spanish wines, 22 samples . .	26·7–41·7
Sicilian wines, 6 samples . .	33·5–36·3
Portuguese wines, 14 samples . .	21·9–42·5
Hungarian wines, 10 samples . .	19·2–26·4
Greek wines, 8 samples . . .	17·8–32 1
Cape wines, 7 samples . . .	36·1–51·7
Atlantic Islands, 3 samples . .	38·2–39·1
Elba wines, 1 sample . . .	34·9
Australian wines, 5 samples . .	23·5–40·1

Sugar solution wines. Musts which are too thin, and deficient in sugar, are sometimes concentrated by evaporation (as in Portugal) or, more frequently, a solution of sugar is added. The latter process was first sanctioned by the French minister, Chaptal, and is known as 'Chaptalising.' A similar process (applied chiefly to acid musts), and known as 'Gallising,' from its inventor Gall, is also practised in Germany. The must of bad years, which contains a deficiency of sugar and an excess of acid, is mixed with sugar, preferably cane sugar, so as to bring the amount of sugar in the liquid to about 20 p.c., and to reduce the amount of acid to about 2 p.c. Frequently, however, commercial glucose is used, and its addition can frequently be detected in the finished product by its dextrorotatory polarisation.

The acidity of natural wine can also be

reduced, as suggested by Liebig, by the addition of neutral potassium tartrate, which throws down the free acid, if present as tartaric acid, as acid potassium tartrate. Wine deficient in alcohol and containing much acid may often be improved by adding to it the pressed residue of a succeeding vintage (*cf.* J. Nessler, Bied. Zentr. 1884).

A considerable quantity of wine is now made by covering the marc with an aqueous solution of sugar, and allowing the mixture to ferment. The sugar solution contains 18 grms. per litre for every degree of alcohol which it is desired to obtain, and 250 grms. of marc are used for each litre of solution. Analyses of wines prepared in this way by Girard, and of other samples found in commerce, prove that these wines have an approximately definite composition. When they contain from 9 to 10 degrees of alcohol, the proportion of soluble matter, cream of tartar, tannin, and colouring matter is much less than in the ordinary vintage wines. The amount of solid matter varies from 14 to 18 grms. per litre; the amount of cream of tartar is about 2 grms., but not less than 1·6 grm. per litre; whilst the proportion of tannin and colouring matter varies considerably with the nature of the marc. Girard concludes that those wines constitute a highly useful beverage, and can be produced at a very low cost (A. Girard, Compt. rend. 95, 227; Chem. Soc. Abstr. 1882, 1335).

Plastering of wine. The practice of adding gypsum or plaster of Paris to must, either before or after fermentation, which prevails in Spain, Portugal, and the South of France, is said to have for its object the reduction of the amount of the water in the juice, and the production, consequently, of a must relatively richer in sugar. The fermentation is much more rapid and complete, and it is alleged that the wine keeps longer when it has been plastered, and that the colour is richer and more lasting. This explanation leaves something to be desired, because the sacrifice of other constituents of juice than water by the absorption of plaster is entirely out of proportion to any gain by the absorption of the water, and the result desired could be attained either by the addition of sugar or the evaporation or freezing out of water. It is probable that the reason for the practice, although unknown to those who employ it, is that gypsum precipitates some albuminous matters which injuriously affect the wine. An obvious advantage to the wine-maker is that it clarifies the wine rapidly and so enables it to be brought sooner to market.

The plaster of Paris, in the form of powder, is either thrown upon the grapes before they are crushed, or added to the must after fermentation has commenced, or even to the finished wine, and the chemical changes that take place vary accordingly. The quantity used is generally from 1 to 2 kilos. to every 100 kilos. of fruit, although sometimes it reaches as much as 10 kilos.

According to Griessmayer, when gypsum is added to the must, it forms, with the tartar present, neutral calcium sulphate and free tartaric acid, which latter reacts on the sulphate, forming bitartrate and acid calcium sulphate. The ash of such wine is neutral, and does not give off carbon dioxide when treated with hydrochloric acid. When gypsum is added to the finished wine, the alcohol prevents its solution, but it carries down many impurities. Kayser (Bied. Zentr. 1881, 632) made experiments which confirmed these conclusions, and states that from the proportions of the ash to the extractive matter, it is possible to declare with certainty whether the wine has been plastered as must or as finished wine; in the first case the ash is disproportionately high, in the other it remains normal. Kayser also states that by the interaction of $KHSO_4$ and KH_2PO_4, free phosphoric acid is formed together with neutral potassium sulphate, the former producing the bright colour of plastered red wines. The main change, however, appears to be a decrease in the tartrates and an increase in the proportion of potash and sulphates.

The injurious effects attributed to plastered wines have been the subject of investigation by several commissions appointed by various foreign governments. The most exhaustive inquiry yet made on the hygienic aspect of the subject was by a commission appointed by the French War Department owing to complaints made by the French army in Algeria, where many cases of illness were said to be due to the use of plastered wines. The symptoms are said to be colic, and slight vomiting. The acid potassium tartrate acts towards many reagents in the same manner as free sulphuric acid, and when introduced into the system may have the effect of reducing the alkalinity of the blood.

In view of the inconclusive nature of the evidence, the Commission recommended the maintenance of the regulation forbidding the sale of wines containing more sulphate than that corresponding with 2 grms. of potassium sulphate in the litre, and this limit has been also adopted in Germany, Switzerland, and other countries.

The attempts to '*de-plaster*' wine are, from a hygienic point of view, more injurious than the plastering, owing to the use of poisonous barium and strontium salts.

Wine is liable to be affected by a number of injurious ferments, and is especially subject to acetous fermentation, due to ***Mycoderma aceti***, which principally attacks the alcohol with production of acetic acid, whilst ***Mycoderma vini*** attacks principally the cream of tartar and extractive matters. The action of foreign ferments may frequently be prevented by the process devised by Pasteur, which consists in heating the wine for some time to about 70° in absence of air. The bouquet, and in some cases the colour, is thus found to be improved. The heating must be quickly performed, and, as far as possible, out of contact with air.

Numerous substances are employed for the preservation of wine by chemical means as *abrastol* or *asaprol* (the calcium salt of β-naphthol sulphonic acid), *benzoic*, *boric*, and *cinnamic* acids, *fluorides*, *formaldehyde*, *saccharin*, *salicylic acid*, *sulphurous acid*, and *sulphites*. It should be noted that of these, boric acid, fluorine, and salicylic acid may be present in minute quantities as natural constituents of the wine (*v. infra*).

Manufacture of 'sparkling' wines. The effervescence of a sparkling wine is due to the presence of carbonic acid, produced by the fermentation of added sugar. The chief wines of this class (champagne) are produced in the departments of Marne and Haute Marne, and in the vicinity of the Moselle and the Rhine. Both white and red grapes are used, and the wine is amber in colour, the depth of tint depending on the vintage and the proportion of dark grapes employed. The vintage is in the early part of October, and in the pressing the must is separated into two portions, that first produced being of the higher quality. The young wine is allowed to ferment until the winter, when it is racked, and after the expiration of a month the operation is repeated, when the wine is fined. It is then mixed with a certain proportion of old wine, and the amount present determined. If necessary, a quantity of cane sugar is added, and the wine is bottled, the bottles being placed horizontally in piles and left at rest throughout the summer. Carbonic acid is formed, together with a quantity of sediment. The pressure of the gas in the bottles can readily be ascertained, when desired, by means of a manometer (such as Salleron's modification of Maumené's 'Aphrometre'), and ranges from 5 atmospheres in *grand mousseux* to less than 4½ in *crémant* wine; in ordinary mousseux wine the pressure varies between 4 and 4½ atmospheres. When required for the market, the bottles are first carefully brought into an inclined position, so as to cause the sedimentary matter to fall gradually on to the cork; on removing the clip which holds the cork within the neck the pressure of the dissolved gas forces out the cork, together with the sediment. A certain amount (from 1 to 4 p.c., depending upon the sweetness desired) of liqueur, made of fine wine, sugar, and cognac or a still spirit, is quickly added, and the bottles are again filled up, corked, and wired.

Dry champagnes—*i.e.* containing relatively little sugar—are mainly exported to this country, the sweeter varieties being usually consumed in America and on the Continent.

Wines of France. The chief wine-growing district in France is the Gironde, which is practically divided into five portions, viz., the Médoc, the Graves, the Côtes, the Palus, and the Entre-deux-Mers. In the Médoc some six or seven different varieties of vine are cultivated.

Most of the *red wine* is obtained from the Carbenet Sauvignon, Franc Carbenet, Malbec, and Merlot grapes. The vintage usually begins towards the end of September, and lasts about a fortnight. The wines (usually known as 'clarets') are divided into *paysan, artisan, bourgeois,* and *fine growths,* the last group being further sub-divided into what are known as 'crus' or 'classed growths,' named after the place (Château or Commune) where they are produced; *e.g. Château Latour, Pauillac*; *Château Lagrange, St. Julien*; *Château Margaux*; *Château Cantenac,* &c.

The chief *white wine* producing district is to the south of Bordeaux. The principal vines are the Semillon, Sauvignon, and Muscatelle. The vintage is much later than in the Médoc—viz. in the last weeks of October or early part of November, when the grapes have entirely ripened. Three qualities of must are produced: the first and ripest juice yields a sweet luscious wine (*vin de tête*), mainly consumed in Russia; the second forms *vin de milieu,* the wine usually known as *Sauterne*; the third quality, or *queue,* yields a dry white wine. The principal varieties are *Barsac, Sauterne, Graves,* and *Bommes, Château Latour-blanche,* and *Château Y'quem.*

The department of the Pyrénées Orientales produces a considerable quantity of wine, mostly from the Grenache noir and Carignane grapes. The generic name of the wine of the district is *Roussillon,* of which the most esteemed varieties are muscat of *Rivesaltes, Maccabeo, Malvoisie,* and *Grenache,* which are liqueur wines (the last-mentioned being simply unfermented must preserved by means of added spirit and sulphurous acid, with frequent racking from deposits); and *Rancios,* dry *Malvoisie,* and *Picfoule.* Languedoc also produces a large quantity of wine (*vins du Midi*), much of which is mixed with the wines of the Gironde and of Burgundy; whilst a considerable amount of the rest is distilled to make 'trois-six' and *eau de vie.* Cognac is produced from the wines of the Charente district (*v.* Brandy).

The Rhône and Saône valleys produce the chief wines of the east of France, which, with the exception of *Hermitage* and the wines of the *Beaujolais,* seldom occur in trade under their own names.

The best qualities of *champagne* (*v. supra, Sparkling wines*) are produced in the departments of Marne and Haute-Marne, the chief centres of the trade being at Rheims, Épernay, Aÿ, Avize, Châlons, and Dizy. The most famous brands are *Ayala, Cliquot, Heidsieck, Irroy, Moët, Mumm, Perrier Jouët, Pommery-Greno, Roederer,* and *St. Marceaux.* Large quantities of sparkling wine are produced in the Saumur, in the department of Maine-et-Loire. Sparkling *Saumur* is made from both black and white grapes—the black being the product of the Breton vine, the white that of the Pineau blanc. The wine is made much in the same way as champagne, except that, as a rule, the finished product is a mixture of two successive vintages.

The wines of *Burgundy* (both red and white) are produced in the departments of Côte-d'Or, Yonne, and Saône-et-Loire. The principal *red* wines are *Mâcon, Beaune, Le Corton, Romanée Conti, Chambertin* and *Clos Vougeot. Hermitage,* when it can be obtained genuine, is a rich wine with purple colour, produced in the department of Drôme. The *white* wine of Yonne is known as *Chablis.*

Spain. *Sherry,* the best known of Spanish white wines, is mainly produced in Andalusia, and derives its name from Jerez or Xeres de la Frontera, the chief centre of the trade, and where most of the wine is produced from must or fruit purchased from the growers. Sherries are usually broadly classed as *Amontillados* and *Manzanillas.* The former are usually deeper in colour and more alcoholic from added spirit; the latter are lighter and drier, and are, as a rule, shipped unbrandied. *Montilla* produced in the province of Cordova somewhat resembles Manzanilla. Sherries are almost invariably fortified and plastered, and the commoner kinds sulphured in addition, for the British market. The sweet red wine known as '*tent*,' which is used for ecclesiastical purposes, is mainly obtained from the Rota district. This and the somewhat similar wines from the Tarragona, Valencia, and

Alicante districts are frequently sold under the name of 'Spanish port.'

Portugal. Port is mainly the produce of the rugged and mountainous district of the Alto Douro in the north-east of Portugal. The vintage usually begins at the end of September. The grapes, from which the stalks are removed, are emptied into stone tanks holding from seven to thirty pipes, and are pressed, first by treading and then by means of a beam or screw press. After from 48 to 60 hours' treading the must is left to ferment, drawn off into vats, and mixed with a sufficient quantity of alcohol to prevent acetous fermentation. After the lees are deposited the wine is again racked and mixed with more alcohol, which is usually obtained by distilling wine. If necessary, the wine is sweetened with 'jeropica,' or sweet must preserved with brandy. In the spring it is sent down to Oporto, where it is stored previous to shipment. 'Vintage wines' are those of the same origin, year, and quality, and are kept separately, whilst 'factory ports,' which constitute the bulk of the wine exported are a mixture of wines of different year and origin. Nearly half the wine exported from Oporto is sent to the United Kingdom.

Port first appeared in England at about the end of the seventeenth century, and its consumption in this country gradually increased up to the middle of the eighteenth century, since when it has gradually declined.

The South of Portugal (Torres Vedras and Collares) produces a considerable quantity of a rough kind of claret, and also a white wine known in England as Bucellas Hock, which is obtained from the Riesling grape.

Italy. It is only within recent years that Italian wines have found much favour in this country. Northern Italy produces *Montferrat* and *Asti*, together with a certain amount of sparkling wine. *Montepulciano* and *Chianti* are made in Central Italy; whilst the Neapolitan district yields *Lacryma Christi* and a variety of Malvoisie and good class Muscat wines.

Sicily. The chief Sicilian wine is Marsala (a white wine of light amber or brown colour, somewhat resembling sherry), obtained from a mixture of selected and thoroughly ripe grapes of the Madeira variety. It is carefully manufactured and is very uniform in quality, although, as a rule, somewhat heavily fortified, but not plastered.

Austro-Hungary. Both white and red wines are made, but those of German Austria are consumed for the most part locally. The best known are from Vöslau and Gumpolds-Kirchen, and the Tyrol. The most famous of Hungarian wines is the Sweet Tokay or Essentia, which is made from the first runnings of the ripe grapes obtained without pressure. Only a small portion is so obtained, and it rarely, if ever, appears in the market. Other varieties of Tokay are known as *Ausbruch* and *Mástás*. *Carlowitz* resembles port in character, and is produced on the banks of the Danube, about 40 miles to the north-west of Belgrade.

Excellent red wines, resembling Burgundy, are now made in Dalmatia. The most esteemed varieties are *Moscato Roso*, *Maraschino*, and *Malvasia*.

Germany. The chief wine-producing districts of Germany are Alsace-Lorraine, Baden, Bavaria, Hesse, the Rheingau, and Wurtemberg. The celebrated *Steinberg*, *Johannisberg*, *Rüdesheim*, *Gräfenberg*, and *Rauenthal* wines are produced in the neighbourhood of the Rhine, not far from Mainz, which is the centre of the hock trade. The vineyards of Hesse yield *Liebfraumilch*, *Nierstein*, and *Scharlachberg*; *Hochheimer* is obtained from the Maingau. The chief Rhine vine is the Riesling, which is said to be indigenous, and which has been transplanted and successfully cultivated in many other parts of the world as South Africa, Australia, and the United States of America. The *Moselle* district also produces excellent wines of characteristic but rather weak flavour, which is often artificially enhanced by the addition of tincture of elder flowers.

The chief product is a white wine. A certain amount of red wine is obtained, notably Assmannshausen, from Riesling and mixed grapes. The results of analyses by König of wines from the principal European countries are shown in the table on next page.

The Atlantic Isles. Grand Canary and Teneriffe produce a small quantity of wine, but since the production of cochineal has fallen off on account of the preference for coal-tar colouring matters, vine culture is increasing, and wines of the Madeira type are being made in larger quantity.

Madeira. The best-known varieties of Madeira wine are *Malmsey*, *Sercial*, *Bual*, and *Tinta*. It is a white wine, usually dry (*i.e.* free from sugar), and its characteristic flavour is probably due to the practice of heating the wine shortly after its manufacture to a temperature varying from 25° to 45°. Formerly the same condition was obtained by sending the wine a voyage to the East or West Indies and back. Very little red wine is made in Madeira.

A small quantity of wine is made in the Azores, particularly on Pico, but it is of very indifferent quality, and is mainly exported as low-class sherry.

Cape of Good Hope. Comparatively little wine is now sent to this country from South Africa, although a century ago the importation of Cape wine into the United Kingdom exceeded that from France. The decline is due to vine diseases and insect pests, to faulty manufacture, and to fiscal changes. The best-known wines are *Drakenstein* or *Cape Hock* from **Paarl**; the sweet pale-red *Constantias* produced near Cape Town; and *Hermitage*, a red wine of Burgundy charcter.

Australia. Of late years the amount of wine from Victoria, New South Wales, and South Australia imported into this country has increased enormously. The industry may be said to be still in its infancy, but the most scientific methods and appliances are adopted, and the produce of such vineyards as Albury, Great Western, Highercombe, and Tintara bids fair to rival the best European wines of similar type.

United States. The manufacture of wine is now firmly established in California. The produce was originally derived from the 'Mission' grape, supposed to have been imported from Mexico by Franciscan monks, but German, French, and Spanish varieties have now been introduced, and wines in some degree resembling

those of these countries (and named after their original types) are now made on a considerable scale. The vine is also cultivated on a large scale in Ohio, and clarets and champagnes are made in the vicinity of Cleveland and Sandusky. Other wine-producing States are New York, Missouri, Illinois, and Pennsylvania. Whilst the finer wines consumed in the United States are still obtained from France and Germany, the importation of foreign wines is steadily decreasing in favour of the home product.

The following are analyses, by Bigelow (U.S. Dept. of Agric. Bur. of Chem. Bull. 59), of 525 samples of wines manufactured in California:—

ANALYSIS OF WINE.

The chemical examination of wine is usually restricted to the determination of those constituents which enable an opinion to be formed concerning its purity or freedom from adulteration, but expert tasting is of great importance, and microscopical examination of the deposits obtained from wine may afford useful information.

For the estimation of the *specific gravity* a determination should be made by the bottle or other form of pyknometer and given accurately to four decimal places. Carbonic acid should first be removed by vigorous agitation.

The *results* are usually given in grms. per 100 c.c. or per litre. Koenig (Zeitsch. anal. Chem. 28, 202), however, deprecates this practice, on the ground that for sweet wines, which are liable to differ widely in sp.gr., the results are no longer directly comparable.

The *alcohol* is best determined by the distillation method, the sp.gr. of the weighed distillate being taken and the proportion of alcohol found from tables. For more exact determinations, the volatile acids should be neutralised before distillation.

Determination of extract. The various methods in use for determining extractive matter in wine differ considerably both in principle and in the details of manipulation. The direct method (by evaporation) does not give comparable results unless the sugar of sweet wines and the potassium sulphate in plastered wines are deducted, and not then unless the estimation is conducted under exactly similar conditions.

The French official method of prolonged heating on a water-bath gives low results, owing chiefly to loss of glycerol. The sugar and potassium sulphate are deducted, an allowance of 1 grm. of each per litre being made to cover the amount of these substances assumed to be naturally present in fully fermented wine. The result is known as the 'reduced extract.'

The most exact determination of extract is made by evaporation (at the ordinary temperature) over sulphuric acid *in vacuó*, but as this requires from 3 to 6 days (according to the temperature) it is unsuitable for ordinary commercial use.

The German official method is as follows :—

(*a*) For wines with an extract amounting to not more than 3 grms. per 100 c.c. (ascertained by the indirect method (*c*) given below): 50 c.c., measured at 15°, are evaporated to a syrupy consistency on the water-bath in a platinum basin of 85 mm. diameter, 20 mm. height, and 75 c.c. capacity, and the residue is dried for 2½ hours in the water oven.

(*b*) For wines containing from 3 to 4 grms. of extract per 100 c.c. an amount yielding from 1 to 1·5 grm. of residue is taken. For the necessity of using dishes of similar area and surface in order to obtain comparable results, *v.* Bouilhon (Compt. rend. 103, 498).

(*c*) For sweet wines, or those containing over 4 grms. of extract per 100 c.c., the indirect method of determining the extract from the sp.gr. of the wine after removal of the alcohol is to be preferred (*v.* Tables in Windisch, Die Chemische Untersuchung und Beurtheilung des Weines, 338; abstracted, J. Soc. Chem. Ind. 1898, 280).

The amount both of extract and of alcohol may be determined by Riegler's refractometer method (Zeitsch. anal. Chem. 1896, 27). One grm. of alcohol and of extract in 100 c.c. of wine are found to raise the refraction by 0·00068 and 0·00145 respectively above that of water. Then if a=the refraction of pure distilled water; $(a+b)$=the refraction of the wine from which the alcohol has been removed made up to the original volume taken; and N=the refraction of the original wine; then the formula $\frac{N-(a+b)}{0{\cdot}00068}$ gives the weight of alcohol, and $\frac{b}{0{\cdot}00145}$ that of the extract as grams per 100 c.c. of the wine.

In completely fermented wines the amount of extract is seldom less than 14 grms. per litre. Wines containing less than this amount after removal of the sugar may be suspected of dilution.

After separation of the non-volatile acids, the remaining extract in natural wine is seldom less than 11 grms. per litre, and after separation of the free acids, as a rule, not less than 10 grms. per litre. The mineral constituents are usually about 10 p.c. of the extract.

The *free acid* is determined by titration with standard potash or soda-solution, using litmus-paper as indicator, and calculating the result as tartaric acid ($C_4H_6O_6$). Carbonic acid should first be expelled, either by heating just below boiling-point (but rapidly so as to avoid loss of acetic acid), or by agitation and subsequent titration in the cold. *Volatile acids* are determined by distillation in steam, or, since this partially volatilises lactic acid (Windisch, Zeitsch. Nahr. Genussm. 1905, 9, 70), by the difference in the acidity of the wine before and after evaporation to a small bulk, and are expressed as acetic acid ($C_2H_4O_2$). The *fixed acids* are estimated by difference between the total and volatile acids, or by direct titration of the extract obtained by evaporation *in vacuô*, and are expressed as tartaric acid. In France the acidity is usually given in terms of sulphuric acid (H_2SO_4).

Old wines have an acid reaction, in consequence of the presence of a certain amount of free acid and potassum hydrogen tartrate. A wine not exhibiting this acid reaction tastes flat. For a long time it was believed that the free acid of wine is tartaric acid alone. Nessler's researches have, however, shown that this is seldom the case. Tartaric and malic acids often exist together, and more frequently the free acids consist of malic acid entirely. Wines containing tartaric acid alone taste more tart than those with only malic acid, or a mixture of malic and tartaric acids.

The presence of free tartaric acid in wine does not necessarily show an improper admixture of tartaric acid with the wine. According to Mach and Rolondi, the amount of free tartaric acid in the grape increases in proportion to the degree of unripeness, so that its absence from wine can only occur under certain conditions of ripeness of the grapes employed. Although unripe grapes are frequently used in considerable quantity in wine-making, yet if the ripe grapes are in excess, the potash salts in them are more than sufficient to separate the free tartaric acid in the form of tartar, and this explains the fact that wine so made generally contains no free tartaric acid. A wine may be suspected of having been sophisticated if, with a small amount of free acid, an undue proportion of it is tartaric (J. Nessler and H. Wachter, Bied. Zentr. 1880; Chem. Soc. Abstr. 1880, 775).

The estimation of *total tartaric acid, free tartaric acid, potassium bi-tartrate,* and *tartrates of the alkaline earths* (lime and magnesia) is best made by the methods of Halenke and Möslinger, and of Barth (Zeitsch. anal. Chem. 1895, 279–290). These methods were officially adopted by a German Imperial Decree of 1896, an abstract of which is given in the J. Soc. Chem. Ind. 1898, 277. Certain modifications were introduced by Kulisch in 1901. Full details of these, as well as the French official methods, will be found in Post and Neumann's Traité complet d'analyse chimique appliquée aux essais industrielle, 1910, tome ii. 661. The last three estimations are necessarily empirical, being founded on the assumption that all the bases present in the organic salts of the wine, or as carbonates in the ash, were originally combined with tartaric acid to form bi-tartrates.

Numerous methods have been suggested for the estimation of *malic* and *succinic* acids, but they are too uncertain and inexact to be of much value for analytical purposes. The methods for *lactic* and *citric* acids are more reliable, and the estimation of these is more important, since the former is a constant constituent of wines, and is often the cause of their excessive acidity, whilst the latter is rarely present in genuine wines, except in slight traces, but is sometimes added to sophisticated wines.

The best methods for estimating *lactic acid* are those of Kunz (Zeitsch. Nahr. Genussm. 1901. 4, 673) and Möslinger (*ibid.* 1901, 4, 1123). *Citric acid* may be estimated by Möslinger's method, weighing as lead citrate, as officially adopted by the U.S. Dept. of Agriculture (Bur. of Chem. Bull. 107, 81).

The determination of *glycerol* in wine has given rise to numerous processes, the best known of which are based upon either extraction by means of alcohol and ether and weighing, or oxidation to and estimation as oxalic acid.

Various methods have been proposed as steam-distillation under reduced pressure (Bordas and Raczkowski, Compt. rend. 1897, 124, 240); or by conversion into triacetin (Böttinger, Chem. Zeit. 1897, 659); or into *iso*propyl iodide and weighing as silver iodide (Zeisel and Fanto, Zeitsch. anal. Chem. 1903, 549). A method by Rothenfusser, claimed to be more rapid and less laborious and expensive than the official method described below, is given in Zeitsch. Nahr. Genussm. 1912, 23, 332.

The older methods, especially extraction with alcohol and ether, are generally preferred, since, although somewhat empirical, they yield results which are comparable with the enormous amount of similar data acquired by previous observers. It is essential, however, that the exact details of the given methods should be rigidly followed.

The method officially adopted in Germany is as follows, (*a*) being adopted in the case of dry wines or those containing less than 2 grms. of sugar per 100 c.c.; and (*b*) for sweet wines containing more than this proportion of sugar.

(*a*) 100 c.c. of wine is evaporated down to 10 c.c. in a porcelain capsule on a water-bath. 1 grm. of quartz sand is added and milk of lime (40 p.c.) equivalent to 1½–2 grms. CaH_2O_2 for each gram of extract present, and evaporation continued almost to dryness. The residue is then repeatedly boiled with small quantities of 96 p.c. alcohol, the various extracts being decanted into a 100 c.c. flask, made up to bulk at 15°, filtered, and 90 c.c. of the filtrate evaporated in a porcelain capsule on the water-bath (without boiling). The residue is washed into a stoppered graduated cylinder with small quantities of absolute alcohol until 15 c.c. are collected, then shaken up with three successive portions of ether (7·5 c.c. each time), and, when clear, the whole (including the rinsings of the cylinder with alcohol-ether, 2 : 3) evaporated on the water-bath to a syrup, but without boiling. The residue is dried for 1 hour at 100°, cooled, and weighed. The weight in grams, multiplied by 1·111, gives the number of grams of glycerol in 100 c.c. of the wine.

(*b*) 50 c.c. of wine are heated on the water-bath in a large flask, 1 grm. of quartz sand added, also milk of lime until the dark colour at first produced disappears, and an alkaline odour becomes evident. After cooling, 100 c.c. of 96 p.c. alcohol are added, the precipitate filtered off and washed with alcohol. The filtrate is evaporated and treated as in (*a*). The factor 2·222 is necessary in this case to obtain the number of grams of glycerol in 100 c.c. of the wine.

The *sugar* in wine is a variable mixture of dextrose and lævulose, and occasionally sucrose. The usual method of examination consists in estimating the total quantity of sugar by titration with copper solution, then ascertaining by the optical method the proportions of the two glucoses and estimating the sucrose after inversion with hydrochloric acid.

Valuable information as to the nature and proportions of the sugars (both natural and added), as well as of other optically active substances introduced for the purpose of sophistication, may be obtained by the use of the polarimeter. Pure wine which still contains unfermented sugars turns the plane of polarisation to the left, whilst perfectly fermented wine either does not polarise at all, or only very slightly to the right. Wines sweetened with commercial glucose may contain considerable proportions of dextrorotatory non-fermentable substances.

It is essential to remove alcohol and colouring matters, and Nessler and Barth show that it is a matter of considerable importance also to remove the tartaric acid present in the wine, and they add, before precipitating with alcohol, a few drops of a strong solution of potassium acetate, thus separating the tartaric acid as potassium hydrogen tartrate.

The wine is carefully neutralised, and the alcohol eliminated by evaporation, the residue filtered, if necessary, and made up to original bulk, decolorised with lead acetate, the excess of lead removed with sodium carbonate or sulphate, and the polarimeter reading corrected for the increased volume due to these additions. The use of bone black should be avoided if possible, and complete decolorisation is not necessary if the liquid is clear. Turbidity can be removed by the addition of alumina cream.

A complete scheme, based upon the German official methods (Veröffentl. d. Kaiserl. Gesundheitsamts, 1896, 20, 557) is given in Allen's Commercial Organic Analysis, 1909, vol. i. 171. The results are obtained from observations in a 200 mm. tube, and expressed in terms of the sugar scale of the Schmidt and Hœnsch half-shadow saccharimeter.

For the estimation of sugar by Fehling's solution, the tannin must first be removed by lead acetate, the excess of lead being precipitated by sodium carbonate or sulphate. Ordinary fully fermented wine usually contains under 0·1 p.c. sugar, and may be decolorised by a small quantity of animal charcoal. Either the gravimetric method (weighing the precipitated copper as CuO) or the volumetric (using as indicator either potassium ferrocyanide or ferrous thiocyanate as recommended by Ling (Analyst, 1905, 182; 1908, 160) may be used.

Sucrose may be determined by difference between the directly reducing sugars formed as just described, and the total reducing sugar after inversion with hydrochloric acid on the water-bath, deducting one-twentieth of the difference (invert sugar) thus found to obtain its equivalent as sucrose; or the Clerget polariscopic method may be employed, using Herzfeld's modification of the Clerget formula (*v.* art. SUGAR).

Gum arabic and *dextrin*, which are sometimes used for sophisticating wines, may be detected by adding to a little of the wine about twice its bulk of the strongest alcohol. If a decided flocculent and viscous precipitate be formed, the gum is obtained by evaporating 100 c.c. of the wine to about 5 c.c., and precipitating by the gradual addition of 90 p.c. alcohol. The precipitate is filtered off, dissolved in about 30 c.c. of water, 1 c.c. of strong hydrochloric acid added, and the liquid heated in a flask provided with a long glass tube as a reflux condenser for 3 hours on a bath of boiling water. The sugar thus produced is then estimated in the usual manner by Fehling's solution.

Tannin. There is no very exact method for the estimation of tannin in wine. That of

Neubauer-Lowenthal is recommended, and is described, with modifications, by Fresenius and Borgmann in 'Analyse des Weines,' p. 99.

Mineral matter is found by cautious incineration of the residue from the evaporation of 50 c.c. of the wine, taking the usual precautions for separation of carbon from the alkaline salts. Rapid weighing is essential owing to the hygroscopic nature of potassium carbonate.

The determination of the ash (and of several other constituents) of wine containing much sugar is often facilitated and made more exact by eliminating the alcohol and removing the sugar by fermentation.

Wine containing less than 1·3 mineral matter per litre may be suspected unless it can be shown that natural wine from the same district and of the same vintage actually contains so small an amount of inorganic matter. The ratio of mineral matter to extract is, as a rule, about 1 to 10.

Estimation of chlorine in wine. It is well known to wine falsifiers that chemists lay much stress on the proportion of mineral matters contained in wine, and therefore they frequently add sodium chloride to artificial or adulterated wines in order to increase the extract and to bring the total amount of ash up to the normal quantity. It is also said to hasten clarification and to have a preservative effect. Owing to the volatility of sodium and calcium chlorides on incineration, chlorine is best determined in the wine itself and not in the ash, but the ordinary method of titration is inapplicable owing to the solubility of silver chromate in the free acid of the wine. The chlorine is either precipitated and weighed as silver chloride, or the method of Nessler and Barth may be employed as follows:—50 c.c. of the decolorised wine are acidified with nitric acid, an excess of standard silver solution is added, and then standard thiocyanate solution is run in until a drop of the liquid when mixed on a plate with ferric sulphate solution just shows a pink coloration.

Wines containing more than 0·05 p.c. sodium chloride may as a rule be suspected. Exceptions may occur in the case of wines which have been produced in the neighbourhood of the sea-shore.

Alkaline earths in wine. The ash of wine always contains calcium and magnesium salts. The amount of calcium (3–11·4 mg. in 100 c.c. of wine) is greatest in young wines and gradually diminishes with age, probably in consequence of the separation of neutral calcium tartrate. The amount of magnesium, on the other hand, remains almost constant and is always in excess of the calcium. The largest amount of magnesium found by Kayser was 24 mg. in 100 c.c. of Malaga wine. The phosphoric acid and magnesia show a constant proportion of 10 : 6, corresponding with the formula $MgHPO_4$ (Kayser, Chem. Zentr. 1881, 394; Chem. Soc. Abstr. 1882, 121).

Barium and *strontium* salts are sometimes added, to remove sulphuric acid, in the process of 'deplastering' wines, and are best detected in the ash, which should be taken up with dilute hydrochloric acid, filtered, and the filtrate evaporated to dryness. The dry residue is then examined by the spectroscope. If barium or strontium is present they are determined quantitatively in the usual manner.

Sulphuric acid is precipitated directly with barium chloride in wine acidified with hydrochloric acid, and determined in the ordinary manner.

A normal wine contains not more than 1·3 grm. K_2SO_4 per litre, and when the amount exceeds 2 grms., the wine may be regarded as plastered or sulphured.

The determination of *phosphoric acid* is to be effected in the ash by the molybdic method. (For details, *see* J. Soc. Chem. Ind. 1898, 280.)

The addition of dicalcium phosphate is sometimes made instead of 'plaster,' and is said to have certain advantages over the use of gypsum.

Nitric acid is sought for by carefully adding a few c.c. of the wine to a solution of diphenylamine in (pure) concentrated sulphuric acid, without mixing, and avoiding rise in temperature. An intense blue colour at the junction of the liquids indicates the presence of nitric acid.

Fresenius (Zeitsch. anal. Chem. 28, 67) finds that in wines containing much sugar a loss of phosphoric acid takes place during the incineration of the residue. A higher result is obtained when the residue is deflagrated with alkaline carbonate and nitrate. Destruction of the sugar by fermentation by addition of a very small quantity of yeast leads to the same result.

The assumption that the better kinds of wine always contain more phosphoric acid than the poorer ones is unfounded. At the same time the amount of the phosphoric acid can, in many cases, serve as a valuable means of ascertaining the character of a wine, especially of wines used for medical purposes, or of those of a particular district in which the amount of phosphoric acid varies between definite limits.

Examination for colouring matters. The principal substances used in red wines are vegetable colouring matters, coal-tar colours (especially fuchsines), and cochineal. White wines are frequently coloured with caramel or coal-tar colours used as substitutes.

According to Jean and Frabot (Ann. Chim. anal. 1907, 12, 52), wines artificially coloured may be distinguished from natural wines by the following test. The wine (50 c.c.) is heated on a water-bath with a little formalin (1 c.c.) and hydrochloric acid (4 c.c.), and when a precipitate is formed the liquid is made alkaline with ammonia and the excess expelled by further heating. The liquid, on cooling and filtration, yields a colourless filtrate in the case of genuine wines, whilst artificially coloured wines yield a coloured filtrate.

(*a*) *Vegetable colours.* These are derived chiefly from bilberries, black cherries, elderberries, hollyhock or rose-mallow, poke-berries (*Phytolacca*), indigo and lichens (archil, &c.), alkanet root, Campeachy, Pernambuco, and other dye-woods.

The wine is mixed with an excess of lead acetate and filtered. The colour of the precipitate in a genuine red wine may be greyish-blue, bluish-grey, ash colour, or greenish. If a precipitate is obtained not greatly differing from these colours, the search for other vegetable pigments can give no certain result. The colouring matter of *bilberries* gives a blue precipitate; *mallow* and *elderberries* a green. The colour of *Phytolacca berries* differs from that of red wine by giving a red-violet lead precipitate (*see* also Lenz, Zeitsch. anal. Chem. 1895, 635).

Alkanna-red, which, with Dupré's test (*v. infra*), behaves very like the natural colouring matter of wine, is very easily taken up from its solutions by amyl alcohol. On adding to the amyl alcohol a solution of a few drops of olive oil or oil of almonds and evaporating off the alcohol, the oily residue (after washing with water) has a fine red colour, which, on saponification becomes a rich blue, or if the alkanna used was old, a green (Herz, Zeitsch. anal. Chem. 23, 637; Chem. Soc. Abstr. 1890, 311).

Beetroot juice is used in colouring wines for the purpose of concealing the presence of magenta. The absorption-bands of magenta are hidden by those of beetroot, but if a few drops of copper sulphate solution are added to the wine, the beetroot bands gradually vanish and the magenta spectrum becomes visible.

The fresh colouring matters of *bilberries* and wines are similar but not identical, and, according to H. W. Vogel (Ber. 21, 1746), they are readily distinguished by their absorption spectra after careful neutralisation with ammonia, or, better still, when they are treated with a trace of alum before addition of ammonia. Care must be taken that the wine is not too concentrated or the ammonia in too great excess.

Detection of logwood in wine. When a solution of logwood is treated with manganese dioxide it becomes brown, and this brown liquid, by the action of zinc and hydrochloric acid, gives a colourless solution of hæmatoxylin. This may be detected by the ordinary reagents for that substance, alkalis and their carbonates giving a blue-violet colouration, calcium hydroxide a red-violet, stannous chloride or ammonium molybdate, in a solution slightly acid with nitric acid, a violet colouration. Advantage has been taken of this reaction for the detection of logwood in wines. 20 c.c. of the wine is agitated with 2 grms. finely powdered manganese dioxide, filtered, and the brown liquid treated with zinc and hydrochloric acid, which reduces the oxidised logwood colouring matter to hæmatoxylin. The solution is then divided into several portions, and tested with the reagents given above. Pizzi has examined wines to which other red colouring matters have been added, and although these yield brown solutions with manganese dioxide, the reduced solution does not give the hæmatoxylin reactions. Brazilwood is the only one which has any analogy to logwood, but here also there are differences (Chem. Soc. Abstr. 1881, 761).

Spaeth (Zeitsch. Nahr. Genussm. 1899, ii. 635; Analyst, 1900, 11) gives a table of reactions which may be found useful for the detection of the most commonly used vegetable colours.

(*b*) *Coal-tar colours.* In most cases the presence of a coal-tar colour in wine may be recognised by the following methods:—

a. By shaking the filtrate after precipitating with basic lead acetate with amyl alcohol, or (i.) the wine itself, also (ii.) a portion of the wine acidified with sulphuric acid, and (iii.) a portion made alkaline with ammonia. In the latter case, excess of ammonia should be avoided, as, if more than 3 p.c. the amyl alcohol may remain colourless, although the wine contains a coal-tar colour. The amyl alcohol extract in (i.) and (ii.) may contain natural colouring matter of the wine, but if the colour remain unchanged by ammonia, the presence of a coal-tar colour may be inferred. The amyl alcohol extract from (ii.) should be shaken up with water and the aqueous solution tested with ammonia or by the wool test.

b. By the wool test, using alum and sodium acetate as a mordant, and adding about 1 p.c. of potassium sulphate in solution.

c. By Cazeneuve's oxide test (Vierteljahrschrift für Chemie der Nahrungsmittel, 1886, 80; Compt. rend. 102, 52).

The oxides employed are yellow mercuric oxide in the proportion of 0·2 grm. per 10 c.c. of wine; lead hydroxide, containing 50 p.c. of water, in the proportion of 2 grms. per 10 c.c.; and gelatinous ferric hydroxide, containing 90 p.c. of water, in the proportion of 10 grms. per 10 c.c.

Mercuric oxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, erythrosin, eosin J, methylene blue, Coupier's blue, and diphenylamine blue. It partially absorbs orange I., safranine, chrysoidine, chrysoine, methyleosin, yellow II., red NN, red I., and Ponceau RR. It does not absorb the sulpho-conjugated derivative of rosaniline, Bordeaux red B, Ponceau R, Ponceau B, orange R, orange RRR, orange II., orange RR, tropæoline M, tropæoline II., yellow I., solid yellow, dinitronaphthol yellow, U. S. yellow.

Lead hydroxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, methylene blue, Coupier's blue, diphenylamine blue, and erythrosin. It differs from mercuric oxide in not absorbing the rosanilines, and also in absorbing the sulpho-conjugated derivative of rosaniline, Bordeaux red B, the purple red, and soluble red of rocelline.

Ferric hydroxide does not absorb erythrosin, the sulpho-conjugated derivative of rosaniline, Bordeaux red B, purple red, soluble red, and solid yellow. It absorbs the natural colouring matter and foreign vegetable colours, cochineal, and all the derivatives of rosaniline, except the sulpho-conjugated derivative.

Zinc hydroxides and stannous hydroxide behave similarly. The latter retains the natural colouring matter, but does not absorb cochineal or orchil. After the wine has been treated with the hydroxides, the colouring matters must be distinguished by special tests. If the wine is treated with magnesia and hot amyl alcohol, a number of blues which are precipitated by the above-mentioned hydroxides can be isolated and distinguished.

d. Shaking the wine with ether before and after supersaturation with ammonia.

Five to 6 c.c. of the wine to be tested are poured into a glass test-tube of about 20 c.c. capacity, and then three-quarters of its bulk of ether is added. After a few minutes the ether rises to the surface of the wine. If the ether be coloured yellow, and assumes, on addition of some drops of ammonia, a deep-red tint, Campeachy-wood has been used to colour the wine. If the ether becomes red and violet, and remains so even on addition of a large quantity of ammonia, the wine contains colouring matter derived from some of the lichens.

If the red-coloured ether loses its tint on mixing with ammonia, without passing into violet, then only the natural colouring matter of the wine, œnolin, is present. If the red-coloured ether loses its red tint with ammonia, without imparting any colour to the latter, then fuchsine has been added to the wine. When the ether rises uncoloured, a fresh sample of the wine to be tested is taken, twice its volume of water is poured into it, and half its volume of ammonia added. If the wine now assumes a brownish-red colour, it contains cochineal; if, however, it turns green, then it can be assumed that none of the substances mentioned is present.

e. The formation of *iso*nitriles when aniline derivatives are warmed with potash and chloroform serves for the direct determination in wine of even minute traces of many of the aniline colours. The evolution of the *iso*nitrile is accelerated by adding excess of strong sulphuric acid.

According to A. Dupré, fraudulent colouring matters added to red wines may be detected by dialysis, which is best accomplished by placing in the wine a cube of jelly about ¾-inch square. These cubes are made by dissolving 10 grms. of gelatin in 100 c.c. of warm water, and pouring the solution into a flat dish or mould; from the plate thus obtained the cubes are cut. After 24–48 hours the cube, on examination by transmitted light, will be found to be coloured more or less deeply by any colouring matter present, excepting the natural colouring matter, which penetrates only to a depth of ⅛-inch at the most. The colouring matter of alkanet root also penetrates but slowly, whereas rosaniline, cochineal, logwood, brazilwood, indigo, litmus, red cabbage, beet-root, *Malva sylvestris*, and *Althea officinalis* penetrate rapidly into jelly (Chem. Soc. Trans. 1880, 572).

The nature of the colouring matter may be determined either by the colour of the jelly or spectroscopically, or by the action of dilute ammonia, which turns cochineal purple, logwood brown, red cabbage dark green, and decolorises rosaniline (*v.* SPECTRUM ANALYSIS).

Bordeaux verdissant or 'colorant introuvable' is a mixture of acid fuchsine with methylene blue and diphenylamine orange, the two latter colours being used to produce a green which becomes visible on decolorising the Bordeaux red with ammonia, thus simulating the effect of ammonia on natural red wine. The diphenylamine orange can be extracted with amyl alcohol, the acid fuchsine detected by Girard's mercuric acetate test, and the methylene blue by dyeing cotton fibre.

A substance known as *Tintura por los vinos* is said to have been largely used for colouring certain Spanish wines. It contains Biebrich red, sodium sulphate, and arsenious oxide. The presence of arsenic is of special importance.

The methods employed in the Paris Municipal Laboratory for the investigation of the colouring matters in wine will be found in Girard and Dupré's 'Analyse des matières alimentaires.'

Detection and estimation of *preservatives* most commonly used in wine. *Abrastol* or *asaprol* (calcium α-monosulphonate of β-naphthol) is a white or slightly reddish scaly powder readily soluble in water and alcohol, and decomposing at 50°. It is extracted from alkaline solution by amyl alcohol, the extract evaporated to dryness, and the residue tested by Simibaldi's method (Mon. Sci. 1893, [iv.] 7, 842; U.S. Dept. of Agric. Bur. of Chem. Bul. 59, 91).

Boric acid (according to Baumert, Ber. 21. 3290) is naturally present in many wines as well as in the leaves and tendrils of the grape-vine. It is detected in the ash by extracting with a large excess of strong hydrochloric acid, and testing with turmeric paper. For its quantitative estimation, *see* Windisch, Die Chemische Untersuchung und Beurtheilung des Weines, 235.

Fluorides are strongly antiseptic and are usually employed in very small quantity in the form of the ammonium or sodium salts which are soluble in water. The fluorine is precipitated as calcium fluoride from alkaline solution by means of calcium chloride, and the precipitate, after filtering, washing, drying, and igniting in a platinum crucible, is tested by means of the 'etching' test. A blank experiment should be made with the reagents employed. For *fluoborates* and *fluosilicates* the ash containing the calcium salts is extracted with dilute acetic acid and filtered. The filtrate contains the boric acid which, if present, is detected as above. The calcium fluoride and silicate remain in the insoluble portion, and can be detected by the usual methods (*v.* Bull. 59, 63, U.S. Dept. of Agric. Bur. of Chem.).

For detecting *saccharin* (which is used as a preservative as well as a sweetening agent), the wine (about 100 c.c.) is shaken up with a mixture in equal parts of ether and light petroleum, and the extract, after evaporating off the solvent, is fused with sodium hydroxide and tested by means of ferric chloride for salicylic acid. It is assumed, of course, that the absence of salicylic acid in the original wine has been proved and the presence of saccharin indicated by the sweet taste of the residue from the ether extraction.

The estimation of the saccharin may be made by acidifying (if necessary) with phosphoric acid, extracting with ether as above, and fusing the evaporated residue with a mixture of sodium carbonate and nitre, precipitating the resulting sulphate with barium chloride and calculating the saccharin from the weight of barium sulphate obtained ($BaSO_4 \times 0{\cdot}785 =$ saccharin).

Saccharin may also be estimated by hydrolising the residue from the ether extract with hydrochloric acid, and estimating the ammonia thus formed by distillation into standard acid (Proctor, Chem. Soc. Trans. 1905, 242).

Salicylic acid is best sought for by agitating the wine with carbon disulphide or a mixture of equal volumes of ether and light petroleum (taking care to avoid an emulsion), evaporating down and testing the residue with ferric chloride. If much more than 100 c.c. are used, a faint colour may be occasioned by other substances giving a similar reaction and present as normal constituents of the wine.

An approximate estimation of the quantity of salicylic acid may be made colorometrically, by comparing the colour given by an alcoholic solution of the residue after ether extraction with that yielded by standard alcoholic solution of salicylic acid of known strength, using, if possible, a liquid similar to that under investigation.

Sulphurous acid and sulphites. Wine wi absorb as much as 0·36 grm. of sulphurous acid per litre when it is shaken in a barrel in which sulphur has been burnt, and if the treatment is repeated the sulphurous acid may reach 0·5 grm. per litre. Sulphur is burnt in the barrels to prevent the formation of mildew, and sulphites are sometimes used as a preservative. Much of the sulphurous acid is combined with aldehyde when it is considered to be much less objectionable than in the free state.

Sulphurous acid is determined by distilling a portion of the wine, to which phosphoric acid has been added, in a stream of carbon dioxide, receiving the distillate in solution of iodine, and determining the sulphuric acid thus formed. The details of the method are as follows (B. Haas, Ber. 15, 154): the wine, to which 5 grms. of syrupy phosphoric acid have been added, is distilled in a current of carbon dioxide, and the distillate is collected in a suitable apparatus (a bulbed U-tube) containing 50 c.c. of iodine solution, containing 5 grms. pure iodine and 7·5 grms. potassium iodide per litre, thus oxidising the sulphurous acid. As soon as the distillate amounts to about half the original volume of the wine used, the contents of the U-tube are washed out, acidified with hydrochloric acid, precipitated with barium chloride, and the barium sulphate washed, dried, heated to redness, and weighed. This method gives very good results.

Opinions vary as to how much sulphurous acid a wine may contain. According to the medical faculty of the University of Vienna, not more than 8 mg. per litre should be allowed, whereas other authorities regard 80 mg. as not an excessive amount. In France and Switzerland the maximum limit is fixed at 200 mg. of SO_2 per litre, of which, in France, not more than 30 mg., and in Switzerland, not more than 20 mg. should be 'free' or uncombined.

Poisonous metallic substances in wine. Traces of *arsenic* may be present owing to the use of impure coal-tar colours (acid fuchsine, &c.), and commercial glucose. *Copper* and *mercury* may be due to the compounds used as insecticides and fungicides, but are, no doubt, largely removed in an insoluble form during the process of fermentation. *Lead* has been traced to the use of litharge to mask acidity and to lead shot used for cleaning bottles. *Zinc* is often present in appreciable quantities when the wine has been stored in vessels of unalloyed zinc. These metals may be detected and estimated by the usual methods.

Alum is occasionally present in the coal-tar colours employed, and is sometimes added to wine as a clarifying agent, and to impart astringency, particularly to wines which have been diluted. The alumina may be estimated as follows (Louvet, Chem. Zentr. 1881, 252): 200 c.c. of wine are evaporated to dryness, the residue incinerated, and the ash fused in a platinum crucible with 3 grms. sodium carbonate, whereby the lime, magnesia, and ferric oxide are converted into insoluble carbonates. The mass is dissolved in water, and the solution filtered. As the solution may contain sodium aluminate, it is acidified with hydrochloric acid treated with a large excess of sodium carbonate, and the alumina collected on a tared filter. The insoluble portion of the fused mass, containing the chief portion of the alumina, is fused with a few grms. of pure soda, and the fused product digested with water and the solution treated for alumina as above described. The precipitates are collected, thoroughly washed, dried, ignited, and weighed. If any considerable proportion of phosphate is present, the phosphoric acid should be estimated and deducted from the total weight, the difference being Al_2O_3.

Adulteration of wine. Of the various processes already described which, strictly speaking, might be considered as 'adulteration,' some, as fortifying with spirit, sweetening with sugar, glucose, or glycerol and 'plastering,' are defended as legitimate trade practices of long standing or are officially tolerated within certain limits. Others, as dilution with water, the addition of antiseptics, astringents, colouring matters, and mineral acids, and of potassium hydrogen tartrate and œnanthic ether to give the fictitious character of age, have, as a rule, no other object than that of fraud.

In addition, wine is mixed with the juice of fruit other than the grape, and spurious wines containing no grape-juice whatever are made to simulate well-known types, as port, sherry, claret, and burgundy. The fruit basis of these is usually apple juice, the other principal ingredients employed being crushed raisins, alcohol, sugar, tartar, flavouring essences, and colouring matters derived generally from the juice of such fruits as bilberry, elderberry, black currant, &c.

For the detection of dilution with water, fortifying with spirit, the addition of acids, tartar, glycerol, sugar, and other forms of sophistication of wines, reliance is placed in France and Germany upon the *ratios* which the proportions of the principal constituents of the genuine wines of those countries bear to each other (*e.g.* in France, alcohol : extract (reduced); and in Germany, alcohol : glycerol); and certain maxima and minima are adopted for the constants of genuine wines; but it does not necessarily follow that these can be accepted as standards applicable to the wines made in other countries and by different methods of manufacture. Whenever possible the suspected wine should be compared with a similar wine from the same district and vintage and known to be genuine. A concise and clear *resumé* of these constants and ratios will be found in Allen's Commercial Organic Analysis, 1909, vol. i. 182–186; *see* also Thudichum and Dupré's Treatise on the Origin, Nature, and Varieties of Wine; Windisch's Die chemische Untersuchung und Beurtheilung des Weines; Villiers et Collin, Traité des alterations et falsifications des substances alimentaires; Leach's Food Inspection and Analysis; and Post and Neumann's Traité complet d'analyse chimique appliquée aux essais industriels. WINE GUM *v.* GUMS.

WINTER GREEN, OIL OF, *v.* OILS, ESSENTIAL, and SALICYLIC ACID.

WITHERITE. Native barium carbonate ($BaCO_3$) crystallising in the orthorhombic system and isomorphous with aragonite and cerussite. The crystals are, however, invariably twinned, giving rise to pseudo-hexagonal forms; these may be either lenticular or pyramidal in habit, and in the latter case the six-sided pyramids present a certain degree of resemblance to crystals of quartz. Globular aggregates and compact fibrous masses also occur. The colour is white or grey; sp.gr. 4·3; H. 3½. The mineral occurs in some abundance in the lead-bearing veins traversing limestones, &c., at several places in the north of England and on the borders of Shropshire and Montgomeryshire. It has been formed, in some instances at least, by the action of carbonated waters on barytes (L. J. Spencer, Min. Mag. 1910, 15, 310); and it is itself sometimes altered to barytes, as shown by the pseudomorphs of barytes after witherite. The best known locality, which has yielded many finely crystallised specimens, is the Fallowfield mine near Hexham; whilst the largest quantity (about 8000 tons per annum) is produced by the Settlingstones mine also in Northumberland. The mineral is also known from a few foreign localities, but only in small amounts.

Witherite is used in the manufacture of plate glass and porcelain, and for the preparation of barium dioxide (used in the manufacture of hydrogen peroxide), barium hydroxide (for refining beet-sugar), and barium salts (used, *e.g.*, for giving the green light of fireworks). The addition of a small proportion of witherite to clay (1 oz. per cwt.) in brick making prevents any efflorescence and discoloration due to soluble sulphates. Although insoluble in water, it is poisonous, since it is readily acted upon by the gastric juice; and the powdered mineral, mixed with meal, is used as rat poison. L. J. S.

WOAD (*Vouède, Pastel*, Fr.; *Waid*, Ger.).

This commercial product is a dark clay-like preparation made from the leaves of the woad-plant, *Isatis tinctoria* (Linn.), an erect, herbaceous, biennial plant, belonging to the *Cruciferæ*, bearing yellow flowers, small flat elliptical pods, and large smooth lanceolate or spathulate leaves.

The term 'woad' is derived from the Saxon 'wad,' which it has been suggested is derived from Woden, the Saxon God of War. It is synonymous with the Gallic *glastum*, with which, according to Pliny, the ancient Britons dyed their skin blue, in time of war and in connection with certain religious observances.

The plant is a native of Southern Europe, and from very early times has been employed in dyeing blue, for which purpose, previous to the introduction of indigo from India, it was largely cultivated in various parts of Europe—*e.g.* Thuringia, Languedoc, Piedmont, &c. Its cultivation has now declined almost to the vanishing point.

In this country, woad is now only grown, to a very small extent, in the fen lands of Lincolnshire and Huntingdon. The seed is sown in the early spring, March or April, and, the young plants having been duly thinned and weeded, the leaves are ready for the first plucking in June, which, at intervals of 5 or 6 weeks, is repeated once or twice, or as often as fresh leaves shoot up.

The newly-gathered leaves are at once crushed or ground in edge-runner mills to a pulp, which is then placed in small heaps to drain, till sufficiently dry to cohere and be submitted to the 'balling' process. This consists in working the pasty mass by hand into balls, 4–6 ins. in diameter. These are at once spread out on wicker-work trays or 'fleaks,' and thoroughly dried in well-ventilated sheds. The balls are stored in a dry airy place till the whole crop has been gathered, and are then submitted to the so-called 'couching'—*i.e.* a fermentation—process. For this purpose the balls are ground to a coarse powder, which is spread on the floor of the couching-house to a depth of 2 or 3 ft., and there reduced again to the consistency of a paste by frequent sprinkling with water and turning over with shovels. During this process, which lasts from 20 to 40 days, the mass becomes heated and abundant offensive odours are given off. The operation needs to be conducted with some care and skill, so that the fermentation is neither so slow that a 'heavy' product is obtained, nor so rapid as to give one which is 'foxy.' When the fermentation has subsided, and the stiff, pasty mass is sufficiently cooled, it is packed in casks ready for the market.

It has been calculated that 9 parts by weight of woad leaves yield 1 part of the prepared product.

Although woad was formerly used for the indigo contained in it, it is at present only employed for the purpose of exciting fermentation in the indigo-vat ordinarily used by the woollen dyer, which is therefore termed the 'woad-vat.'

According to Wendelstadt and Binz (Ber. 1906, 39, 1627) woad contains two distinct micro-organisms, one of which under suitable conditions appears to be able to reduce indigo.

Spurious woad was sometimes prepared from the leaves of the rhubarb, cabbage, &c., but these products were very inferior to the true woad.

The colouring principle of woad leaves, considered by Schunck to be identical with that present in the *Indigoferæ*, is now known to be a distinct substance. This has not been isolated in a pure condition, but in its general reactions resembles indoxylic acid (*see* Indigo, natural).

WOLFRAMITE or **WOLFRAM.** A mineral consisting of iron and manganese tungstate (Fe,Mn)WO$_4$, crystallising in the monoclinic system. The name *ferberite* is applied to the members at the iron end of the series (FeWO$_4$), and *hübnerite* to those richest in manganese (MnWO$_4$). With this wide difference in composition the percentage of tungsten varies only slightly (WO$_3$, 76·3–76·6 p.c.; analyses of the pure mineral show 74–77 p.c.). The mineral fuses readily before the blowpipe to a black, magnetic bead; and it is decomposed by *aqua regia*, with the separation of yellow tungstic oxide. Distinctly formed crystals are rare, but cleavage masses are of common occurrence. There is a perfect cleavage in one direction, parallel to the plane of symmetry. The mineral is opaque with a bright, sub-metallic lustre and a dark brown to black colour; the streak is dark reddish-brown to black; H. 5½. The high sp.gr. (7·2–7·5) and the perfect cleavage are characters which assist in the identification of the mineral.

Wolframite usually occurs in veins traversing granitic rocks, and is often associated with tin ore. It is, in fact, obtained commercially mainly from tin mining districts; and formerly, before the mineral was of value, it was a source of trouble to the tin miner, since having about the same density as cassiterite it could not be separated from the ore by the ordinary mechanical methods. At one time it was eliminated in a soluble form by fusing the ore with soda (Oxland's process); but now it is extracted by the electromagnet (wolframite being weakly magnetic), and it forms a product as valuable as the tin ore itself. The principal wolfram-producing countries, arranged approximately in the order of their outputs, are: North Queensland (at Wolfram Camp, &c.), United States (Black Hills in South Dakota, Boulder and Gilpin counties in Colorado, Arizona, Nevada, &c.), Portugal, Bolivia, Spain, Cornwall (near Redruth), France, and Rhodesia.

The mineral is used mainly for the manufacture of ferro-tungsten and the hard and tough tungsten-steel, and of some other alloys (*e.g.* 'partinum,' an alloy of tungsten and aluminium). Metallic tungsten is now used as the filament of the so-called 'osram' electric lamps. Wolframite is also used for the preparation of sodium tungstate and other salts.

WOLLASTONITE *v.* CALCIUM.

WONGSKY, WONGSHY, WONGSCHY, HOANG-TCHY. A Chinese yellow dyestuff. It consists of the fruit of the *Gardenia grandiflora.* According to Rochleder (J. 1858, 475), it contains *rubichloric acid* (*see* MADDER) and *crocin,* the glucoside of *Crocetin,* which is also present in saffron (*Crocus sativus* [Linn.]). Wongsky dyes aluminium and tin mordanted fabrics a yellow, whereas with iron mordant an olive colour is produced.

WOOD APPLE GUM *v.* GUMS.

WOODBURYTYPE *v.* PHOTOGRAPHY.

WOOD, DESTRUCTIVE DISTILLATION OF.[1] Wood completely freed from water has the following composition:—

Carbon, 50 p.c.
Hydrogen, 6 p.c.
Oxygen, 42·75 p.c.
Ash, 1·25 p.c.

The chemical nature of wood may be said to consist principally of cellulose, lignin, water, and of ash-forming materials.

If wood is heated in a closed vessel with the air partly or entirely excluded and the vapours and gases are allowed to escape, the cellulose and lignin molecules are broken up by processes, the nature of which is little understood, but which are characterised by the formation of charcoal, which is left as a residue, and by the formation of gases and vapours, the latter of which, when condensed, is known as pyroligneous acid. P. Klason, Heidenstam and Norlin[2] concluded that the destructive distillation of wood may be represented by the following equation:—

$$\underbrace{2C_{42}H_{60}O_{28}}_{\text{Wood}}=\underbrace{3C_{16}H_{10}O_{2}}_{\text{Charcoal}}+28H_2O+5CO_2+3CO+\underbrace{C_{28}H_{32}O_9}_{\substack{\text{Total amount of products, contained in the pyro-}\\\text{ligneous acid, in the tar, and in the wood gases}}}$$

They proved further that the destructive distillation of cellulose forms the most important products, viz. charcoal, acetic acid and tar; whilst lignin forms principally charcoal, acetic acid, wood alcohol and tar.

The destructive distillation of wood is occasionally carried out for the purpose of producing charcoal only, but at present it is more frequently the case that the by-products, acetic acid and the wood alcohol, are the most important substances yielded.

As regards the value of various kinds of wood for the process of destructive distillation, it has been shown that hard woods give the best yields of charcoal, acetic acid, and wood alcohol, whilst soft woods give smaller amounts of these products. Soft woods, however, show a larger yield than pine wood, which yields, besides the above-named products, a certain amount of turpentine, pine oils and pine tar oils. Local market conditions must decide in each case what is the most desirable wood for the purpose.

All wood for destructive distillation is split into cord-wood averaging 6 ins. in diameter and 4 ft. long. This initial preparation is usually carried out in the forest, but at manufactories recently erected in the United States large logs are brought to the saw mill where all the timber is utilised, and only those logs unfit for other purposes are used for cord wood. The cord wood is stacked in an exposed situation if possible, where it is allowed to dry and season for about 18 months, after which the moisture content will be found to be quite constant. The length of time required for this seasoning varies with the climate, and although it is thought that the moisture content of 20 p.c. is the most desirable, it is frequently found necessary to use wood containing 30 p.c. or more. A high percentage of moisture in the wood is undesirable owing to the fact that it delays the distilling process, decreases the yields of acetic acid, wood alcohol and charcoal, whilst at the same time it increases the amount of noncondensable gases and also the amount of fuel used for the purpose of supplying heat for the distillation.

The process of destructive distillation is carried out in closed vessels built of brick or iron, and heated either by allowing the products of combustion to come directly in contact with the wood, excluding any excess of air; or by transmitting the heat through the walls of the vessel. In either case the distilling apparatus is connected with a condenser, the purpose of which is to condense the vapours formed during the reaction.

The apparatus for the destructive distillation of wood may be said to consist of three principal parts:—

1st. The container for the wood.

2nd. The arrangement for generating and supplying the heat to the container.

---

[1] M. Klar, Technologie der Holzverkohlung, 1910. Second Edition. Julius Springer, Berlin.

[2] Ark. Kemi Min. u. Geol., 1908, Bd. 3, 9.

3rd. A condenser connected with the container by an intermediate vapour pipe.

After the wood has been placed in the distilling apparatus and the heating started, the water contained in the wood is first driven off; when this is accomplished the destructive distillation of the cellulose and lignin begins and will be indicated by the formation of non-condensable gases and by the appearance of the so-called pyroligneous acid, a brown liquor of characteristic odour, in which considerable tar is found. When the temperature reaches 270° an exothermic reaction sets in which supplies most of the heat necessary for the distillation process. The end of the process will be indicated by the cooling of the pipe which connects the distilling apparatus with the condenser.

In carrying out this distilling process on a commercial scale, the three phases of the distillation, namely: the expulsion of the water, the heating of the wood to the point at which the exothermic reaction sets in, and the completion of the process by means of the above-named reaction, will not necessarily take place consecutively, owing to the fact that the large-sized apparatus used will not allow the heat to be transmitted uniformly to all the wood in the vessel. Hence part of the wood situated near the heating surface may be in the third phase of the process, whilst that not so near the source of heat may be still in the first phase.

In general, yields of various products from air-dried hard wood in percentage by weight will be as follows:—

Charcoal, 25 to 27 p.c.
Crude pyroligneous acid, 45 to 50 p.c.
Gases, 25 to 28 p.c.

The composition of the charcoal will be variable, depending upon the process used and particularly upon the temperature at which the distillation has been finished. The following table gives the composition of charcoal produced by several processes:—

Process	P.c. C	P.c. H	P.c. O+N	P.c. ash	Temperature
Old 'Meiler' process	90·36	2·74	5·72	1·1	above 600°
Kiln process	84·18	3·32	11·72	0·78	450°
Retort process	81·15	4·24	13·64	0·97	350°

The *crude pyroligneous acid* will be found to be composed chiefly as follows:—

Water, 81 p.c.
Wood alcohol, 3 to 4 p.c.
Acetic acid, 6 to 8 p.c.
Dissolved and suspended tar, 7 p.c.

Other compounds contained, such as aldehydes, ketones, allyl alcohol, amines, phenols, and hydrocarbons are not of commercial importance and are of interest only in the refining of wood alcohol. The wood tar obtained from hard wood has little commercial value and is generally used as fuel. Small amounts, however, are used for the manufacture of creosote and wood tar pitch.

The *non-condensable gas* obtained by the destructive distillation of wood, amounting to 25–28 p.c. of the weight of the wood, varies in composition during the different phases of the process, and is composed on an average of carbon dioxide, 60 p.c.; carbon monoxide, 30 p.c.; hydrogen and hydrocarbons, 10 p.c. This gas is generally used for heating the retorts or boilers, and its heating value is equivalent to about 4–5 p.c. of the heating value of the wood decomposed in the process of distillation.

Destructive Distillation of Pine Wood.

The destructive distillation of pine wood containing rosin and turpentine, besides the cellulose and lignin, will produce products different from those obtained from hard wood. The turpentine being volatile with water vapour is almost completely distilled over during the first phase of the distillation. In this phase, also, the rosin melting and flowing from the wood cells, covers the surface of the wood and the bottom of the distillation retort. During the second phase, this rosin will be decomposed, yielding such products as pinoline, rosin oils, and a residue of rosin coke. The pinoline will be mixed, more or less, with the turpentine originally contained in the wood, the rosin oils will combine with the tar formed in the usual course of wood distillation, and the rosin coke will be mixed with the charcoal. The mixture of turpentine and pinoline is known as crude wood turpentine. The presence of the rosin oils in the pine wood tar gives it a peculiar orange colour when painted on wood, which property makes it of considerable value. The amounts of acetic acid, wood alcohol and charcoal obtained from pine wood are considerably less than in the case of hard wood distillation.

An active demand for wood turpentine, for pine wood tar and pine wood tar oils, with good prices for these products and cheap prices for the wood, may cause, under certain circumstances, pine wood to be preferred to hard wood. But these conditions will not be frequent, and since the yields of acetic acid and wood alcohol and also of charcoal are considerably less, as the container can be filled with a larger weight of hard wood than of pine wood (on account of the lower specific gravity of the latter), the efficiency of a distilling plant using hard wood is higher than one of the same size employing pine wood.

Various Forms of Distilling Apparatus for Cord Wood.

The number of forms of apparatus actually used for this purpose is large, and still larger is the number of designs which have been described in the literature or by patents taken out in different countries.

Only the most important types in practical use are given in what follows.

I. Distilling Apparatus made of Brick.

a. *Charring of the wood in brick kilns by fire gases which come directly in contact with the wood.*

1. *Fire gases generated inside the distilling apparatus by burning a part of the charge.* To this type belongs the so-called 'American kiln,' seen in Fig. 1. This apparatus consists of a brick chamber, of about 15,000 cubic ft. capacity, holding 80 cords of wood filled in by a top iron door *a*. There is a bottom iron door provided for discharging the charcoal. 4 ins. × 4 ins. air inlet holes *d*, *d* are provided in the lower parts of

the wall, and a couple of these kilns are connected by a brick goose neck *e* with the main smoke pipe, mostly built of wood. This main smoke pipe connects the kilns with the condenser plant *f g h*, and a fan is used for transporting the vapours and the gases from the kilns to the condensers and also for supplying the kilns with a certain amount of air, sufficient to generate the heat required for the destructive distillation of the wood by burning a certain amount of the wood, but avoiding any excess of air.

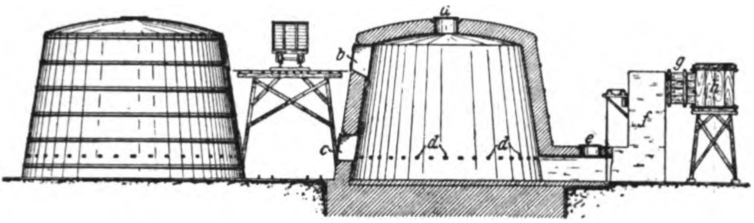

Fig. 1.

Brick wood-distilling apparatus for an 80-cord charge heated by burning a portion of the charge.

In the large plants at work in Michigan, often as many as 80 kilns are connected with condensers, using as much as 250 cords of wood per day, and condensing up to 50,000 gallons of crude pryoligneous acid. Unfortunately these kilns do not afford the proper amount of volatile by-products (acetic acid and wood alcohol) and about 50 p.c. of the possible yield is lost by being burnt to carbon dioxide and water. These kilns should only be used when wood is very cheap and fuel and labour prices high and when there is not much demand for calcium acetate and wood alcohol. As these conditions seldom coexist, the kiln system must be considered wasteful and should be no longer used.

2. *Fire gases are generated outside of the distilling apparatus by fuel (mostly wood) in a special fireplace and conducted from there to the wood.* Fig. 2 represents such a type, originally known as the 'Schwartz kiln.' The Swedish kilns of Ljungberg and of Ottelinska are of a similar type.

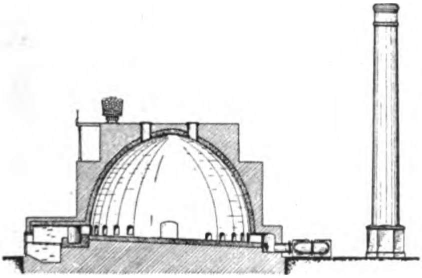

Fig. 2.

Brick wood-distilling apparatus, according to Schwartz, heated by a special open fire.

b. *Heating the wood in brick kilns by fire gas which, passed through radiators, transmits the heat by radiation to the wood.*

Inside a brick chamber, cast-iron or steel radiators are provided, through which fire gases are passed, which transmit the heat by radiation to the wood surrounding these radiators.

The oldest type of this kind of a wood distilling apparatus is represented by the 'Reichenback kiln.'

Sweden developed a new form of this type called the 'Tube Oven,' seen in Fig. 3.

These brick kilns do not permit the charcoal to be discharged immediately after the distillation is finished. In fact, every hole of the oven has to be closed by bricks so as to allow the charcoal to cool with absolute exclusion of air. This cooling process requires, in the case of large sized kilns (50 cords or more) as much as eight days, and the efficiency is decreased correspondingly. In order to discharge the charcoal from kilns heated by radiators, immediately after the close of the distillation, the wood must be loaded on iron cars capable of being pulled or pushed into the brick container. After the distillation is finished the cars, loaded with hot charcoal, are pulled out quickly and transferred to a steel chamber of the shape of the brick container, when cooling will not require more than 24 to 48 hours. After the cars are withdrawn, other cars, already loaded with new wood and ready for charging, will be put into the brick chamber, still hot by the previous operation.

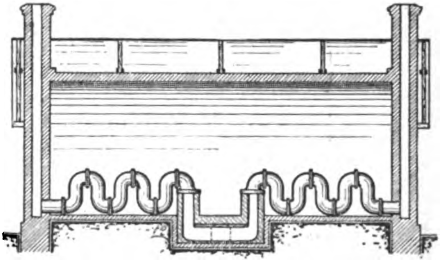

Fig. 3.

Brick wood-distilling apparatus heated by steel coil radiators.

These brick kilns, heated by radiators, charged and discharged by iron cars, are the newest form of brick distilling apparatus.

A distilling apparatus built of brick is cheaper to build and possibly cheaper to maintain, but gives lower yields than steel apparatus as regards acetic acid and wood alcohol, on account of the difficulty of preventing the brick walls from leaking.

II. Steel Distilling Apparatus.

A. *Intermittently operated apparatus.*

The most important representative of this type is the Swedish 'Carboven,' shown in Fig. 4. This apparatus can be loaded with 100 cords of wood, and will require about three weeks for filling, distilling, cooling and discharging.

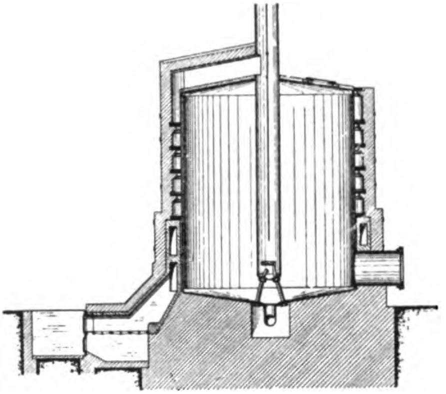

FIG. 4.

Vertical steel wood-distilling apparatus for large charges, heated by fire-gases circulating around the steel container, called 'Carboven'; used in Sweden.

A couple of inner vertical heating tubes, instead of one large one, is the characteristic feature of the bosnic steel distilling apparatus.

B. *Apparatus for discharging the charcoal immediately after the close of the distillation without cooling the charcoal before discharging.*

1. *Horizontal types.*—*a. Apparatus for small charges.* To these belong the distilling apparatus, generally called 'retorts,' largely used in the past and still employed in Germany, Austria, Russia, Pennsylvania, and other countries or states. These retorts are about 39 ins. in diameter by 10 ft. in length, are round in section, and contain ½ cord wood. But they are also built for one cord capacity. Usually, one pair of these retorts is heated by the same fireplace, the products of combustion being conducted around the horizontally placed steel cylinders. One side of the retort is provided with a cast-iron door, the other tight end with a nozzle which serves to connect the retort with a condenser (see Fig. 5).

The wood is loaded by hand into these retorts. Inside the retort there is a semicircular scraper, which is pushed to the rear before the retort is loaded and is provided with a rod with a handle ending near the door. After the distillation is finished, a steel container is placed underneath the front of the door. The door is opened, and by means of the scraper the hot and burning charcoal is quickly emptied into the steel container, the cover of which is then closed air tight. A new charge is loaded immediately after discharging. While the new charge is distilling, the charcoal cools inside the container, which is built of thin sheet steel.

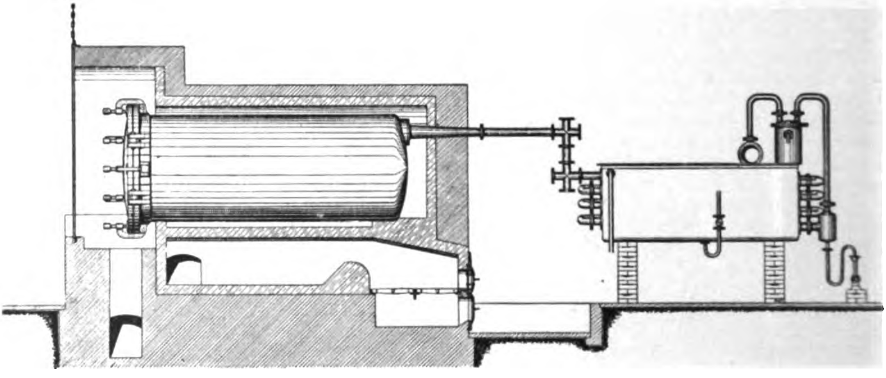

FIG. 5.

Horizontal steel retort for small charges; type, F. H. Meyer, Hanover-Hainholz.

As one of these 39 ins. × 10 ft. retorts can handle only ¾ cord of wood in 24 hours, this type of distilling apparatus is not well adapted for the destructive distillation of wood on a large scale.

These small, horizontal retorts have the further disadvantage that the scraper used in discharging them causes much of the charcoal to be broken into small pieces. The charging of the retort by hand also requires many workmen, causing loss of time and decreasing the efficiency of the plant.

β. Wood-distilling apparatus for large charges arranged for mechanically charging and discharging. The disadvantages above mentioned may be avoided by employing retorts of large capacity, provided with mechanical contrivances for filling them with wood and also for discharging the charcoal. The distilling apparatus which meets these conditions best is the so-called 'car retort.' A distilling apparatus of this kind consists of a horizontal steel retort, capable of working off a charge of 6 to 10 cords of wood (see Fig. 6). The wood is loaded on cars which are pulled or pushed into the retort; this has rails on the bottom and, according to its capacity, one or two doors for filling and discharging. Each car, made of steel, contains

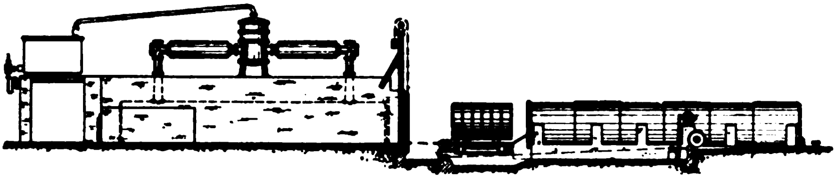

FIG. 6.

Horizontal steel retort, filled and discharged by cars; for charges up to 10 cords; type, F. H. Meyer, Hanover-Hainholz.

usually two cords of wood. The retort is connected by necks with one or two condensers of the usual tube type. The heating of these retorts is mainly effected by an open wood or coal fire and, to some extent, also by burning the tar and the gases obtained in the destructive distillation of the wood. The combustion gases travel by flues round the retort and escape in a smoke stack. The heating by an open fire has latterly been replaced by producer-gas, obtained either in the usual way, that is generated by gas producers, or as a by-product in the destructive distillation of the wood. A gas-heated retort will last longer, will use less fuel and will yield higher results. The question of the best kind of gas producer for this purpose is dealt with later. After the distillation is finished the doors of the retort are opened and the cars, containing the hot charcoal, withdrawn and transferred as soon as possible to a horizontal steel cylinder, exactly corresponding in shape with the retort and also provided with doors for filling and discharging. The withdrawal of the cars is mostly done by means of a locomotive or by means of transportable electric or steam hoists, and has to be done quickly in order to avoid the combustion of the charcoal. After the cars containing the hot charcoal are transferred to the horizontal steel cylinder, placed opposite the retort, the doors of the cylinder are closed air tight and the charcoal allowed to cool with exclusion of air. The cooling requires, according to the weather and character of the wood, from 24 to 40 hours.

This kind of wood-distilling apparatus further allows of the preliminary heating of the wood before filling it into the retort, by means of the waste combustion gases, which escape from the last retort flue into the smoke stack. In order to utilise this waste heat, the cars loaded with the wood are placed in a brick channel located opposite the charging door of the retort. The waste combustion gases are driven over the wood by means of a fan.

Fig. 6 shows a modern distilling apparatus, having a higher efficiency than any other wood-distilling apparatus in practical operation.

A charge of 10 cords of wood is worked off in 24 hours, including filling, distilling and discharging, and it requires also very few workmen to attend to the firing, charging and discharging. By discharging the charcoal in a cold state and without the use of scrapers, a better class charcoal is obtained with the production of only a very small amount of powder or small pieces.

A revolving retort of a capacity corresponding to a charge of 6 to 10 cords of wood has been tried but discarded on account of the difficulty of contriving proper outlets and of keeping these outlets tight. Moreover, revolving retorts gave, of course, large amounts of charcoal powder and small charcoal.

2. *Vertical steel retorts.* Vertical steel retorts, either built stationary or transportable, are in use in Germany, Belgium, France, Italy, and also in Russia. France, in particular, is the country of vertical retorts, which are almost always constructed as transportable ones. These retorts contain a charge of 1 to 1½ cords of wood and are heated by an open fire or by a gas fire from underneath (see Fig. 7). They are filled outside of the settings, after being placed in a horizontal position. After the retort is loaded and closed it is lifted, by means of a travelling crane, above the open space in the settings to which the retort belongs. Then the retort is lowered into its place and its cover connected by means of a copper goose-neck, with the condenser. After the distillation is finished, this copper goose-neck is taken off, the goose-neck hole in the cover closed, and then the whole retort is lifted out of the settings by means of the crane and transported outside of the building, placed in a horizontal position and then allowed to cool down, which will require from 12 to 24 hours, according to the charge and the

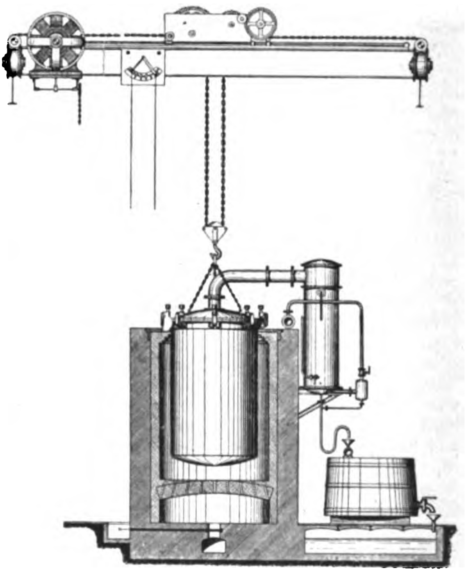

FIG. 7.

Vertical transportable retort; type, F. H. Meyer, Hanover-Hainholz.

weather. These retorts give good yields and afford good charcoal, but their efficiency is not so good as that of the car retorts already described.

Sometimes these vertical retorts are constructed stationary and provided with a charcoal discharging door on the bottom. They are not as convenient as the transportable ones and do not give the same quality of charcoal, because the discharging is done by dumping, which cause breakages of the charcoal.

C. *Continuously-working wood-distilling apparatus.*

The distilling apparatus above described is either operated intermittently or only partly continuously.

But there are some types of distilling apparatus which are designed for continuous working, as, for instance, the Swedish Groendal retort, which belongs to the type of the car retorts described on p. 777.

The Groendal retort consists of three main parts, namely:

1st. The drying chamber, built either of brick or of steel.

2nd. The distilling apparatus consisting of a horizontal steel retort.

3rd. The cooling apparatus for the charcoal, consisting of a steel cylinder of the shape of the retort.

These three parts are connected together but can be separated one from the other by means of vertical sliding doors of iron. The wood, loaded on cars, is filled in the drying chamber through which the exhaust combustion gases, escaping from the retort flues, are passed. After the drying is complete, the sliding doors between this drying chamber and the retort are lifted and the load transferred into the distilling zone of the system. This distilling apparatus is heated by any kind of heat generated by open fire or gas producers. The combustion gases travel around the steel shells, thus transmitting the heat to the wood inside the shell.

After the wood cars have passed the distilling part of the system, another slide door is opened and the cars with the finished charcoal are transferred into the charcoal cooling chamber, through which the cold non-condensable gases, escaping from the condensers of the wood-distilling apparatus, are passed in order to do the cooling work and preheat the gases. A double sliding door at the other end of the system allows the cooled cars with the cooled charcoal to be continuously passed out.

Another continuously working wood-distilling apparatus which may be mentioned here is the wood-gas producer, which, however, does not yield any charcoal. This wood-gas producer is used for the generating of heating gas from second-class cord wood or wood refuse in order to heat boilers and retorts, but also to recover, at the same time, the by-products of the destructive distillation of wood, viz. acetic acid and wood alcohol. These gas producers (Fig. 8) consist of a vertical brick or brick-lined steel furnace provided on the top with a funnel with double doors for filling the gas producer with wood while in work. The bottom of this gas producer is provided with an iron grate through which a certain amount of air is allowed to enter. The upper part is connected with a condenser. In order to start the gas producers, charcoal has to be put upon the grate and allowed to become red hot. Then the filling in of the wood is started by means of the double-door funnel above-mentioned. The condenser, connected with this gas producer, communicates by means of a gas flue with the smoke stack of the boilers or the retorts, and by the natural draught of this smoke stack a certain amount of air enters through the grate into the gas producer, generating producer gas when coming in contact with the hot charcoal. This hot producer gas carbonises the wood on the top of the charcoal zone on its way up to the outlet, and forms, at the same time, the products of the destructive distillation. These escape, together with the producer gas obtained by passing air through the hot charcoal layer, into the condenser, and while the non-condensable gases escape by the main gas flue, the vapours of pyroligneous acid and of tar are condensed and discharged by means of a siphon. In such a gas producer, there will be a hot charcoal zone on the bottom, above this there will be wood in the distilling state, and above this zone there will be another zone of wood in the drying period, and on the top of this drying zone there will be the zone of the green wood, filled through the funnel.

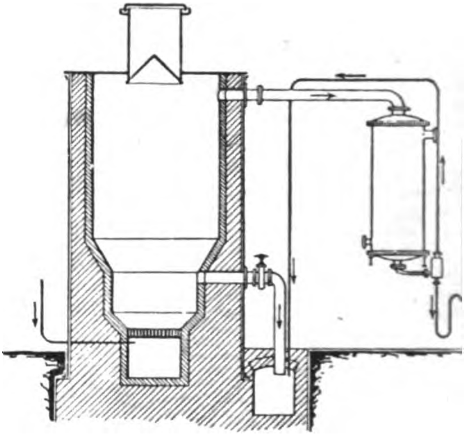

FIG. 8.

Wood-gas producers; type, F. H. Meyer. Hanover-Hainholz.

These gas producers are not very efficient; they yield no charcoal and only 50 p.c. of the amount of acetic acid and wood alcohol obtainable from the same amount of wood when distilled in retorts. But considering that they produce heating gas and at the same time allow 50 p.c. of the acetic acid and the wood alcohol to be recovered, they are important and economical in working under favourable conditions.

Apparatus for the destructive distillation of pine wood, rich in turpentine and rosin. As already mentioned, some varieties of pine wood contain, besides cellulose and lignin, large quantities of rosin and turpentine.

As it is the purpose of the pine wood distillation to separate the turpentine in its original state as much as possible before the destructive distillation of the cellulose, lignin and rosin sets in, the apparatus for the destructive distillation of pine wood of this kind must be provided by a heating system which allows a uniform transmission of heat to any and every part of the wood contained in the retort, or which at least allows the temperature to be under control.

It has been proposed to heat the retorts for this purpose by electricity instead of by an open fire or by superheated air or gases circulating around the retort; by oil or metal bath contained in a double jacket; or by superheated steam brought directly in contact with the wood.

These proposals are still in the experimental stage, but it would seem that these methods of heating are too expensive, inasmuch as a carefully designed gas-heating system, using gas producer gas or natural gas, will do the same work more economically.

Any one of the apparatus already described may in general be employed for pine wood distillation. But for recovering the turpentine in its original state, or at least not very much contaminated with the products of the destructive distillation of the wood and rosin, the smaller units (6 cords capacity) of car retorts, heated by means of uniformly distributed gas burners, are most to be recommended.

DESTRUCTIVE DISTILLATION OF WASTE WOOD OR SPENT WOOD.

The splitting of the logs and cutting these into cord wood furnishes a large amount of small-sized wood waste. Also cutting the log into timber and working up the timber furnishes another class of waste wood known as slabs, edgings, shavings, sawdust, and so on.

As long as this wood waste consists of pieces large enough to furnish charcoal of the usual size, it can be handled just as cord wood in the standard retorts, and it will yield almost the same amount of charcoal, wood alcohol and calcium acetate as cord wood obtained from the same log, when these figures are referred to the weight and not to the volume of the wood, as a cord of slabs or edgings will weigh very much less than a cord of real cord wood.

With regard to the destructive distillation of sawdust or shavings, this raw material is not capable of being distilled in any one of the standard apparatus previously described, on account of its voluminous character or by reason of the fact that there is not enough air space between the small, single wood pieces whereby the escape of the vapours and gases, formed on distillation, is rendered impossible. Back pressure, and under unfavourable circumstances even an explosion, will be the consequence of trying to distil sawdust or other wood of this form in the standard wood-distilling apparatus.

There have been numerous proposals to distil sawdust or other fine wood, and almost every one of these proposals is based either on the use of thin layers of sawdust or the use of stirring contrivances, or of a combined system of thin sawdust layers and stirring contrivances or scrapers, or finally on the briquetting of the sawdust before it is distilled.

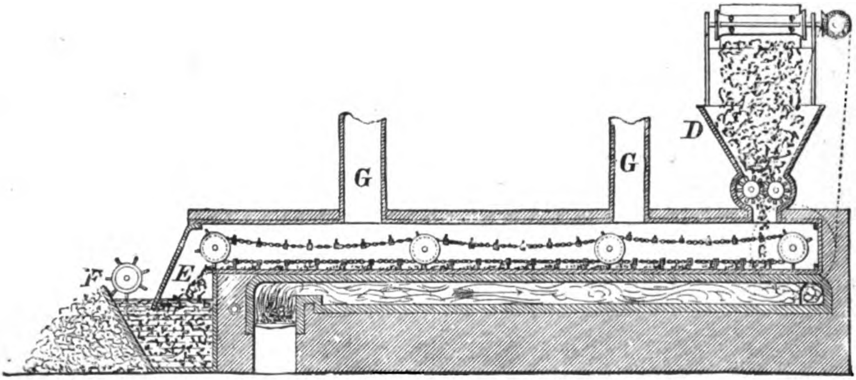

FIG. 9.

Retort for distilling small wood waste.

None of these apparatus has taken a practical form, at least on a large scale. Up to the present time, neither small nor large plants which handle sawdust or a similar class of wood, are operated economically on account of the large initial outlay, which is out of proportion to the value of the output and on account of the fact that there is no market, at a sufficient price, for the large quantities of charcoal powder produced.

Figs. 9 and 10 show types of apparatus which are used for this purpose. The apparatus (Fig. 9) transfers the sawdust continuously by means of scrapers over fire-heated steel plates, while in the apparatus in Fig. 10 the sawdust continuously drops down in thin layers by its own gravity between the space of the fire-heated shell of the vertical retort and the cast-iron rings, which serve as outlets for the vapours and gases.

TREATING THE CRUDE PYROLIGNEOUS ACID.

Crude pyroligneous acid consists of a watery solution containing acetic acid, wood alcohol and its companions (aldehydes, ethers, ketones, allyl alcohol, phenols) and tarry matters in solution. This brown liquid is further mixed with tar in suspension.

Crude pyroligneous acid cannot be sold in large quantities, but acetate of lime and crude wood alcohol are in large demand.

The object of treating the crude pyroligneous acid is to separate the acetic acid and the wood alcohol from the water and the tarry materials.

First the tar, suspended in the liquid, is separated by allowing the liquor to stand. The tar will settle either on the top or on the bottom of the pyroligneous acid and is then drawn off.

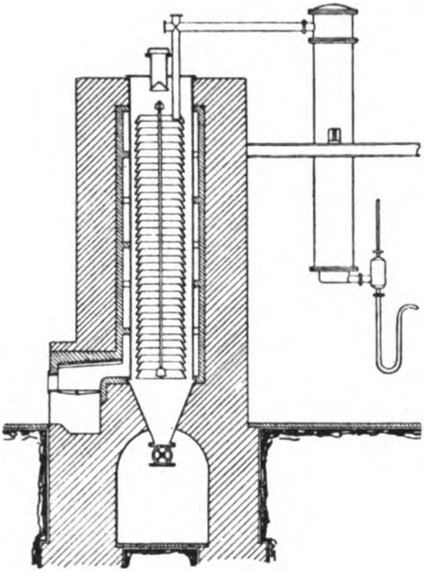

Fig. 10.

Vertical retort for the continuous distillation of small wood waste; type, F. H. Meyer.

But the remaining liquid still holds tar in solution and this dissolved tar must be separated in order to make marketable acetate of lime, which must contain at least 80 to 82 p.c. $(CH_3COO)_2Ca$.

There are several methods employed in order to separate the tarry matters in solution or suspension from the crude pyroligneous acid. The oldest process, still in use in some plants, consists in a simple redistillation of the crude pyroligneous acid in copper stills, connected with a condenser and heated either by an open fire or better by a steam coil (Fig. 11). The tar remains as a residue. The distillate is a more or less water-white liquid, which is now practically free from tar and contains principally water, acetic acid, wood alcohol and its associated products above mentioned.

This method of removing the dissolved tar by simple distillation requires about 50 p.c. of the total amount of fuel or steam generated in a wood-distilling plant.

The author of this article introduced new methods of distillation of the crude pyroligneous acid, and up to date the crude pyroligneous acid of about 1000 cords of wood is so treated.

This process is based on the principle of the multiple effect evaporators, originally used in the manufacture of sugar (Fig. 12). Two or more distilling stills are used, one connected with the other and provided with contrivances to maintain a different but gradually lowered boiling-point or a different but gradually lowered working pressure in each one of the stills. For instance, still 1 will be heated by steam of 15 lbs. pressure, using a steam coil or any other heating contrivance.

The liquor, surrounding this steam-heated contrivance, is kept under atmospheric pressure. The pyroligneous acid vapours, generated in still 1 by means of the heating effect of the steam, enter the heating contrivance of the second still, kept under a lower pressure by means of vacuum and therefore a lower boiling-point of the liquid than in still 1. Therefore the pyroligneous acid vapours, escaping from the first still, heat and distil the crude pyroligneous acid in the second still. This system can be continued indefinitely theoretically, but a system of four combined stills is all that can be reached practically.

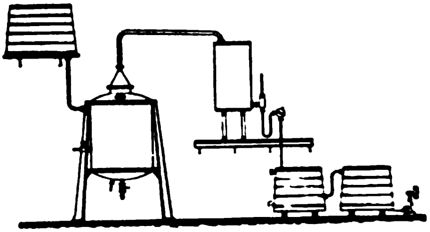

Fig. 11.

Apparatus for distilling crude pyroligneous acid; type, F. H. Meyer.

A distilling apparatus of this type requires only one-third of the amount of steam or fuel hitherto used for distilling the crude pyroligneous acid in simple distilling apparatus; or the saving may amount to 100 p.c. when sufficient exhaust steam is available. Fig. 12 shows such an installation, based on the multiple effect distilling system.

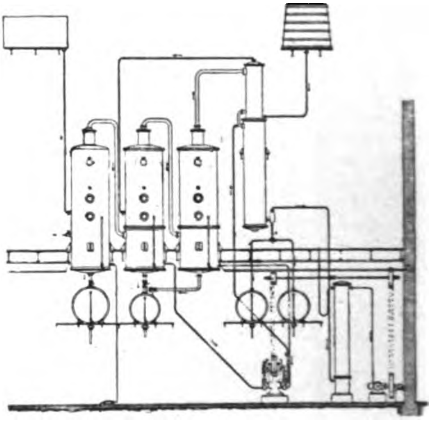

Fig. 12.

Apparatus for continuous distillation of crude pyroligneous acid in multiple effect distillers; type, F. H. Meyer.

Besides these two processes, used for redistilling the crude pyroligneous acid, there is another, employed more particularly in German plants.

This process combines the distillation of the crude pyroligneous acid with the neutralisation of the tar-free distillate by means of milk of lime or soda ash and the separation of the wood alcohol from the acetate solution.

The pyroligneous acid is distilled in a copper still, heated by a steam coil. Instead of passing the vapours of pyroligneous acid into a condenser, they are forced through milk of lime or soda ash solution, contained in closed copper or iron tanks, which are connected with a condenser (Fig. 13). The acetic acid thus combines with the lime or the soda, forming acetate solutions, whilst the wood alcohol and water vapours escape to the condenser from which an aqueous solution of the alcohol is discharged containing 5 to 12 p.c. wood spirit.

All the processes described above for removing tarry matters before treating the pyroligneous acid with milk of lime or soda ash solution, are based on the *distillation principle* and handle the gross distillate discharged from the condensers connected with the wood distilling apparatus.

The writer has introduced another patented process which is not based on the redistillation of crude pyroligneous acid, but depends on separating the total amount of tarry matters from the vapours escaping from the wood-distilling apparatus *before* these vapours are condensed. This is effected by washing the vapours and gases by means of crude wood tar or a mixture of crude wood tar and pyroligneous acid in two or more gas washing apparatus, which are combined together, and maintaining in each one a gradually decreasing temperature.

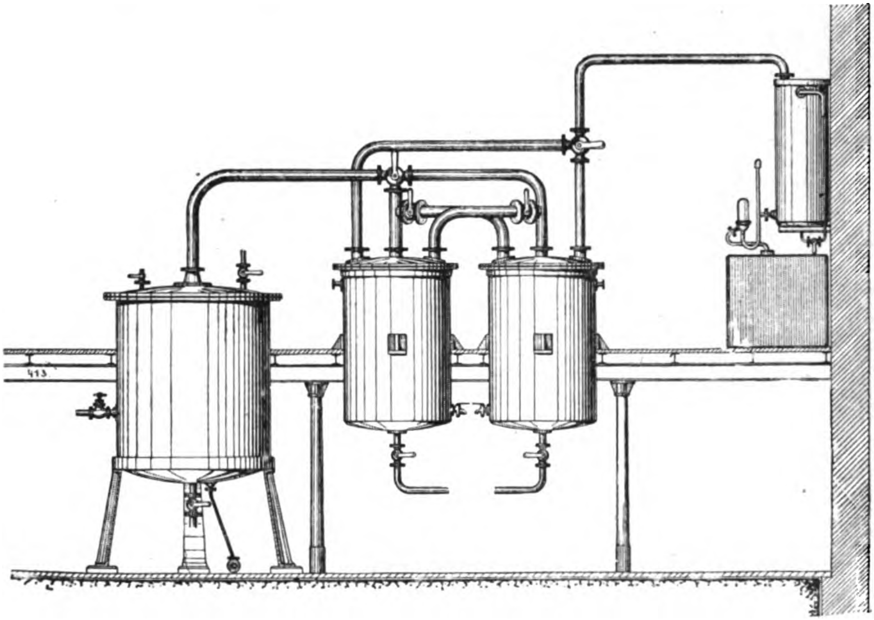

Fig. 13.

Apparatus for distilling crude pyroligneous acid by passing acid vapours through layers of milk of lime; type, F. H. Meyer.

For instance, in the tar washer 1, a temperature of about 300°F. may be maintained and in the last tar washer, or the washer next the condenser, a temperature of 212°F. may be maintained.

By the combined effect of the fractional condensation of the tar and of the absorbing affinity of the large amounts of tar used as a washing liquid, for the small amounts of tar contained in the form of vapours in the products, the pyroligneous acid discharged from the condenser will be practically free from tar and ready to be neutralised by milk of lime or soda ash.

This process is successfully used in many wood-distilling plants and saves entirely the expenses of the redistillation of the crude liquor.

Manufacture of Acetate of Lime from Crude Pyroligneous Acid.

As already mentioned, gray acetate of lime 80 to 82 p.c., is the product into which the acetic acid, contained in the pyroligneous acid, has to be transformed for the purposes of shipment.

The manufacture of gray acetate of lime starts with the tar-free distillate, obtained from the crude tar containing pyroligneous acid by one of the processes already described. This distillate is neutralised either by mixing it with milk of lime in a wooden tank, provided with a stirrer and cover, or by passing the vapours through layers of milk of lime.

The milk of lime combines with the acetic acid; it partly saponifies any methyl acetate; it transforms some of the aldehydes into insoluble rosins; and it combines with phenols, forming insoluble lime compounds. After adding the milk of lime, the neutralised liquor is allowed to stand in order that the precipitates, formed by the neutralising processes, shall settle.

The next operation on the settled liquid, containing principally wood alcohol and its associates, acetate of lime and water, consists in separating the wood alcohol from the aqueous solution of the acetate of lime, either in form of a weak alcohol solution by means of a simple intermittently operated still, or in form of concentrated wood alcohol by means of an intermittently or continuously operated rectifier.

The simple distilling still furnishes a weak wood alcohol solution, containing from 8 to 10 p.c. of wood alcohol, whilst the rectifier turns out by a single operation crude wood alcohol from 30 to 95 p.c., depending upon the design of the rectifier.

The simple still consists of a steel or copper still, provided with a copper heating coil and connected with a condenser.

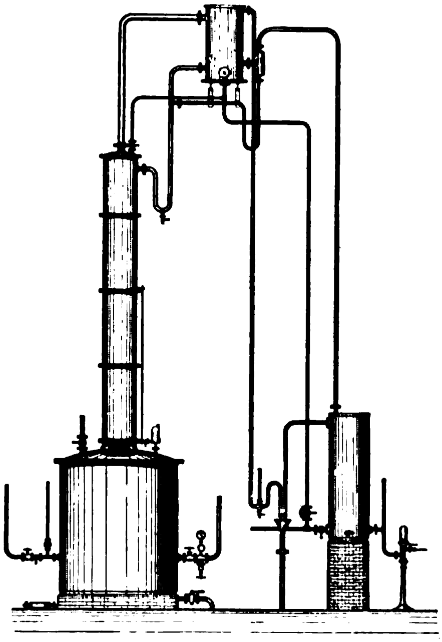

FIG. 14.

Intermittent-working rectifier for wood alcohol; type, F. H. Meyer.

The intermittently operated rectifier, shown in Fig. 14, is built of a steel or copper still with a copper heating coil, a copper column with rectifying sieve or bell plates, a separator and condenser. The working principle of these rectifiers is based on fractional distillation, and the 'columns' used for this purpose are very similar to those employed in manufacturing grain alcohol and known as the 'Savalle apparatus' from the name of the inventor. The continuously working rectifiers, for separating the crude wood alcohol in a concentrated state from the neutralised liquor, are the most modern and most economically working apparatus for this purpose (Fig. 15). They have been introduced in the wood-distilling industry by the author of this article, and they furnish by a single operation the so-called 'crude wood alcohol' of 95 p.c. and separate at the same time the oils, originally contained in the neutralised liquor and also the acetone, if desired.

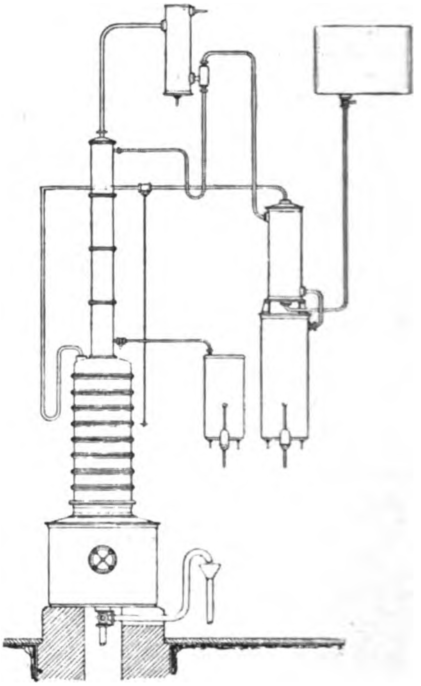

FIG. 15.

Continuous-working rectifier for wood alcohol; type, F. H. Meyer.

The continuously working apparatus are principally built of two columns; at the top of one column the neutralised liquor enters and the second column takes the wood-alcohol vapours escaping from the first column. The neutralised liquor travels in the first column *downwards* from plate to plate and meets on its way down the steam, entering into the bottom section. The wood alcohol, containing about 30 p.c. of wood alcohol and 70 p.c. of water, escapes from the top section of the first column, while the acetate of lime solution freed from wood alcohol, is continuously discharged from the bottom section of this column. The 30 p.c. wood alcohol vapours enter the bottom part of second column, and on their way *upward* from plate to plate they are concentrated by means of fractional distillation and discharged from the top section to a separator and from there to a final condenser, leaving the latter as a product containing up to 95 p.c. wood alcohol.

This product corresponds in chemical composition and physical characters with the so-called 'American Crude Wood Alcohol,' shipped in immense quantities from the United States to Europe. It still contains the total amount of acetone, aldehydes, ketones, esters, ammonia, amines, and allyl alcohol, originally contained in the neutralised liquor, and also some of th 'wood oils,' which always accompany the wood alcohol.

The average composition of this product may be given as follows :—

16 p.c. acetone and other ketones.
6 p.c. aldehydes, methyl acetate, amines, allyl alcohol and oils.
70 p.c. methyl alcohol.
8 p.c. water.

In order to manufacture 'pure' methyl alcohol from the crude wood alcohol, all these contaminating products have to be separated.

This is done by fractional distillation, carried out systematically by means of intermittently or continuously operated rectifiers, similar to those above described. The separation is usually assisted by adding chemicals—for instance, caustic soda and sulphuric acid—which destroy, polymerise, or saponify the products to be separated—for instance, aldehydes, esters, ketones, phenols, amines and so on.

The separation of the acetone and the allyl alcohol, which are always associated with the methyl alcohol, is *entirely done* by a carefully repeated fractional distillation, which yields the concentrated acetone in form of 'head ends' and the allyl alcohol in form of 'tail ends.'

A mixture containing in specified proportion these head ends and tail ends represents the 'denaturing wood alcohol,' used practically everywhere for denaturing alcohol. This material must conform to certain specifications and tests prescribed by the different Governments.

The final product of such a repeated fractional distillation, carried out either by intermittently working or continuously working rectifiers, represents the 'pure' methyl alcohol, which is free from acetone or contains only traces of it, and contains up to 99 p.c. real CH_3OH.

Besides this final product, free from acetone, and the 'denaturing wood alcohol' containing acetone, allyl alcohol, and other impurities, a number of other wood alcohol grades are on the market; for instance, 'pure' methyl alcohol of 99½ p.c. with 0·1 to 1 p.c. of acetone and many other grades demanded by customers.

The pure grades are used for the manufacturing of aniline colours, of formaldehyde, of perfumes; the other grades for varnishes, as solvents, and the poorest grades for denaturing or burning.

The distillation of the neutralised liquor yields, as above shown, two products :

Wood alcohol, as a volatile product;
Acetate of lime solution as a non-volatile residue.

This latter solution holds in suspension insoluble polymerised products, formed by a reaction between phenols and aldehydes with acetate of lime or traces of lime in excess, which must be settled by allowing the liquor to stand.

The settled solution contains varying quantities of acetate of lime, according to the nature of the original liquor and to the process used for distilling off the crude wood alcohol.

These quantities differ from 7 to 25 p.c.; this means, 100 lbs. acetate of lime solution may contain from 7 to 25 lbs. dry acetate of lime, 80–82 p.c. As it is impossible to recover the acetate of lime by a crystallising process on account of its equal solubility in cold and hot water, the solution must be boiled down until the salt is left in the solid state.

Up to the present this boiling was done in two steps. By the first step, the acetate of lime solution is evaporated in open, steam-heated, double-jacket pans (Fig. 16) just to the point at which the concentrated solution becomes solidified by crystallising. This point is reached when the acetate of lime solution contains about 35 to 40 p.c. of the dry salt. The crystallised magma is then spread out in thin layers upon an open drying floor, built of cast-iron plates or steel plates, heated by an open fire or by waste fire gases.

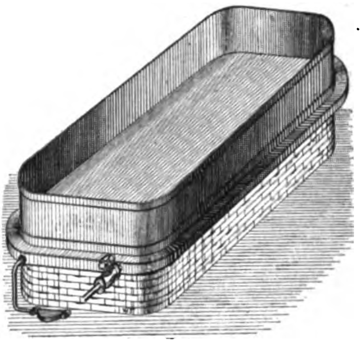

Fig. 16.

Open pan for evaporating acetate of lime solution.

The operation of boiling down the acetate of lime solution to a magma of crystal requires very large amounts of steam on account of the coating of the heating surface by crystals and scales and by the immense reduction of the heat transmitting capacity.

Furthermore, the drying upon an open drying floor necessitates much hand work, as the material must be turned over and gradually transferred from one end of the drying floor to the opposite one, whereby it travels with the current of the fire gases. This ensures that the wet acetate of lime, which can stand a high temperature, comes in contact with the hot fire gases, while the dried salt or partly dried salt comes only in contact with the fire gases of a lower temperature, in order to protect it against decomposition into acetone.

The author has introduced a drying process, in which the solution of acetate of lime will be continuously and mechanically evaporated and dried, doing away entirely with the steam-heated open pans and the high wages required by open drying floors.

By this new process, already in successful operation in plants of all sizes from 30 cords up to 250 cords, the acetate of lime solution is continuously evaporated in specially designed multiple effect evaporating apparatus, operated on the same principle as above described for the multiple green liquor distillers.

The weak solution enters the first evaporator, travels from there to the second, and from the second to the third, leaving the same or the last one as a concentrated liquor, which contains up to 30 to 35 p c. dry salt. This liquor will not crystallise when kept hot.

The liquor flows to a pan into which a rotary drum is dipping, heated inside by steam. This drum becomes coated with a thin layer of the concentrated solution.

While rotating, the thin layer dries quickly, and before the drum dips again into the concentrated solution the magma of crystals, which now coat the surface of the drum, is scraped off by means of knives, working on the surface of the drum (Fig. 17).

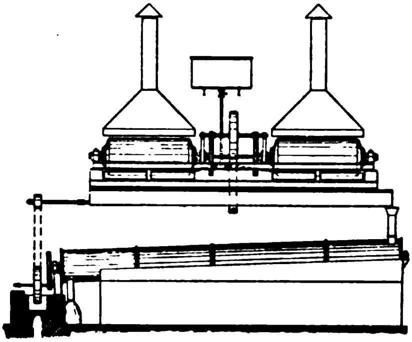

Fig. 17.

Continuous-working rotary evaporator for evaporating and drying acetate of lime; type, F. H. Meyer.

The magma of crystals then travels by means of a conveyor to a belt dryer, built of endless canvas belts or wire cloth belts, upon which the wet salt is transferred against a current of hot air or over pipe coils, heated by exhaust steam. This new type of apparatus for evaporating and drying acetate of lime does away with any kind of hand work; it obviates the disagreeable and unhealthy work of drying upon an open floor; and it saves almost all the wages hitherto spent for drying, and it saves, too, large amounts of fuel. Moreover, the acetate of lime obtained by this process, is of an even form like peas; it does not contain much dust; it is of a brighter colour and is soft and voluminous, yielding on this account more acetic acid and acetone, when worked up into these products.

Manufacture of Acetate of Soda.

Next to acetate of lime, acetate of soda is the most important salt of acetic acid manufactured in wood-distilling factories.

In order to produce sodium acetate in a crystallised state, the distillate of pyroligneous acid, obtained by one of the processes already described, is neutralised by soda ash. The acetate of soda solution is then freed from wood alcohol by the methods before mentioned, and boiled down by open double-jacket pans, or by modern multiple effect evaporating apparatus, until the crystallising point is reached. By the next step the condensed solution is completely dried in cast-iron, fire-heated pans, provided with scrapers, and the heating is continued until the whole of the water is driven off and the anhydrous sodium acetate is completely melted, when the liquid mass will have a temperature of about 320°. At this temperature, sodium acetate is not decomposed, but sodium propionate and butyrate, as well as tarry or resinous matters present in the original product, will be destroyed and converted into insoluble matters.

After melting, the mass is dissolved in water to form a concentrated solution and the charred matter separated by filtering the solution, usually by a filter press. The filtrate is transferred to crystallising vessels and the crystals

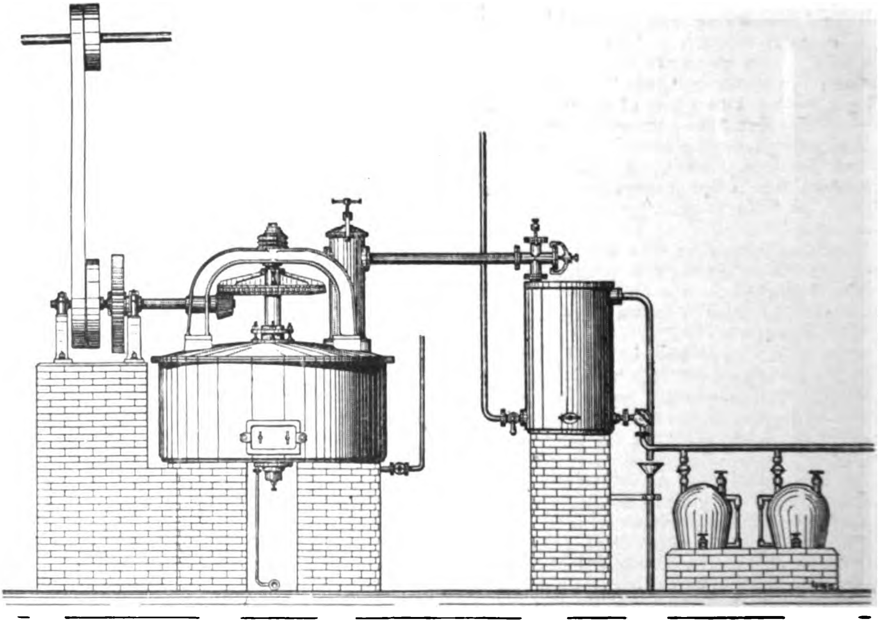

Fig. 18.

Cast-iron still for decomposing acetate of lime by sulphuric acid; type, F. H. Meyer, Hanover-Hainholz.

and mother liquor separated by a centrifugal machine. The crystals are recrystallised and the mother lees returned to the evaporating pans.

Treating of the Primary Marketable Products resulting from the Destructive Distillation of Wood.

The first products resulting from the destructive distillation of wood are: charcoal, crude pyroligneous acid, tar, when hard wood is distilled; or charcoal, crude pyroligneous acid, crude turpentine, crude pine oil and crude pine tar, when pine wood, containing turpentine and rosin, is employed. Of these, the charcoal only is ready for sale. The other products must be further treated in order to convert them into marketable commodities.

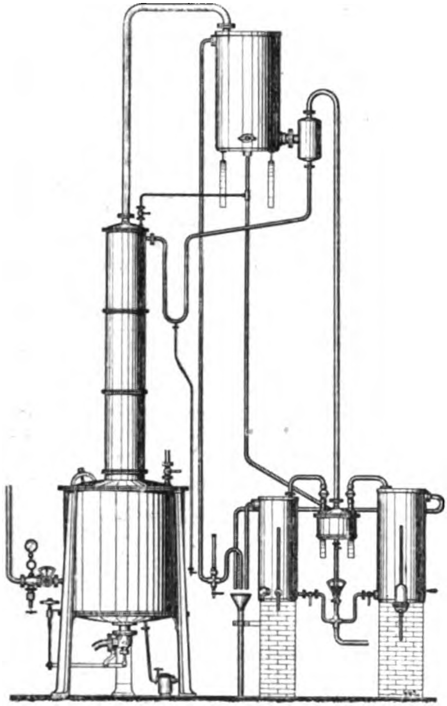

Fig. 19.

Apparatus for rectifying crude acetic acid in order to manufacture glacial acetic acid; type, F. H. Meyer.

From the crude pyroligneous acid acetate of lime, acetate of soda and crude wood alcohol are obtained, and from the latter the 'pure' methyl alcohol, the refined wood alcohol, and the denaturing alcohol as above described.

Many of the wood distilling factories work up the acetate of lime into acetic acid or acetone and the methyl alcohol into formaldehyde.

Manufacture of acetic acid. In order to manufacture acetic acid, only acetate of lime, 80–82 p.c., is used nowadays as raw material. This is mixed with sulphuric acid of 92 to 98 p.c. in a closed cast-iron still, provided with stirrer and scrapers and heated by high-pressure steam, (Fig. 18). After the mixing process is finished the acetic acid is distilled off, a vacuum being maintained in the still during the process of distilling. The crude acetic acid, resulting from the process, contains about 80 p.c. acetic acid (propionic and butyric acid included), traces of sulphur dioxide, and is of a yellow colour. This acid can be used for many purposes in the arts, as, for instance, manufacturing white lead, amyl acetate, &c.

In order to produce 'pure' glacial acetic acid of 96 to 99½ p.c., the crude 80 p.c. acetic acid, obtained by the action of sulphuric acid on acetate of lime, must be rectified in a copper rectifier (Fig. 19).

First a weak acetic acid is obtained containing propionic and butyric acid; then the distillate becomes gradually stronger and after distilling over 40 to 50 p.c. of the original charge, glacial acetic acid distils over: this has a melting-point of 14°–16° and contains 99 to 99½ $CH_3{\cdot}COOH$. At the end of the process the melting-point again falls, and with it the content of acetic acid owing to the presence of propionic and butyric acids.

In order to manufacture 'pure' acetic acid, 99½ p.c., corresponding to the requirements of the pharmacopœas of different countries, the glacial acetic acid, obtained from the first rectification of the crude 80 p.c. acetic acid, will be oxidised and then redistilled by use of a simple still connected with a silver condenser.

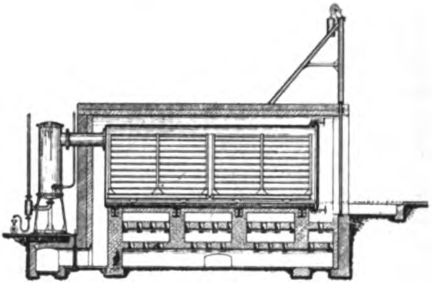

Fig. 20.

Retort for decomposing calcium acetate; type, F. H. Meyer.

Manufacture of acetone. Acetone is manufactured by the dry or destructive distillation of calcium acetate. The process corresponds theoretically with the equation:

$$\left.\begin{matrix}CH_3COO\\CH_3COO\end{matrix}\right\}Ca=CaCO_3+CH_3-CO-CH_3$$

According to the author's patented process, used in most of the existing acetone factories, acetate of lime is spread out in thin layers on steel plates, to be placed one above the other upon platforms on steel cars, allowing sufficient clearance from platform to platform (Fig. 20). These cars are pushed into horizontal steel retorts, heated by fire gases. The retorts are capable of treating from 3000 to 15,000 lbs. of calcium acetate in 24 hours and are connected with a condenser. The destructive distillation sets in at about 300°. After the charge is charred, the cars are withdrawn and other cars, already loaded, charged into the retort.

By the older acetone process, calcium acetate was distilled in charges not exceeding 1000 lbs.

by means of fire-heated, closed, cast-iron pans, provided with a stirrer and scrapers. But these forms of apparatus yielded only 17 lbs. 'pure' acetone from 100 lbs. of calcium acetate instead of from 20 to 21 lbs. as obtained by the process above described.

There is a third process used, based on the distillation of calcium acetate by means of a stream of superheated steam which is brought directly in contact with the acetate.

The crude acetone obtained by one or other processes contains, besides the acetone, tarry matters, formic and acetic acids, aldehydes, ketones formed by the propionic acid and butyric acid originally contained in the crude material, hydrocarbons, and other products.

By means of repeated fractional distillation, assisted by the use of small amounts of caustic soda and sulphuric acid, acetone of 99½ p.c. is obtained, whilst the tarry matters remain in the residue. The acids are fixed by the alkalis, which destroy the aldehydes, and the foreign ketones and hydrocarbons are obtained as 'tail ends' from the rectifier, from the fact that their boiling-point is considerably higher than that of acetone.

FORMALDEHYDE.

This important disinfectant is obtained from the 'pure' methyl alcohol by oxidising it by the oxygen of the air under the influence of catalytic agents: $2CH_3{\cdot}OH+2O=2CH_2O+2H_2O$. The manufacturing process differs in some respects from the theoretical equation, as side reactions set in whereby a part of this formaldehyde is broken up into carbon monoxide and hydrogen, according to the equation $CH_2O=CO+2H$.

The excess of oxygen under the influence of the red hot catalytic material combines with the carbon monoxide as well as the hydrogen:

$$CO+O=CO_2$$
$$H_2+O=H_2O$$

Carbon dioxide and water are products formed by another side reaction.

Theory indicates that 93·75 lbs. of formaldehyde of 100 p.c. should be obtained from 100 lbs. methyl alcohol of 100 p.c., but by the best practical process only 80 lbs. formaldehyde, as a maximum, can be obtained, which means only about 85 p.c. of the theoretical yield.

The product on the market is an aqueous solution of formaldehyde, containing from 35 to 40 p.c. CH_2O by weight. This solution is liable to polymerise, forming paraformaldehyde by the condensation of 3 mols. of CH_2O, a product which is not soluble in water and therefore causes the solution to become more or less turbid.

In order to avoid this polymerisation and to meet commercial demands, various substances are added to the formaldehyde solution. As methyl alcohol has the peculiar property of preventing polymerisation, a certain amount is added to the formaldehyde solution of the market, which averages

35–40 p.c. (by weight)	CH_2O
12–15 p.c.	$CH_3{\cdot}OH$
53–45 p.c.	H_2O

This solution is manufactured by mixing vapours of methyl alcohol with a corresponding amount of air.

The processes adopted for manufacturing formaldehyde differ in regard to the apparatus or contrivances used for furnishing this vapour mixture *of a constant composition*.

About half the factories existing at present are using the author's process, which is a continuous one, whereby liquid methyl alcohol is introduced in the form of a spray into the top section of a so-called 'carburator' (constructed on the same principle as that used for carburetting coal gas with benzene) and at the same time blowing a stream of hot air which enters the bottom of the 'carburator' against the methyl alcohol spray, whereby the methyl alcohol will be evaporated and mixed with the air in the right proportion. The mixture of methyl alcohol vapour and air is passed over the catalytic material, consisting of rolls of copper wire-net heated to about 400°, before allowing the mixture of methyl alcohol and air to enter.

To avoid explosions and to prevent the methyl alcohol burning into carbon dioxide and water, an excess of methyl alcohol must be used.

The product of the reaction, that is the vapours escaping from the apparatus, contain this excess of methyl alcohol, which is recovered by a fractional condensation of the escaping vapours, whereby the formaldehyde solution will be condensed first and the methyl alcohol last.

As already mentioned, the whole process is a continuous one, as methyl alcohol and air enter at one end of the apparatus, and the formaldehyde solution, the excess of the methyl alcohol used, and the nitrogen with the gases formed by the reactions will be discharged, of course each one separately, on the other end of the apparatus (*v.* FORMALDEHYDE).

CRUDE HARD-WOOD TAR.

The hard-wood distilling process yields two kinds of tar, namely: *the settled tar*, deposited from the crude pyroligneous acid; the *residue tar*, obtained as a residue by distilling the crude pyroligneous acid.

The composition of these two varieties of tar is quite different, as the 'residue tar' contains principally pitch and pyroligneous acid, whilst the 'settled tar' contains, besides pitch and pyroligneous acid, the total amount of phenols and hydrocarbons, usually called 'tar oils.'

There are no two samples, taken from different plants, which are alike, and therefore exact figures concerning the composition of tar, obtained by the destructive distillation of wood, cannot be given.

Wood-tar is a burden on the hands of the wood distillers, on account of the difficulties it causes in the treatment of the pyroligneous acid, and on account of its small value as a commercial article.

The coal tar industry furnishes pitch and tar oils much cheaper and in much greater quantities than can be obtained from wood tar. The treatment of tar has therefore no great importance for the wood distiller, and usually it is limited to the recovery of the wood alcohol and acetic acid, the remaining tar compounds being, for the most part, used as fuel.

In order to recover methyl alcohol and

pyroligneous acid, contained in both varieties of tar, the tar is subjected to distillation in copper stills, provided with a heating coil and also a perforated coil for adding live steam.

The water with the acetic acid, as well as with the wood alcohol, and light wood oils floating on water, is distilled, and when by increased steam supply the amount of distillate diminishes, live steam is added by the perforated coil and the distillation continued until the distillate contains only a small amount of acids. The distillate is allowed to stand, whereby the light oils rise to the top. The clear liquid is drawn off and treated together with the distillate obtained from the bulk of the crude pyroligneous acid.

The residue of this tar distillation, or that obtained by distilling off the pyroligneous acid from the tar, is a liquid similar to thick molasses, and is generally used as fuel which is burned by spraying it by means of steam into the fireplaces of boilers or retorts. Sometimes the settled tar is subjected to distillation in order to recover the heavy tar oils, containing the phenols and creosote and to manufacture pitch. Such distillation must be carried out in cast-iron stills, heated by an open fire. First the light oils, floating on water, and the pyroligneous acid distil over, as in the process described above. This phase of the distillation must be done very carefully on account of the frothing to which the tar is liable. After this period is over and when only small amounts of water flow from the condenser, the fire can be increased, when heavy tar oils, sinking in water, distil over. The distillation will be continued until the pitch, left as a residue in the still, proves to have the melting-point desired.

Sometimes hard pitch with a high melting-point, sometimes soft pitch with a low melting-point is the purpose of this distillation.

The heavy tar oils or the oil which sinks in water are usually sold to chemical works, which manufacture creosote, and only exceptionally are they sold for the manufacture of dyes. Only a very few factories deal with the recovery of creosote, which is contained up to 1 p.c. in the hard wood tar, particularly in beech tar.

The raw material is the 'heavy tar oil' obtained by the distillation of the settled tar in fire-heated stills. These oils still contain considerable amounts of tar and must be redistilled before being subjected to any other treatment. The redistilled oils are then subjected to a systematic extraction by means of caustic soda solution, which separates the total amount of phenols from the bulk of hydrocarbons contained in the tar oils.

The alkaline solution of phenols is then mixed with acid, usually a mineral acid, liberating the phenols, which are drawn off from the salt solution, after allowing the mixture to stand. Repeated fractional distillation is the next operation to which these mixtures of phenols are subjected in order to concentrate the fractions which contain the real creosote. These fractions are again subjected to repeated treatment with caustic soda and mineral acid, and from the last fractions of the distilled creosote, 'pure' creosote is obtained.

Crude turpentine and crude pine tar. As described above, the destructive distillation of pine wood, rich in turpentine and rosin, yields the turpentine, partly in the state as originally contained in the wood, partly contaminated or mixed with the products of the destructive distillation of cellulose, lignin and rosin, *i.e.* with tar, tar oils, rosin oils, &c. The more nearly the distilling apparatus allows of a uniform distribution of heat to each piece of wood contained in the retort, the better will be the separation of the real turpentine, uncontaminated with the products above mentioned.

The destructive distillation of pine wood containing turpentine and rosin, yields three fractions, which are usually taken separately:

Fraction 1, containing only small amounts of tar, tar oils and rosin oils.

Fraction 2, containing less than 50 p.c. of the contaminating products.

Fraction 3, containing more than 50 p.c. of the contaminating products.

Fraction 1 represents the material, called 'crude wood turpentine,' which is exported from Sweden and Russia and which is also manufactured in many factories situated in the Southern States of America, as Georgia, Alabama, Virginia, &c.

The 'crude wood turpentine' obtained by destructive distillation consists principally of terpenes. In addition it contains tar, acids, phenol, aldehydes, furfural, 'silvan,' dimethylfurfural, benzene, toluene, xylene, diacetyl, acetyl-propionyl, &c.

The first treatment consists in fractionally distilling the crude wood turpentine by means of steam-heated stills, which allows also of the addition of live steam (Fig. 21), whereby the turpentine is separated from the products of lower and higher boiling-point. After the products of lower boiling-point have been got rid of, live steam is turned on and the mixture of vapours of turpentine and water is passed through caustic soda solution or milk of lime in a container connected with the still and the condenser.

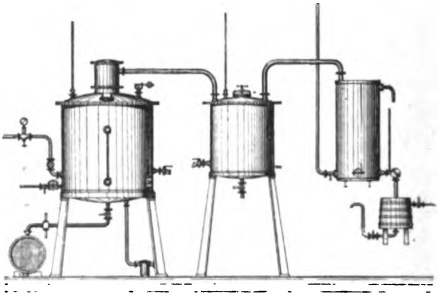

Fig. 21.

Distilling apparatus for separating turpentine from pine-wood tar-oils and pine-wood tar; type, F. H. Meyer.

Phenols, rosin oil, aldehydes, acids, &c., are kept back or destroyed by the alkaline bath, whilst the turpentine and water vapours escape to the condenser and are separated after their condensation by their varying specific gravity.

The refined turpentine obtained by this process is of a water-white colour, but its smell is not 'sweet' enough to meet the requirements of the market.

It is therefore subjected to a second alkaline treatment and then to a treatment with sulphuric acid, whereby other contaminating products will be separated or destroyed.

Finally a fractional vacuum distillation by means of steam-heated rectifiers yields a product, which is now of a water-white colour, of a 'sweet' smell, and has the same boiling-point, specific gravity, and optical characteristics as ordinary turpentine.

'Pine wood tar' is obtained as the residue of the first distillation of the crude wood turpentine.

The second fraction of the destructive distillation of pine wood, containing up to 50 p.c. tar and rosin oils, is also subjected to distillation as above described. The distillate is a mixture of turpentine, other terpenes and hydrocarbons of a higher boiling-point, called 'pine oil,' and the residue consists of pine tar.

The mixture of turpentine and pine oil is then subjected to fractional distillation by means of a vacuum rectifier and the turpentine obtained by this treatment mixed and treated together with the refined turpentine obtained from the first fraction.

The third crude fraction, mainly consisting of tar, is subjected to similar treatment and furnishes pine oils and, as a residue, the bulk of pine tar. M. K.

WOOL. The woolly covering of the sheep is composed of modified hairs which grow in the same manner as the hairs of other animals, but differ from them considerably in physical structure and characteristics, including fineness, softness, waviness, and highly serrated surface. The wool fibre arises in the dermis or middle layer of the skin. Its root or follicle is a gland which produces a lymph-like secretion which nourishes the hair during its development and growth. This gland also secretes an oily substance, the wool-oil, which becomes a constituent part of the fibre and improves its elasticity and flexibility. Contiguous to the follicle are the sebaceous glands which secrete a fatty substance, the wool-grease, which coats the surface of the fibres, thereby protecting them from mechanical injury during growth and preventing them from becoming matted or felted together.

The dried perspiration of the animal also adheres to the fibres and can be removed by means of cold water in which it is soluble. It consists largely of a mixture of potassium salts, and is usually recovered as a by-product of the industry. The residue obtained after treating the wool with cold water and evaporating the solution to dryness is known as 'sudorate of potash.' Raw wool yields about 8 p.c. of this product.

Before the wool can be used for the manufacture of textiles, not only must the dried perspiration be removed, but also the wool-grease; the extraction of the latter is generally effected by the process of scouring with soap and water. In order to avoid the removal of the wool-oil from the interior of the fibre, the temperature at which the scouring is carried out does not usually exceed 50°.

When examined with the microscope, the typical wool fibre presents the appearance of a more or less cylindrical rod covered with irregularly-shaped scales which overlap one another by their free margins and cause the fibre to exhibit numerous serrations. The free edges of the scales always point in the direction of growth of the fibre. It is to this peculiar imbricated nature of the surface that the felting property of wool is due. The shrinking which wool fabrics undergo on washing is also attributable to the serrations; the rubbing of the material causes the projecting edges of the scales to become closely interlocked, and thus reduces the amount of space occupied by the fibres, and this behaviour is facilitated by the lubricating action of the soap. The cortical layer beneath the scales constitutes the bulk of the fibre and is composed of long, narrow cells with pointed ends. Within this is the medulla which consists of larger and rounded cells and often contains pigment to which certain wools owe their characteristic colour. In the finer wools, the medulla is often so much reduced as to be almost indistinguishable. The wool of carelessly-bred sheep frequently contains defective fibres in which the scales and cellular structure are but slightly developed; these appear as stiff, straight, coarse, opaque hairs which cannot be dyed, and are termed 'kemps.'

The value of wools and their suitability for different purposes depend very largely on their physical properties, such as length, strength, elasticity, fineness, softness, curliness or waviness, lustre, felting property, colour, and freedom from impurities and kemps. The extent to which a wool possesses these characters varies greatly with the particular breed of sheep, the climatic conditions, the nature of the pasturage, and the care exercised in selection and rearing. The quality of the fibre also varies considerably in different parts of the same fleece. The wools of commerce may be roughly divided into three classes: (1) long-stapled, (2) medium-stapled, and (3) short-stapled.

(1) The long-stapled class includes the typical English varieties, such as the Lincoln, Leicester, and Cotswold wools. The fibre is from 6 to 10 ins., or even up to 15 ins. in length, has an average diameter of about 0·001 inch, and bears from 600 to 1400 serrations per inch. It is nearly white, lustrous, of good elasticity, and has a smoother surface and less wavy character than the fibres of the other classes. The scales are horny and closely attached to the cortical layer and, in consequence, the felting power is poor. These wools are specially adapted for the manufacture of worsted yarns.

(2) The medium-stapled class is represented by the wools produced by the Southdown sheep and those of the Cheviot Hills, Shropshire, Hampshire, Oxfordshire, and Dorsetshire; it also includes certain cross-bred wools, such as those of Australia, New Zealand, and South

America, which are produced in very large quantities. The characters of the fibre are intermediate between those of the long- and short-stapled kinds. The length is from 3 to 8 ins., the average diameter about 0·0008 in., and the average number of serrations is about 2000 per inch.

(3) The short-stapled class comprises the finest grades of wool, including those of the merino type of Australia, South America, and the Cape Province of South Africa. The fibre is from 2 to 5 ins. long, has an average diameter of about 0·0005 in., and bears about 2800 serrations per inch. It is either white or of a greyish tint, has little or no lustre, and is very elastic, very soft, and curly. The scales are small and adhere to the cortical layer by only a small portion of their length, so that the upper part is free and protruding, and for this reason the wool has good felting properties. Wools of this class are particularly suitable for the manufacture of woollen fabrics.

Wool fibre is composed of a protein substance of the group known as the keratins, which also includes those derived from hair, horn, whalebone, feathers, and egg-membrane. All the members of this class differ from other proteins in yielding a large proportion of cystine on hydrolysis. The average elementary composition of wool keratin is approximately as follows: C, 51; H, 7; O, 21; N, 17; S, 4 p.c.

Sulphur is the most variable constituent and ranges from 2·5 to 4·5 p.c. Raikow (Chem. Zeit. 1905, 29, 900) found that when wool is kept for some time in contact with syrupy phosphoric acid, sulphur dioxide is evolved. Baudisch (*ibid.* 1908, 32, 620) confirmed this result and also showed that the sulphur of wool is partly oxidised to sulphur trioxide by the action of hydrogen peroxide. The experiments indicate that some of the sulphur is in direct combination with oxygen and is probably present in the form of a sulphite-like complex. This conclusion, however, has been challenged by Strunk and Priess (Zeitsch. physiol. Chem. 1912, 76, 136).

Schützenberger (Compt. rend. 1878, 86, 767) investigated the decomposition of wool keratin by solution of barium hydroxide at 170°, and found that 100 grms. of purified wool yielded nitrogen (evolved as ammonia), 5·25 grms.; carbon dioxide, 4·27 grms.; oxalic acid, 5·72 grms.; acetic acid, 3·2 grms.; pyrrole and volatile products, 1–1·5 grm.; whilst the residue consisted of leucine, tyrosine, and other nitrogenous substances.

The hydrolysis of wool keratin by hydrochloric acid was studied by Abderhalden and Voitinovici (Zeitsch. physiol. Chem. 1907, 52, 348), and it was found that various amino acids were produced in the following quantities p.c.: glycine, 0·6; alanine, 4·4; valine, 2·8; leucine, 11·5; tyrosine, 2·9; serine, 0·1; cystine, 7·3; proline, 4·4; aspartic acid, 2·3; and glutamic acid, 12·9. A comparison of these results with those obtained by the hydrolysis of the keratins of hair, horn, and feathers showed that all these substances are different, and led to the conclusion that keratin is a mixture of proteins.

Purified wool contains 1–2 p.c. of mineral constituents. The following analyses of the ash of a sample of Lincoln wool are due to Bowman. The wool, after being scoured, washed, and dried, yielded 1 p.c. of ash, of which 75 p.c. was soluble in water.

	Whole ash	Soluble ash	Insoluble ash

Scoured wool usually contains about 13–14 p.c. of water. The fibre is hygroscopic and the amount of moisture present therefore varies a good deal with the state of the atmosphere. On this account, it is the custom for the moisture in a consignment of wool to be estimated before sale, and the true selling weight calculated on a certain standard percentage of moisture, the so-called 'regain.' The standard adopted at Bradford and Manchester for scoured wools is 16 p.c. of the weight of the dried fibre.

Wool is very susceptible to attack by dilute alkali hydroxide and is easily dissolved by a boiling 5 p.c. solution of sodium hydroxide. This reaction is employed for estimating the amount of wool in a material composed of a mixture of this fibre and cotton. When, however, wool is treated at the ordinary temperature with a strong solution of sodium hydroxide (sp.gr. 1·4–1·5), the fibre is not destroyed, but becomes white and lustrous, acquires a 'scroop' (the grating sound caused by rubbing the fibre) resembling that of silk, shows a greater affinity for dyestuffs, and increases in strength to an extent of about 30 p.c. Wool treated in this manner is said to be 'mercerised.' The process results in the removal of a large proportion of the sulphur; Matthews found that a sample of wool, originally containing 3·42 p.c. of sulphur, retained only 0·53 p.c. after being mercerised.

Strong solutions of potassium and sodium carbonate at high temperatures cause the disintegration of the fibre; but weak solutions at moderate temperatures are not injurious, and are extensively used in the scouring process.

By boiling purified wool with solution of barium hydroxide, removing the excess of the reagent with carbon dioxide, and adding solution of lead nitrate, a precipitate is produced which on treatment with hydrogen sulphide yields a product termed 'lanuginic acid' (Champion, Compt. rend. 1871, 72, 330). This substance has been re-examined by Knecht (J. Soc. Dyers, 1889, 71), who describes it as a brownish-yellow solid which dissolves slowly in cold water and easily in hot water. Its aqueous solution precipitates acid and basic colouring matters with formation of coloured lakes. Knecht found the substance to have the following composition: C=41·61; H=7·31; N=10·26; S=3·35; O=31·44.

Wool is completely destroyed by strong mineral acids, but is little affected by dilute acids. When heated with dilute nitric acid, the fibre assumes a permanent yellow colour. If it is warmed with dilute sulphuric or hydrochloric acid, it becomes harsher to the touch and acquires an increased affinity for dyes. The resistance of wool to the action of sulphuric acid enables it to be quantitatively estimated in a fabric composed of a mixture of wool and cotton or other vegetable fibre. The fabric is steeped for some hours in a mixture of equal volumes of concentrated sulphuric acid and water, with the result that the vegetable fibre is destroyed, whilst the wool is not attacked and can be collected, washed, dried, and weighed.

Nitrous acid seems to diazotise the amino groups of wool keratin. Wool which has been treated with this reagent is harsh to the touch, non-hygroscopic, and assumes various colours when brought into contact with alkaline solutions of certain phenols.

Wool is very little affected by dry chlorine, but is decomposed by the gas in presence of moisture. The fibre is capable of absorbing chlorine from weak solutions and becomes harsh, acquires a 'scroop,' loses its felting properties, thus becoming 'unshrinkable,' and also acquires an increased affinity for colouring matters.

For further information, reference should be made to Bowman's Structure of the Wool Fibre, or to Matthews' Textile Fibres. E. G.

WOOL BLACK, *v.* Azo- colouring matters.

WOOL OILS. Under the trade term 'wool oils' or 'cloth oils' are comprised all those oils that are used by woollen manufacturers for lubricating the wool before spinning, or for oiling the rags before 'grinding' and 'pulling.'

The best wool oils consist of pure fatty oils, such as olive oil, lard oil, neat's foot oil. Besides these, oleic acid ('saponification oleine' or 'saponified oleine,' 'distillation oleine' or 'distilled oleine' (*see* Saponification)) is used largely as a cheaper kind of wool oil.

The tendency to produce cheap wool oils, especially those for use with the lowest textile goods, has led to the employment of 'distilled grease oleine,' and even 'waste oils,' such as 'black recovered oil,' 'seek oil,' and 'brown grease oil.' The last-named oils contain considerable amounts of unsaponifiable matter. Besides these oils there are found in commerce large quantities of 'manufactured oils,' representing blends of the above-named wool oils, as also blends containing mineral oils. For the examination of wool oil *see* Lewkowitsch, Chem. Techn. iii. 77. J. L.

WOOL SCARLET *v.* Azo- colouring matters.

WOOTZ. An Indian name for steel.

WORMSEED *v.* Santonica.

WORMSEED, OIL OF, *v.* Oils, essential.

WORMWOOD. The leaves and tops of *Artemisia Absinthium* (Linn.) contain a volatile oil, *absinthol* (*q.v.*) and a bitter principle, *absinthin* (*q.v.*). Wormwood is a bitter stomachic tonic, and is used in medicine as a remedy for atonic dyspepsia, and as an anthelmintic.

WORT *v.* Brewing.

WOURALI, WOURARA, WOURARI *v.* Curara.

WULFENITE (*Gelbbleierz Molybdänbleispat*, Ger.). A mineral consisting of lead molybdate $PbMoO_4$ crystallising in the tetragonal system (hemimorphic-tetratohedral class) and isomorphous with scheelite (*q.v.*). Next to molybdenite (*q.v.*) it is the most abundant of the few minerals containing molybdenum. It has been found in some quantity at Bleiberg in Carinthia, and at several places in Arizona, Nevada, and Utah, often as beautifully crystallised specimens of rich yellow or red colours. L. J. S.

WURTZITE. A native form of zinc sulphide (ZnS) crystallising in the hexagonal system, and thus dimorphous with the more common cubic mineral blende (*q.v.*). It was described from Oruro in Bolivia by C. Friedel, and named after the French chemist C. A. Wurtz (1817–1884). Crystals are hemimorphic and very like those of zincite (ZnO, *q.v.*); but, as a rule, the mineral forms fibrous masses. Much fibrous and shelly blende which is optically birefringent, and known by the names 'spiauterite' and 'Schalenblende,' really belongs to this species; and it sometimes, no doubt, forms an important part of massive zinc sulphide ore. The phosphorescence shown by the mineral when struck has often been observed by miners. The hexagonal zinc sulphide used for coating phosphorescing screens in Röntgen ray work is the artificially prepared material. This was first obtained by J. Durocher in 1851, by E. H. Sainte-Claire Deville and L. Troost in 1861, and more successfully by T. Sidot in 1866 (Compt. rend. 62, 999; 63, 188). Sidot obtained long, colourless and transparent, hexagonal prisms by subliming blende in a current of sulphur dioxide.

L. J. S.

X

XANTHEIN. The name applied by Fremy and Cloez to the soluble yellow colouring matter of flowers.

XANTHENE COLOURING MATTERS, a name sometimes applied to the dyestuffs containing the group  and including the *pyronines*, colouring matters and triphenylmethane colouring matters (*q.v.*).

XANTHIC ACIDS (*Alkyloxydithiocarbonic acids*) RO·CS·SH, may be prepared by dissolving sodium in the required pure dry alcohol and adding the calculated quantity of dry carbon disulphide, the mixture being stirred and cooled. In this way a sodium xanthate is formed, which, on treatment with dilute sulphuric or hydrochloric acid, yields the free xanthic acid (Ragg, Chem. Zeit. 1908, 32, 630, 654, 677; *ibid.* 1910, 34, 82).

Xanthic acid (*ethoxydithiocarbonic acid*) is a colourless, transparent, heavy oil, insoluble in water and decomposing at 24° into alcohol and carbon disulphide. It forms a large number of metallic salts. The sodium or potassium salts when treated with a copper salt yield *cuprous xanthate* and *ethyldioxythiocarbonate* (*dixanthogen*) thus:

$$4NaS{\cdot}CS{\cdot}OEt+2CuSO_4 \\ =Cu_2(S{\cdot}CS{\cdot}OEt)_2+S_2(CS{\cdot}OEt)_2+2Na_2SO_4.$$

The cuprous salt is yellow, and it is this reaction which led to the adoption of the name for these salts. When the metallic xanthates are heated to 350° they decompose with evolution of hydrogen sulphide, carbon dioxide, and small quantities of combustible gases containing carbon monoxide. Amongst the liquid products are carbon di- and oxy-sulphide, ethyl hydrogen sulphide, ethyl mono- and disulphide, and ethyl alcohol, but in the case of the silver and nickel salts, the liquid product consists of almost pure ethyl xanthate and the dry distillation of the nickel salt is recommended for the preparation of the ethyl salt (Hébert, Compt. rend. 1911, 152, 869).

Potassium propylxanthate has been proposed as a reagent for cobalt and nickel salts; with the latter it yields a yellow precipitate, whilst with the former a green precipitate is formed. In dilute solutions the nickel is precipitated before the cobalt. Potassium methyl xanthate is also a good reagent giving with nickel a soluble, with cobalt an insoluble, salt in ammonia (Ferrer Hernández and Campo y Cerdan, Anal Fis. Quim. 1911, 9, 173).

When sodium or potassium alkyl xanthate is treated with chloracetyl carbamides, the following products are obtained: chloracetyl carbamates, arylamines, xanthylacetyl carbamides, ethyl carbamates, and arylamides (Frerichs and Rentschler, Arch. Pharm. 1906, 244, 77).

The esters of xanthic acid and its homologues may be obtained by treating the alkali salts with alkyl halide. They are volatile liquids which react with alkali alkoxides thus:

$$RO{\cdot}CS_2{\cdot}R+R'OK+H_2O \\ =R'O{\cdot}CO{\cdot}SK+R{\cdot}OH+R{\cdot}SH$$

(Salomon, Ber. 1875, 8, 1507; Wallach, *ibid.* 1880, 13, 530).

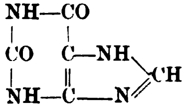
When treated with ammonia they yield mercaptan and *xanthamides* (alkylthiocarbamates) $RO{\cdot}CS{\cdot}NH_2$. The *ethyl salt*

$$C_2H_5O{\cdot}CS{\cdot}NH_2,$$

which is known as *xanthamide*, has m.p. 40°–41° (Debus, Annalen, 1850, 75, 128; *ibid.* 1852, 82, 262; Salomon, J. pr. Chem. 1874, [ii.] 8, 115; Rosenheim and Stadler, Zeitsch. anorg. Chem. 1906, 49, 1).

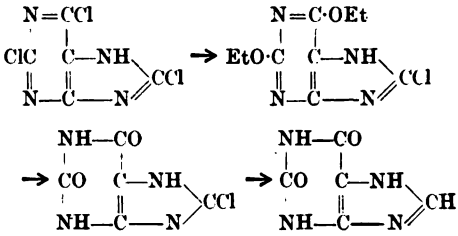
Xanthic derivatives of certain carbohydrates such as starch, have been prepared by first saturating the dry powdered carbohydrate with carbon disulphide and then adding the required quantity of caustic soda solution (Fr. Pat. 370505, 1906; J. Soc. Chem. Ind. 1907, 267). For other literature, *see* Tschugaeff, Ber. 1900, 33, 735; Bull. Soc. chim. 1901, [iii.] 26, 184, 298, 502; Leuckart, J. pr. Chem. 1890, [ii.] 41, 179; Holmberg, *ibid.* 1905, [ii.] 71, 264; Biilmann, Annalen, 1906, 348, 133.

XANTHINE, 2:6-dioxypurine



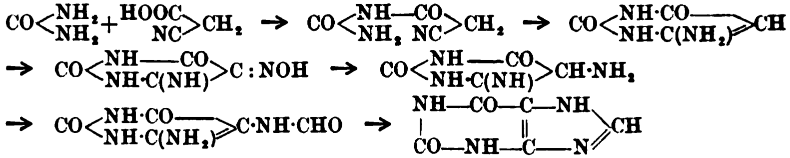
was discovered in 1817 by Marcet in a urinary calculus and called 'xanthic oxide,' because of the yellow residue it left when evaporated to dryness with nitric acid. Wöhler and Liebig analysed the compound, which they isolated from another calculus, and found that it differed from uric acid in containing one atom of oxygen less in the molecule (Annalen, 1838, 26, 340). It occurs in guano (Strecker, *ibid.* 1861, 118, 157), to a small extent in urine, 10,000 litres contain 10·11 grms. (Krüger and Salomon, Zeitsch. physiol. Chem. 1898, 24, 371; 26, 367); in the muscles, liver, spleen, pancreas, thymus and brain (Micko, Zeitsch. Nahr. Genussm. 1903, 6, 781; 1904, 7, 257). It is also found in the actively growing tissues of plants, in yeast, tea, and seedlings of lupins and malt; and has been isolated, together with other purine bases, from the soil (Schreiner and Shorey, J. Biol. Chem. 1910, 8, 385).

Synthesis. Xanthine can be prepared by heating 2:6:8-trichloropurine with sodium ethoxide, and reducing the 2:6-diethoxy-8-chloropurine either directly by hydrogen iodide, or after preliminary hydrolysis, to 2:6-dioxy-8-chloropurine (Fischer, Ber. 1897, 30, 2232).



Xanthine is also obtained by heating 2:6-di-iodopurine with hydrochloric acid under pressure (Fischer, *ibid.* 1898, 31, 2550). Traube (*ibid.* 1900, 33, 1371, 3043) has effected the synthesis of xanthine from cyanacetyl urea; this is converted by the action of alkalis into 4-amino-2:6-dioxypyrimidine which, by the action of nitrous acid and subsequent reduction, yields 4:5-diamino-2:6-dioxypyrimidine: on heating the sodium salt of the formyl derivative of this compound, xanthine is obtained (see scheme at top of next page).

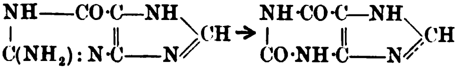
When uric acid is reduced by nascent formic acid, it yields xanthine. This may be effected by heating a mixture of uric acid, formic acid, chloroform, and alkali on the water bath; or by heating a mixture of equal weights of uric acid, calcium formate and calcium hydroxide in a combustion furnace until evolution of gas begins; or, more simply and with a yield of 30–33 p.c., by heating at 200° uric acid mixed



with oxalic acid and excess of glycerol (Sundvik, Zeitsch. physiol. Chem. 1897, 23, 476; 1898, 26, 131; 1912, 76, 486; Skan. Arch. Physiol. 1911, 25, 256).

The following technical preparation of xanthine from thioxanthine is described by C. F. Boehringer and Soehne, D.R.PP. 141974, 142468, 143725. An alkaline solution of *iso*uric acid absorbs sulphuretted hydrogen, forming a salt of γ-thio-ψ-uric acid, which is converted by boiling with mineral acids into thioxanthine (2:6-dioxy-8-thiopurine); or the thioxanthine may be prepared by warming 4:5-diamino-2:6-dihydroxypyrimidine with carbon disulphide and potassium hydroxide. On oxidising thioxanthine by means of nitrous acid, hydrogen dioxide in alkaline solution or manganese dioxide in neutral solution, it is converted into xanthine.

Xanthine is most conveniently prepared from guanine by the action of nitrous acid, or more readily and with a yield of 60–70 p.c. by heating in a reflux apparatus for 32 hours with 25 p.c. hydrochloric acid (Fischer, Ber. 1910, 43, 805)



Properties. Xanthine crystallises with one molecule of water which it loses at 125°–130°, forming a colourless micro-crystalline powder that acquires a waxy lustre by friction (Wöhler and Liebig, *l.c.*); it dissolves in 14,151 parts of water at 16° or 1300–1500 parts at 100°, and is insoluble in alcohol or ether. It dissolves readily in solutions of sodium or potassium hydroxides or in ammonia, but is precipitated from the solution by acids, even carbon dioxide. Xanthine sublimes slightly when heated, but decomposes without melting, yielding carbon dioxide, ammonia, hydrocyanic acid and cyanogen.

Xanthine is oxidised by chlorine oxides or chlorine water, yielding alloxan and urea (Fischer, Annalen, 1882, 215, 253).

Detection and estimation. Xanthine gives the murexide reaction when evaporated to dryness with chlorine water or hydrochloric acid and potassium chlorate and the residue moistened with ammonia solution; this is commonly called 'Weidel's test' for xanthine, although this author described it as a test for *hypoxanthine* (Annalen, 1871, 158, 365), and Kossel showed that the reaction was due to the presence of *xanthine*, pure *hypoxanthine* not responding to the test (Zeitsch. physiol. Chem. 1882, 6, 431).

Xanthine dissolves in hot nitric acid without evolution of gas, and the yellow residue obtained on cautious evaporation of the acid solution turns reddish-yellow on addition of sodium or potassium hydroxide and changes to reddish-violet on heating. If ammonia be used instead the alkali hydroxides, no violet colour is produced, and this test distinguishes xanthine from uric acid which gives the murexide reaction when similarly treated.

If dry xanthine be sprinkled on an alkaline solution of bleaching powder, each particle becomes surrounded with a dark green ring or scum which quickly changes to brown and finally disappears. Xanthine develops a red colour when added to an alkaline solution of diazobenzenesulphonic acid.

Xanthine can be estimated by precipitating the insoluble silver compound by means of silver nitrate from an ammoniacal solution, and estimating the nitrogen present in the carefully washed precipitate by the Kjeldahl method; or the silver may be estimated gravimetrically or volumetrically.

For the separation of xanthine from the purine bases in urine or extract of tissues, see Abderhalden's Handbuch der Biochemischen Arbeitsmethoden, vol. iii. part 2, p. 894.

Salts and derivatives. Xanthine forms compounds with certain metallic oxides and salts, the compound with *silver oxide*

$$C_5H_4O_2N_4\cdot Ag_2O$$

is a flocculent precipitate obtained by precipitating an ammoniacal solution of xanthine with ammoniacal silver nitrate; with *silver nitrate* $C_5H_4O_2N_4\cdot AgNO_3$ a flocculent precipitate prepared by mixing a nitric acid solution of xanthine with silver nitrate solution; the compound with *lead* $C_5H_2O_2N_4Pb$ is white and crystalline; and the compound with *barium hydroxide* $C_5H_4O_2N_4\cdot Ba(OH)_2$ is sparingly soluble. Xanthine forms crystalline salts with the mineral acids which are generally readily hydrolysed by solution in water; the *sulphate*

$$C_5H_4O_2N_4\cdot H_2SO_4,H_2O$$

crystallises in pearly rhombic plates from hot strong sulphuric acid, or in microscopic needles from dilute acid; the *hydrochloride*

$$C_5H_4O_2N_4\cdot HCl$$

crystallises in warty masses; the *nitrate* $C_5H_4O_2N_4\cdot HNO_3$ is precipitated as a heavy crystalline powder, when a warm solution of xanthine in sodium hydroxide is added to a cold solution of nitric acid (2:3); the *periodide* $C_5H_4O_2N_4\cdot HI\cdot I_3$ forms characteristic green crystals from alcohol (Linarix, J. Pharm. Chim. 1909, [vi.] 30, 241).

Xanthine-7-diazobenzensulphonic acid

$$(C_5H_3O_2N_3)N\cdot N:N\cdot C_6H_4\cdot SO_3H$$

dark red crystalline needles that do not decompose at 265°, soluble in water or alkalis, insoluble in ether, sparingly soluble in alcohol (Burian, Ber. 1904, 37, 703).

8-*Chloroxanthine* $C_5H_3ClO_2N_4$, obtained by hydrolysing 2:6-diethoxy-8-chloropurine with hydrochloric acid, forms a sparingly soluble crystalline powder that blackens without melting when heated (Fischer, Ber. 1887, 30, 2236).

8-*Bromoxanthine* $C_5H_3BrO_2N_4$ obtained by direct bromination at 100°, or by the action of nitrous acid on bromoguanidine; is a crystalline powder, insoluble in cold, sparingly soluble in hot water, insoluble in alcohol or ether, and decomposes without melting (Fischer and Reese, Annalen, 1883, 221, 343).

8-*Thioxanthine* $C_5H_3(SH)O_2N_4$, obtained by heating 8-bromoxanthine with potassium hydrogen sulphide solution in a sealed tube at 120° (Fischer, Ber. 1898, 31, 433), or by methods already referred to in the description of the synthesis of xanthine: is a colourless heavy crystalline powder that blackens without melting on being heated, sparingly soluble in concentrated hydrochloric acid and readily soluble in alkalis.

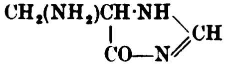
Deoxyxanthine $$\begin{array}{l}NH\cdot CH_2\cdot C—NH\diagdown \\ \quad\quad\quad\quad\quad\ \| \quad\quad\quad\ \ \ >CH \\ CO\cdot NH\cdot C—N\diagup\!\!\diagup\end{array}$$
obtained by the electrolytic reduction of xanthine dissolved in sulphuric acid, using lead electrodes; forms colourless crystals that decompose without melting after becoming brown at 250° (Tafel and Ach, Ber. 1901, 34, 1166). It is very readily hydrolysed when gently heated with acids, yielding carbon dioxide, ammonia and 5-aminomethyl-4-iminazolone



$$\begin{array}{l}CH_2(NH_2)CH\cdot NH\diagdown \\ \quad\quad\quad\ \ | \quad\quad\quad\quad >CH \\ \quad\quad\quad CO—N\diagup\!\!\diagup\end{array}$$

(Tafel and Mayer, Ber. 1908, 41, 2546).

M. A. W.

XANTHINE (CHRYSANILINE) *v.* ACRIDINE DYESTUFFS.

XANTHOCREATININE, CRUSOCREATININE and **AMPHICREATININE** are the chief members of the creatinine leucomaines isolated by Gautier from the muscles of large animals; they are alkaloidal in properties, and when administered to animals act more or less powerfully on the nerve centres inducing sleep, and in some cases vomiting and purging in a manner similar to the alkaloids of snake poison. These bases are formed during life and occur in the urine, saliva, and various glandular secretions (J., Pharm. Chim., [v.] 13, 354, 401).

Xanthocreatinine $C_5H_{10}ON_4$ is the most abundant of the creatinine leucomaine group of bases. It was extracted from muscle by Gautier and also by Monari (Gazz. chim. ital. 1887, 16, 538) and from the urine of the lion by Colosanti (*ibid.* 21, ii. 188). In chemical properties it closely resembles creatinine from which it differs in empirical constitution by CH_3N. It crystallises in light sulphur-yellow spangles, which have a slightly bitter taste and an odour similar to that of crude acetamide. The base is soluble in cold water and can be crystallised from boiling alcohol. It is amphoteric in character, turning blue litmus red and red litmus blue. It forms a salt with hydrochloric acid which yields soluble crystalline double salts, with the chlorides of gold, platinum, mercury and zinc. The latter compound has the formula

$$(C_5H_{10}N_4O)_2ZnCl_2.$$

Crucocreatinine $C_5H_8ON_4$, crystallises in orange-yellow crystals, is feebly alkaline towards litmus paper and has a slightly bitter taste. It forms a crystalline non-deliquescent hydrochloride, which yields crystalline double salts with platinic, auric and zinc chlorides respectively.

Amphicreatinine $C_9H_{19}O_4N_7$ crystallises from boiling water in bright, pale yellow prisms and is less readily soluble than either of the two preceding bases. When heated at 110° the crystals become colourless and opaque without, however, changing their form. It forms a crystalline *hydrochloride*. The *platinochloride* is soluble in water, and insoluble in alcohol and crystallises in lozenge-shaped plates, and the *aurichloride* is very readily soluble and crystallises in microscopic hexhahedral and tetrahedral crystals.

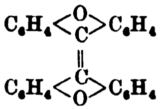
XANTHONE AND XANTHONE COLOURING MATTERS. *Xanthone, Diphenyleneketone oxide, Benzophenone oxide, Carbonyldiphenylene oxide,* $C_{13}H_8O_2$, was first prepared by Kolbe and Lautemann (Annalen, 1860, 115, 197) by the action of phosphorus oxychloride on sodium salicylate, and has been subsequently obtained from salicylic acid and its derivatives by the employment of various dehydrating agents. The most convenient method consists in distilling a mixture of acetic anhydride and salicylic acid (Perkin, Chem. Soc. Trans. 1883, 43, 35; *cf.* also Graebe. Annalen, 254, 265), when the higher boiling fraction, on cooling, deposits crystals of xanthone. Phenyl salicylate (Siefert, J. pr. chem. [ii.] 31, 472) by long digestion at the boiling temperature yields xanthone, and it is also produced when salicylic acid phenylether $COOH\cdot C_6H_4\cdot O\cdot C_6H_5$ is warmed with sulphuric acid (Graebe, Ber. 21, 503). Other methods of this type have been described by Richter (J. pr. chem. [ii.] 28, 275), Jeiteles (Monatsh. 17, 66), Staedel (Annalen, 283, 179), Goldschmiedt (Monatsh. 4, 123). and Klepl (J. pr. chem. [ii.] 28, 217). For the theory of xanthone formation the paper of Strohbach (Ber. 34, 4136) should be consulted. Ullmann and Zlokasoff (*ibid.* 1905, 2111), by the interaction of sodium phenoxide and sodium *o*-chlorbenzoate in presence of copper powder, obtained *o*-phenoxybenzoic acid (1) which, by elimination of water, passes into xanthone (2).

(1) 
(2) 
and this method is generally applicable for the production of xanthone derivatives.

Xanthone crystallises in long colourless needles, m.p. 173°–174°, and dissolves in sulphuric acid to form a blue fluorescent liquid. By distillation with zinc dust or by the action of fuming hydriodic acid at 160°, it is converted into *xanthene* (methylene diphenylene oxide)

from which by oxidation with chromic acid, xanthone can be reproduced (Merz and Weith, Ber. 14, 192). Boiling alcoholic soda and zinc dust gives *xanthydrol* (Meyer and Laub, Ber. 26, 1276),

zinc dust and acetic acid *dioxyxanthylene* (Gurgenjanz and v. Kostanecki, Ber. 28, 2310),



$$C_6H_4{<}\overset{O}{\underset{C}{}}{>}C_6H_4 \;\; \| \;\; C_6H_4{<}\overset{C}{\underset{O}{}}{>}C_6H_4$$

whereas by fusion with alkali *xanthonic acid* (dihydroxydiphenylene ketone) $CO(C_6H_4(OH))_2$ is obtained.

a-Dinitro-xanthone, m.p. 190° (Richter, *l.c.*; Graebe, *l.c.*), *b-dinitroxanthone*, m.p. 262° (Perkin, Chem. Soc. Trans. 43, 189), *a-diamino-xanthone*, m.p. 209 (G), *b-diaminoxanthone* (P), *xanthonedisulphonic acid* (P.), *monobromxanthone*, m.p. 125°–127° (G.), *dibromxanthone*, m.p. 212° (P.), *thioxanthone*, m.p. 209° (Graebe and Schultess, Annalen, 263, 8), *xanthone phenylimine*, m.p. 134°–135° (Graebe and Röder, Ber. 32, 1689), *xanthoneoxime* (G. and R.), *xanthione*, m.p. 156° (G. and R.)

$$O{<}\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}{>}CS$$

and *dithioxanthone*

$$S{<}\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}{>}CS$$

(Meyer and Szanecki, Ber. 33, 2580) have been described.

Special interest is attached to the hydroxyxanthones in that certain natural representatives, euxanthone and gentisin, are included in this group. A general method for the preparation of these compounds consists in distilling a mixture of a phenol, and an *o*-hydroxycarboxylic acid with acetic anhydride, and this has been employed in numerous syntheses. In this manner 1-*hydroxyxanthone* (Michael, Amer. Chem. Soc. 5, 91; Graebe, Annalen. 54, 290), m.p. 146°–147°, 2-*hydroxyxanthone* (v. Kostanecki and Rutishauser, Ber. 25, 1648), m.p. 231°, 4-*hydroxyxanthone* (K. and R.), m.p. 224°, 3-*hydroxyxanthone* (v. Kostanecki and Nessler, Ber. 24, 3981), m.p. 242°, 3:6:*dihydroxyxanthone* (iso*euxanthone*) (v. Kostanecki, *ibid.* 18, 1986), m.p. 243°, 2:5-*dihydroxyxanthone* (v. Kostanecki, *ibid.* 27, 1991), m.p. 280°, *gentisein* (1:3:7-trihydroxyxanthone) (v. Kostanecki, Monatsh. 12, 207), and *euxanthone* (3:5-dihydroxyxanthone) (v. Kostanecki and Nessler, Ber. 24, 3983) can be prepared. Whereas euxanthone is the colouring matter of Indian yellow, gentisein monomethyl ether is identical with the gentisin of gentian root (see articles). According to Tschirch and Polacco (Arch. Pharm. 1900, 238, 459), rhamnocitrin, a yellow colouring matter which is present in the berries of the *Rhamnus cathartica* (L.) is probably a trihydroxydihydroxanthone (see article Persian Berries). For the preparation of euxanthone see also Ullmann and Panchaud (Annalen, 350, 108). A. G. P.

XANTHORHAMNIN *v.* Glucosides; Persian berries.

XANTHORRHŒA RESINS or **BALSAMS** *v.* Balsam.

XENON. Sym. X. At.wt. 130·2.

An inert gas, discovered along with krypton in the final residues obtained after evaporating considerable quantities of liquid air (Ramsay and Travers, Proc. Roy. Soc. 1898, 63, 405). For the separation of xenon from these residues, *v.* Krypton. Xenon may also be separated by passing a current of air through a spiral tube filled with glass wool and immersed in liquid air (Dewar, *ibid.* 1901, 68, 360). Xenon occurs in the gases evolved from many thermal springs (Moureu and Lepape, Compt. rend. 1909, 149, 1171).

Xenon is the least volatile and least abundant of the inert gases which exist in the atmosphere, being present only to the extent of 1 part in 170 million parts of air by volume (Ramsay, Proc. Roy. Soc. 1903, 71, 421; 1908, 80, A. 599). It boils at −109·1°, at which temperature its density is 3·063 and its atomic volume 42·7. The critical temperature is +16·6°, the critical pressure 58·2 atmospheres, and the critical density 1·115 grms. per c.c. The 'rectilinear diameter' is given by the equation

$$D_t = 1{\cdot}205 - 0{\cdot}003055t$$

where D_t = mean density of liquid and saturated vapour at t° C. (Patterson, Cripps and Whytlaw-Gray, Proc. Roy. Soc. 1912, A, 579). At the temperature of liquid air xenon readily solidifies (Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329).

At N.T.P. 1 litre of xenon weighs 5·851 grms.; its density is therefore 65·35 (O=16) (Moore, Chem. Soc. Trans. 1908, 93, 2181; Watson, *ibid.* 1910, 97, 833). The refractive index at N.T.P. for the green mercury line (λ=5461) is 1·0007055 (Cuthbertson and Cuthbertson, Proc. Roy. Soc. 1908, 81, A, 440; 1910, 84, A, 13). At 20° the absorption coefficient is 0·1109 (Antropoff, *ibid.* 1910, 83, A, 474). For the spectrum of xenon *v.* Baly, (Phil. Trans. 1903, A, 202, 183): Liveing and Dewar (Proc. Roy. Soc. 1901, 68, 389).

Xenon is monatomic since the ratio of its specific heats is 1·66 (Ramsay).

XEROFORM. Trade name for bismuth tribromophenoxide used as an antiseptic, *v.* Bismuth, organic compounds of; Synthetic drugs.

XYLENES, *Dimethylbenzenes*,

$$C_8H_{10} \text{ or } C_6H_4(CH_3)_2.$$

A hydrocarbon of the formula C_8H_{10} (in reality a mixture) was obtained by various investigators from the fraction of coal-tar, or of wood-tar, boiling between 137·5°–142°. De la Rue and H. Müller isolated a similar substance from Rangoon tar. Fittig (Annalen, 1870, 153, 265) showed that the crude xylene from coal tar contained two isomeric hydrocarbons—*m-xylene*, which he had previously obtained by distilling mesitylenic acid

$$C_6H_3(COOH)(CH_3)_2(1{:}3{:}5)$$

with lime; and *p-xylene*, which he had prepared by the action of sodium on a mixture of crude bromotoluene and methyl iodide; this was first prepared in a purer form by Jannasch (Annalen, 1874, 171, 79), by employing pure *p*-bromtoluene in the same reaction. *o-Xylene* was first isolated from coal-tar by Jacobsen (Ber. 1877, 10, 1010), but had previously been obtained by Fittig and Bieber (Annalen, 1870, 156, 239) by the distillation of *p*-xylic acid $C_6H_3(COOH)(CH_3)_2(1{:}3{:}4)$ with lime.

Crude coal-tar xylene, containing paraffins and other hydrocarbons, was formerly used only as solvent naphtha. At present, purified xylene is employed in the manufacture of xylidine scarlet and other azo- colours.

The xylenes are formed, like other methyl homologues of benzene, by the decomposition of complex organic substances by heat, hence their occurrence in coal-tar and wood-tar. The *m*- compound is formed in the largest quantity; but the relative proportion of the three isomerides varies both with the material distilled and with the temperature at which the distillation is conducted. In like manner xylenes are formed, together with other hydrocarbons, when the vapour of oil of turpentine is passed through a red-hot tube. *O*-xylene, with about 5 p.c. of para-xylene, is formed when methyl chloride is passed into warm toluene containing aluminium chloride. The xylenes are also formed by the distillation of the dimethylbenzoic acids with lime.

In order to separate the isomerides, a commercial xylene, boiling at about 140°, and freed from phenols and bases by treatment with alkali and acid, is employed as the starting-point. If only the *m*- compound, which alone is of technical importance, is required, the mixture is boiled with dilute nitric acid (1 part of commercial acid of sp.gr. 1·4 with 2 parts of water); the *o*- and *p*- compounds are thus converted into acids, whilst the *m*- compound is hardly attacked (Fittig and Velguth, Annalen, 1868, 148, 10). The product is steam-distilled, the distillate shaken with alkali to free it from acids and nitro-xylenes, dried, and rectified.

O. Jacobsen (Ber. 1877, 10, 1013; 1878, 11, 17) has described a method by which the three isomerides may be isolated from coal-tar xylene. The crude xylene is shaken in the cold with concentrated sulphuric acid, which dissolves *o*- and *m*-xylene, converting them into sulphonic acids, whereas *p*-xylene is hardly attacked, even on heating. In order to obtain the *o*- and *m*-xylene, the acid solution is treated with excess of calcium carbonate, filtered from calcium sulphate, the filtrate, containing the calcium sulphonates, precipitated with sodium carbonate, and the solution of the sodium xylene-sulphonates concentrated by evaporation and allowed to crystallise. Sodium *o*-xylene-sulphonate separates, whilst the sodium salts of two isomeric *m*-xylene-sulphonic acids remain in solution. In order to purify the *p*-xylene, it is gently warmed with fuming sulphuric acid, in which it dissolves, leaving behind a paraffin and other impurities. The three xylenes are then liberated from their sulphonic acids by hydrolysis with concentrated hydrochloric acid at 195° (*see* also Armstrong and Miller, J. Chem. Soc. 1884, 151; Levinstein, J. Soc. Chem. Ind. 1884, 354).

The hydrocarbons may, of course, also be regenerated from the sulphonic acids by the dry distillation of the ammonium salts alone, or of the other salts with dry ammonium chloride.

A somewhat modified form of Jacobsen's separation which may also be employed for estimating the relative quantities of the isomerides in the mixture is described by Crafts (Compt. rend. 1892, 114, 1110; *see* also Eng. Pat. 8665, 1898).

Noelting and Palmer (Ber. *1891, 24, 1955*) have shown that commercial xylene contains ethylbenzene, and that in Jacobsen's method of separating the isomerides the *p*-xylene is obtained mixed with this hydrocarbon (*see* also Moore and Roaf, Proc. Roy. Soc. 1905, B, 77, 80; Ward, Proc. Cambridge Phil. Soc. 1905, 13, 81; Stohmann, J. pr. Chem. 1887, [ii.] 35, 41).

Commercial xylene should have been previously washed with sulphuric acid, and should, therefore, give only a pale-brown colouration on treatment with concentrated sulphuric acid. The boiling-point of the product should lie within a few degrees; thus not more than 10 p.c. should distil below 138°, and not more than 10 p.c. above 140·5°, the remainder passing over between these two temperatures.

The xylene of commerce is a product of very variable composition. The relative proportion of the three isomerides varies in different samples, and as these three compounds have almost identical boiling-points, the boiling-point of such a mixture affords no clue to its composition. The value of a commercial xylene depends on the quantity of *m*-xylene which it contains.

To identify the *m*- and *p*-xylenes in a mixture of the three isomerides, 50 c.c. of the mixture may be heated with a mixture of chromic and sulphuric acids, whereby *o*-xylene is completely oxidised to carbon dioxide, whereas *m*-xylene yields *iso*-phthalic acid and *p*-xylene yields terephthalic acid (Worstall and Burwell, Amer. Chem. J. 1897, 19, 830).

Methods for the quantitative estimation of the three xylenes in the commercial product have been devised (*v.* Levinstein, *l.c.*; Reuter, Ber. 1884, 2028; and J. Soc. Chem. Ind. 1884, 626; *ibid.* 1889, 874; Chem. Zeit. 13, 830; Crafts, *l.c.*).

When the xylenes are oxidised with chromic acid in the presence of acetic anhydride and sulphuric acid, the corresponding tetra acetate of phthalaldehyde is formed (Thiele and Winter, Annalen, 1900, 311, 353).

The xylenes and similar coal-tar hydrocarbons may be rendered soluble in water by heating them with a suitable soap, as, for instance, with oleic acid and potash. The products which are soluble both in ordinary and in sea water may be used for washing and other purposes such as drilling, turning, and similar processes in the working of metals (Fr. Pat. 422963, 1910; J. Soc. Chem. Ind. 1911, 610).

Xylene has also been employed in the removal of naphthalene stoppages in pipes (Breitkopf, J. Gasbeleucht. 1899, 42, 671).

Like the other homologues of benzene, xylene reacts with cellulose forming desoxyns (Nastukoff, Zeitsch. Farb. Ind. 1907, 6, 70).

***ortho*-Xylene** $C_6H_4(CH_3)_2$. Liquid, boiling at 144° (corr.), m.p. −25° (Fischer, Zeitsch. Elektrochem. 1910, 16, 161), sp.gr. 0·8903 at 4°/4°: sp.gr. 0·8818 at 15°/15°. Oxidised by dilute nitric acid to *o*-toluic acid

$$C_6H_4(CH_3)(COOH),$$

melting at 102°. A hot solution of potassium permanganate oxidises it to *o*-toluic and phthalic acids, whilst chromic acid totally destroys it. When heated with hydrogen iodide at 250°–280° *o*-xylene yields toluene, methyl- and dimethyl*cyclo*hexane, and methylated pentamethylene (Markownikow, Ber. 1897, 30, 1218).

m*-Xylene** (iso*-xylene**) $C_6H_4(CH_3)_2$. Liquid, boiling at 139° (corr.); m.p. −50° (Fischer, *l.c.*); sp.gr. 0·8779 at 4°/4°: sp.gr. 0·8691 at 15°/15°. Not attacked by dilute nitric acid. Chromic acid oxidises it to *iso*phthalic acid. When warmed with concentrated nitric acid it yields a trinitro derivative $C_6H(CH_3)_2(NO_2)_3$, melting at 176°, very sparingly soluble in alcohol.

For its reaction with aluminium chloride, *see* Anschütz, Annalen, 1886, 235, 182, 323; Heise and Töhl, *ibid.* 1892, 270, 169; Jacobsen, Ber. 1885, 18, 342; also Boeseken, Rec. trav. chim. 1905, 24, 1.

***p*-Xylene** $C_6H_4(CH_3)_2$. Monoclinic prisms, m.p. +5° (Fischer, *l.c.*), +15° (Jannasch, Annalen, 1874, 171, 80), b.p. 138·5°; sp.gr. 0·8661 at 15°/15°; sp.gr. 0·8593 at 25°/25°. Dilute nitric acid oxidises it to *p*-toluic acid

$$C_6H_4(CH_3)(COOH),$$

melting at 178°; chromic acid to terephthalic acid.

When *p*-xylene is heated with sulphur at 250°–300°, 4 : 4′-dimethylstilbene and 4 : 4′-dimethyldibenzyl are formed (Aronstein and Nierop, Proc. K. Akad. Wetensch. Amsterdam, 1902, 5, 288; Rec. trav. chim. 1902, 21, 448).

Halogen derivatives. The bromo and dibromo derivatives of all three xylenes may be obtained by direct bromination of the hydrocarbon, the product obtained depending on the conditions of the experiment (Atkinson and Thorpe, Chem. Soc. Trans. 1907, 1695).

The magnesium derivative of bromo-*p*-xylene condenses with chloral forming *βββ*-trichloro-*α*-xylyl ethyl alcohol, b.p. 158°/10 mm., which on prolonged boiling with potassium carbonate solution yields *xylylaldehyde* $C_6H_3Me_2{\cdot}CHO$ (Savariau, Compt. rend. 1908, 146, 297; Carré, *ibid.* 1909, 148, 1108). *o*-Xylyl bromide reacts with methyl aniline yielding *o*-xylylmethylaniline, b.p. 200°/35 mm., m.p. 34° (Von Braun, Ber. 1910, 43, 1353).

o-Xylylene bromide when treated with potash forms o-*xylylene oxide*  $C_6H_4<\begin{matrix}CH_2\\CH_2\end{matrix}>O$, b.p. 192° (Willstätter and Veraguth, Ber. 1907, 40, 957). It also condenses with quinolines, aliphatic amines, and with *p*-amino-acetophenone (Scholtz and Wolfrum, *ibid.* 1910, 43, 2304).

The six possible tribromo xylenes have been obtained by Jaeger and Blanksma, by brominating the corresponding xylidines in glacial acetic acid and subjecting the dibromo xylidines so obtained to Sandmeyer's reaction; also by other methods (Proc. K. Akad. Wetensch, Amsterdam, 1905, 8, 153.

Recent literature on the xylyl and xylylene halogen derivatives: Radziewanowski and Schramm, Chem. Zentr. 1898, ii. 1019; Gabriel and Pinkus, Ber. 1893, 26, 2210; Klages and Knoevenagel, *ibid.* 1894, 27, 3024; *ibid.* 1896, 29, 310; Rupp, *ibid.* 1628; Curtius and Sprenger J. pr. Chem. [ii.] 62, 111; Halfpaap, Ber. 1903, 36, 1672; Noelting, *ibid.* 656; Fries, *ibid.* 1904, 37, 2338; Thiele and Balhorn, *ibid.* 1463; Willgerodt and Schmierer, *ibid.* 1905, 38, 1472; Dinesmann, Compt. rend. 1905, 141, 201; Stallard, Chem. Soc. Trans. 1906, 808; D. R. P. 230172.

Bromo- and *dibromo-*m*-xylylindigotin* are described in D. R. P. 154338, 1904.

Nitro derivatives. The nitration of *o*-xylene is fully described by Crossley and Renouf (Chem. Soc. Trans. 1909, 202); Crossley and Wren (*ibid.* 1911, 2341); Crossley and Morrell (*ibid.* 2345). The products obtained depend on the relative quantity of nitric acid used, on the temperature, the admixture of acetic or sulphuric acid, and on whether the nitric acid is added to the xylene or *vice versa* (*see* also Errera and Maltese, Gazz. chim. ital. 1903, 33, ii. 277; Konowaloff, J. Russ. Phys. Chem. Soc. 1905, 37, 530, 537).

Some recent literature: Morgan and Micklethwait, Chem. Soc. Trans. 1907, 360; Green, Davies and Horsfall, *ibid.* 2080; Errera and Maltese, Gazz. chim. ital. 1905, 35, ii. 370; *ibid.* 1909, 39, i. 517; Meisenheimer, Ber. 1906, 39, 2526; Blanksma, Rec. trav. chim. 1909, 28, 92; Chem. Weekblad, 1910, 7, 727).

Halogen nitro compounds are described by Crossley (Chem. Soc. Trans. 1904, 266); Konowaloff (J. Russ. Phys. Chem. Soc. 1904, 36, 537); Blanksma (Rec. trav. chim. 1906, 25, 373).

***p*-Xylylhydazine** $C_6H_3Me_2{\cdot}NH{\cdot}NH_2$ is formed by the reduction of sodium-*p*-xylenediazonium sulphite with zinc dust and acetic acid. The product is decomposed with hydrochloric acid and then treated with sodium hydroxide. It forms glistening, white slender needles, m.p. 78°, and yields many derivatives (Willgerodt and Lindenberg, J. pr. Chem. 1905, [ii.] 71, 398; Busch and Meussdörffer, *ibid.* 1907, [ii.] 75, 121; Plancher and Caravaggi, Atti. R. Accad. Lincei, 1905, [v.] 14, i. 157).

1 : 2 : 4-*Xylylhydrazine* forms yellowish-white needles, m.p. 57°.

Xylyl hydrazones and a number of their double compounds with aldehydes and their phototropy are discussed by Graziani (Atti. R. Accad. Lincei, 1910, [v.] 19, i. 489; *ibid.* ii. 193).

The reactions of *xylyl hydroxylamines* are described by Bamberger (Ber. 1902, 35, 3886; *ibid.* 1907, 40, 1893).

Xylyltriazine compounds have been prepared (Jovitschitsch, *ibid.* 1906, 39, 3821).

o-*Xylylene cyanide* condenses in presence of sodium ethoxide with *o*-diketones, keto acids, and esters of oxalic acid forming naphthalene derivatives (Hinsberg, Ber. 1910, 43, 1360; Wislicenus and Penndorf, *ibid.* 1837).

Xylene sulphonates are obtained by treating xylene with fuming sulphuric acid, and also by other methods (Jacobsen, *l.c.*; Wischin, Ber. 1890, 23, 3113; Pfannenstill, J. pr. Chem. 1892, [ii.] 46, 152, 154; Moody, Chem. Soc. Proc. 1891, 189; Junghahn, Chem. Zentr. 1903, i. 572; Maué, Annalen, 1903, 330, 46; Stallard, Chem. Soc. Trans. 1906, 808; Karslake and Bond, J. Amer. Chem. Soc. 1909, 31, 405).

Xylene sulphinic acids, -anhydride, and *-sulphoxide* are described by Smiles and Rossignol (Chem. Soc. Trans. 1908, 761); Hilditch (*ibid.* 1621); Knoevenagel and Polack (Ber. 1908, 41, 3323); Knoevenagel and Kenner (*ibid.* 3315).

p-*Xylylene hydrosulphide* is prepared by adding a boiling solution of *p*-xylylene bromide to alcoholic potassium hydrosulphide saturated with hydrogen sulphide. It is then separated from the glycol which forms at the same time.

by means of aqueous caustic soda. In the presence of hydrochloric acid it condenses with aliphatic aldehydes forming amorphous indefinite compounds, but with aromatic aldehydes it yields beautiful crystalline stable duplomercaptals containing an eighteen-membered ring. The *m*- and *o*- compounds yield similar derivatives (Autenrieth and Beuttel, Ber. 1909, 42, 4346, 4357).

Sulphides and *sulphones* have been prepared by Martynowicz (Chem. Zentr. 1910, ii. 1048), Strzelecka (*ibid.* 1135).

Xylyl ethers $(C_6H_4Me{\cdot}CH_2)_2O$ are described by Pawlowsky (J. Russ. Phys. Chem. Soc. 1911, 43, 214).

Xylene forms a large number of other derivatives, the following being some of the more recent literature on these: Blanksma, Rec. trav. chim. 1902, 21, 327; Stoermer and Atenstädt, Ber. 1902, 35, 3560; Scholl and Kačer, *ibid.* 1903, 36, 322; Kuhling and Falk, *ibid.* 1905, 38, 1215; Ullmann and Zlokasoff, *ibid.* 2111; Schmid and Decker, *ibid.* 1906, 39, 933; Bresler, Friedemann and Mai, *ibid.* 876; Jaweloff, *ibid.* 1195; Fecht, *ibid.* 1907, 40, 3890; Bamberger and others, *ibid.* 1932, 1949, 1956, 2258; Jacobson and Huber, *ibid.* 1908, 41, 660; Bülow and Schaub, *ibid.* 2355; Zeltner and Tarassoff, *ibid.* 1910, 43, 941; Braun, *ibid.* 1350; Morgan and Micklethwait, Chem. Soc. Trans. 1905, 1307; Clayton, *ibid.* 1906, 1054, 1295; Tröger and Hille, J. pr. Chem. 1905, [ii.] 71, 201, 236; Johnson, J. Amer. Chem. Soc. 1903, 25, 483; Andreasch and Zipser, Monatsh. 1905, 26, 1191; Haager and Doht, *ibid.* 1906, 27, 267; Barbier and Grignard, Compt. rend. 1909, 148, 646; Guyot and Esteva, *ibid.* 564; Layraud, Bull. Soc. chim. 1906, [iii.] 35, 223; Kozniewski and Marchlewski, Bull. Soc. Acad. Sci. Cracow, 1906, 81; Strzelecka, *ibid.* 1909, 731; Scholtz, Arch. Pharm. 1909, 247, 534; Fromm and Schneider, Annalen, 1906, 348, 161; Zincke, *ibid.* 1905, 339, 202; Gattermann, *ibid.* 1907, 357, 313; Auwers, *ibid.* 1909, 365, 291; Heinrich, *ibid.* 1910, 376, 139; Haller and Bauer, Compt. rend. 1911, 153, 21; Zincke and Breitwieser, Ber. 1911, 44, 176; Scholtz, *ibid.* 480; Diepolder, *ibid.* 2498; D. R. P. 234917; Halla, Monatsh. 1911, 32, 747; Buchner and Schulze, Annalen, 1910, 377, 259 (*v.* AZO-COLOURING MATTERS).

XYLENOL *v.* PHENOL AND ITS HOMOLOGUES.

XYLIDINES (*Aminoxylenes, Aminodimethylbenzenes*). Theory predicts the existence of six isomeric aminodimethylbenzenes, all of which are known. They are obtained by the reduction of the corresponding nitro compounds with tin and hydrochloric acid, or with iron filings and acetic acid, or, in the case of the commercial product, with iron turnings and hydrochloric acid.

1. *o*-3-**Xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:CH_3:NH_2=1:2:3)$.

Liquid, boiling at 225° (corr.); sp.gr. 0·991 at 15°. Melting-point of the acetyl compound $C_6H_3(CH_3)_2NH(C_2H_3O)$, 131° (Töhl, Ber. 1885, 18, 2562; Jaeger and Blanksma, Rec. trav. chim. 1906, 25, 352).

2. *o*-4-**Xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:CH_3:NH_2=1:2:4)$.

Lustrous rhomboidal tables, or large monoclinic crystals, melting at 50°; b.p. 226°; sp.gr. 1·0755 at 17·5°; m.p. of acetyl compound 99° (Limpach, Ber. 1888, 21, 646; Jaeger and Blanksma, *l.c.*).

3. *m*-2-**Xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:NH_2:CH_3=1:2:3)$.

Liquid, boiling at 216° (corr.); m.p. of acetyl compound 177° (Grevingk, *ibid.* 1884, 17, 2430).

4. *m*-4-**Xylidine** or *as*-*m*-**xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:CH_3:NH_2=1:3:4)$.

Liquid, boiling at 212°; sp.gr. 0·9184 at 15°; m.p. of acetyl compound 129° (Müller, *ibid.* 1887, 20, 1041; Limpach, *ibid.* 871; *ibid.* 1888, 21, 641; D. R. P. 34854).

5. *m*-5-**Xylidine** or *s*-*m*-**xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:CH_3:NH_2=1:3:5)$.

Liquid, boiling at 220°–221° (corr.); sp.gr. 0·9935 at 0°; m.p. of acetyl compound 140·5° (Noyes, Amer. Chem. J. 20, 800; Töhl, Ber. 1885, 18, 362).

6. *p*-**Xylidine**

$C_6H_3(CH_3)_2NH_2,(CH_3:NH_2:CH_3=1:2:4)$.

Liquid, boiling at 215°; sp.gr. 0·980 at 15°; m.p. of acetyl compound 138°–139° (Witt, Noelting and Forel, Ber. 1885, 18, 2064; D. R. P. 34854; Frdl. i. 19).

According to Michael (Ber. 1893, 26, 39) *p*-xylidine, if chemically pure, crystallises when subjected to prolonged cooling, in large colourless tablets, m.p. 15·5°, b.p. 213·5°/762 mm. The acetyl derivative has m.p. 139·5°.

COMMERCIAL XYLIDINE.

The nitroxylene used in the manufacture of this product is prepared by the action of nitric acid on coal-tar xylene—a mixture of the three isomeric xylenes together with a small quantity of ethylbenzene (*v.* XYLENE). As *o*-xylene yields by direct nitration two mononitroxylenes, *m*-xylene two, and *p*-xylene one, it is evident that these five nitroxylenes will be contained in commercial nitroxylene, and, therefore, that the five corresponding xylidines will be present in the commercial xylidine obtained from it by reduction with iron turnings and hydrochloric acid. *m*-4-Xylidine is present in largest quantity; next to it, *p*-xylidine is the chief constituent, occurring to the extent of 20–25 p.c. Vaubel (J. Soc. Chem. Ind. 1897, 639) describes a method for estimating the various xylidines. If commercial xylidine is mixed with excess of concentrated hydrochloric acid, a magma of crystals separates, consisting mainly of the hydrochloride of *m*-4-xylidine (Schultz, Steinkohlentheer, 1, 339). *p*-Xylidine may be separated by the greater solubility of its sulphonic acid in dilute sulphuric acid, the base being afterwards regenerated by distilling the sodium salt of the sulphonic acid with dry ammonium chloride (Witt, Noelting, and Forel, J. Soc. Chem. Ind. 1889, 274; D. R. P. 139457). Commercial xylidine also contains amino-ethylbenzene (Noelting and Palmer, Ber. 1891, 24, 1957).

For the preparation of colouring matters, Limpach (Eng. Pat. 6899, May 9, 1888; J. Soc. Chem. Ind. 1889, 281) described the following method of separating the xylidines from the commercial product; 121 grms. of commercial xylidine are treated with 30 grms. of 100 p.c.

acetic acid, and allowed to stand for 24 hours. Crystals separate, which consist of pure *m*-4-xylidine acetate. The mother liquors are treated with hydrochloric acid, and after standing 3–4 days, about 20 p.c. of *p*-xylidine separates as hydrochloride.

A slightly modified form of this process has been described by Hodgkinson and Limpach (Chem. Soc. Trans. 1900, 65). The last filtrate which contains 2·7 p.c. of the *m*-2-xylidine and the two *o*- isomerides may be evaporated, and when the excess of acid and water is removed, on gently heating, the *m*-2-xylidine sublimes as the hydrochloride in beautiful silky needles. It may also be separated on a larger scale by conversion into the formyl derivative. The black residue, after the separation of the *m*-hydrochloride, is now dissolved in water and hydrolysed with sodium hydroxide. The product obtained on distilling alone or with steam is treated with formic acid, and the formyl derivatives of the two *o*-xylidines are separated by fractional crystallisation, the *o*-3-isomeride crystallising fairly readily, the *o*-4-isomeride only with difficulty. The *p*- and *m*- xylidines may also be separated by means of benzaldehyde, with which the *p*- isomeride yields di-*p*-amino-di-*p*-xylyl phenyl methane, m.p. 208° (Schultz, J. pr. Chem. 1907, [ii.] 76, 331).

Commercial xylidine is employed exclusively in the preparation of azo- colours, for which purpose it is either converted direct into diazoxylene, or first into amino-azo-xylene or into cumidine.

It should distil for the most part between the temperatures of 212° and 218°.

The xylidines form a large number of halogen, nitro-, sulphonic, and many other derivatives, many of which are used in the preparation of dyestuffs, thus:

m-4-Xylidine-5-sulphonic acid is obtained by heating *m*-4-xylidine (121 grms.) with con. sulphuric acid (106 grms.) *in vacuô* or in a current of air or indifferent gas for about 3 hours. It forms white, flat, quadratic rods or plates, is insoluble in common organic solvents and dissolves in water to the extent of 1 in 28·5 parts of water at 100°, and 1 in 250 at 0°. When diazotised it combines with β-naphthol, forming yellow and orange dyes for wool (Junghahn, Ber. 1902, 35, 3747).

Some of the more recent literature on the xylidines and their derivatives: Jablin-Gonnet, Bull. Soc. chim. 1891, [iii.] 6, 21; Menton, Annalen, 1891, 263, 361; Jacobson, *ibid.* 1895, 287, 211; Fries, *ibid.* 1906, 346, 128; Wallach. *ibid.* 1907, 353, 318; Heller, *ibid.* 1908, 358. 349; Lemoult, Compt. rend. 1904, 138, 815; *ibid.* 1906, 142, 1193; Simonet, *ibid.* 1905, 140, 788; Blanksma, Rec. trav. chim. 1905, 24, 46; Mannino and Donato, Gazz. chim. ital. 1908. 38, ii. 20; Fries, Ber. 1904, 37, 2338; Knoevenagel, *ibid.* 4073; *ibid.* 1909, 42, 3619; Diepolder. *ibid.* 2916; D. YELLOW WOOD *v.* OLD FUSTIC.

YELLOW CEDAR. The *Rhodosphacra rhodanthema* [Engl.] or yellow cedar, a tree growing to the height of 70 or 80 ft., is indigenous to the northern part of New South Wales.

The colouring matter of this dyewood is *fisetin*, which is readily isolated by the method described in connection with YOUNG FUSTIC (Perkin, Chem. Soc. Trans. 1897, 71, 1194).

A second substance $C_{26}H_{30}O_{16}$?, colourless needles, m.p. 215°–217°, is also present in small amount, and may be identical with *fustin*, the glucoside of fisetin (Schmid, Ber. 1886, 19, 1755).

The shades given by the yellow cedar are slightly weaker and differ considerably from those given by young fustic (*Rhus Cotinus*), although both contain the same colouring matter. Employing mordanted woollen cloth, the following distinctions are observed—

	Chromium	*Aluminium*	*Tin*	*Iron*
Young fustic .	Reddish brown	Orange	Orange yellow	Brown olive
Yellow cedar .	Yellowish brown	Brownish yellow	Golden yellow	Olive

and these may be due to varying amounts of a brown extractive matter, which is contained in both plants. A. G. P.

YEW (*Taxus*; *If commun*, Fr.; *Eibe*, Ger.). It has long been known that the leaves and berries of the common yew, *Taxus baccata* (Linn.), (Bentl. and Trim. 253), possess powerful toxic properties. Yew is a reputed emmenagogue, and it has been used for the purpose of procuring criminal abortion, but its efficiency is more than doubtful, and its employment often leads to fatal consequences (*cf.* Redwood, Pharm. J. [iii.] 8, 361). The first thing to do in cases of poisoning is to empty the stomach; milk may then be given to allay irritation, and such stimulants as alcohol or ammonia employed. Yew is seldom used in medicine.

Chevallier and Lassaigne (J. Pharm. Chim. 1818, 4, 558), Peretti (*ibid.* 1828, 14, 537), Lucas (Arch. Pharm. [ii.] 85, 145), and others have examined yew chemically, but no definite compound was isolated till the discovery of an alkaloid *taxine* by Marmé in 1876 (Chem. Zentr. 1876, 166). Taxine was further studied by Amato and Capparelli (Gazz. chim. ital. 10, 349), who also obtained a non-nitrogenous crystalline compound *milossin*, and a *volatile oil* which distils with steam, and has the odour of fennel. The chemical reactions of taxine obtained by Marmé's process have been examined by Hilger and Brande (Ber. 23, 464). Taxine is prepared by exhausting yew leaves or seeds with alcohol or ether. The residue, after distilling off the alcohol or ether, is extracted with acidified water, and from the clear aqueous solution alkalis precipitate the base in white flakes, which, when washed and dried over sulphuric acid, assume the appearance of a white crystalline powder. The leaves contain more alkaloid than the seeds. The preliminary extractions of the leaves with alcohol or ether may be dispensed with; they can be treated directly with a weak solution of an acid. Thorpe and Stubbs (Chem. Soc. Trans. 81, 874) have investigated the conditions under which taxine can be extracted. They find that it undergoes change with extreme ease during the process of extraction, thus accounting for the difference in the description of its properties by earlier investigators. The method of extraction giving the best results was found to be treatment with dilute sulphuric acid (1 p.c.) in the cold. Taxine, so obtained, consists of very fine glistening particles or a white amorphous powder. It does not crystallise. It is odourless, but possesses a very bitter taste. It is very slightly soluble in water, is soluble in dilute acids, alcohol, ether, benzene, or chloroform, and insoluble in light petroleum. At 82° taxine practically melts, undergoing at the same time some decomposition. Analysis gives figures agreeing with the formula $C_{37}H_{52}O_{10}N$ proposed by Hilger and Brande. Taxine gives reactions characteristic of the alkaloids when treated with the usual reagents, and also combines with acids to form definite salts, which have, however, not been obtained crystalline. From the residue, insoluble in very dilute acids, after the removal of the taxine, alcohol and animal charcoal extracts milossin. Its purification is tedious and difficult. It crystallises in stellate groups of needles, which melt at 86°–87°, and which are insoluble in water, but soluble in boiling alcohol (Amato and Caparelli).

A glucoside, *taxicatin*, has been found in the leaves of the yew by Bourquelot (J. Pharm. Chim. [vi.] 23, 369). Taxicatin $C_{13}H_{22}O_7$, crystallises from alcohol in colourless needles, m.p. 169°–170° (corr.); the crystals obtained from aqueous solutions contain $2H_2O$. It is hydrolysed by emulsin or by 2 p.c. sulphuric acid into dextrose and a substance readily soluble in ether or chloroform (Lefebvre, *ibid.* [vi.] 26, 241).

The twigs of *Taxus baccata* were found to contain invertin and emulsin (Lefebvre), and raffinose and sucrose have been isolated from the leaves and twigs (Hérissey and Lefebvre, *ibid.* [vi.] 26, 56).

The amount of taxine present in the Irish yew, *Taxus baccata*, var. *Fastigiata* has been investigated by Moss (Sci. Proc. Roy. Dubl. Soc. 12, 92). The results seem to indicate that the Irish yew contains much more taxine than the common yew (*v.* VEGETO-ALKALOIDS). A. S.

YLANG-YLANG *v.* OILS, ESSENTIAL.

YOUNG FUSTIC consists of the wood of the stem and larger branches of the *Rhus Cotinus* (Linn.), a small tree which is a native of Southern Europe, and the West Indian Islands. It is a hard compact yellow wood, and is usually imported in small bundles or faggots. Within the last few years young fustic has almost disappeared from the market, not only on account of the artificial colouring matters, but because the shades it yields lack permanence, and the percentage of colouring matter it contains is small. The leaves of the *R. Cotinus* constitute *Venetian sumach*, a tanning material which is employed to some extent in Italy and Southern Europe.

Fisetin $C_{15}H_{10}O_6$. the colouring matter of young fustic was first isolated by Chevreul (Leçons de Chemie appliqués à la Teinture, A, ii. 150), who gave it the name '*Fustin*.' Bolley

(Schweiz. polyt. Zeitschr. 1864, 9, 22) considered that it was identical with quercetin, but Koch (Ber. 5, 285) maintained that fisetin was probably an aldehyde of quercetinic acid.

Schmid (Ber. 1886, 19, 1734), who carried out an exhaustive examination of this dyewood, obtained fisetin in a pure condition and proved that it was not identical with quercetin. He found that in addition to the free colouring matter, young fustic contains a glucoside of fisetin combined with tannic acid to which he gave the name of *fustin tannide*.

To prepare fisetin, Schmid (*l.c.*), and later Herzig (Monatsh. 12, 178) employed 'cotinin' (*v. infra*), a commercial preparation of young fustic which is no longer on the market. According to Perkin and Pate (Chem. Soc. Trans. 1895, 67, 648) fisetin is readily isolated from the dyewood as follows:—

Young fustic is extracted with boiling water, and the extract treated with lead acetate solution. The lead compound of the colouring matter is collected, made into a thin paste with water, and in a fine stream run into boiling dilute sulphuric acid. After removal of lead sulphate the dark-coloured filtrate, on cooling, deposits a semi-crystalline brownish mass, which is collected and purified by crystallisation from dilute alcohol.

Schmid assigned the formula $C_{23}H_{16}O_9$ to fisetin, but it was found by Herzig that the analyses agreed equally well with $C_{15}H_{10}O_6$, and that this formula was correct was supported by the work of Perkin and Pate (*l.c.*), who gave to fisetin sulphate the formula $C_{15}H_{10}O_6 \cdot H_2SO_4$.

Fisetin forms yellow needles, melting at above 360°, easily soluble in alcohol. Alkaline solutions dissolve it with a deep yellow colour which, on exposure to air, gradually changes to brown; with alcoholic ferric chloride it gives a deep green colouration, and with lead acetate a bright orange-red precipitate. *Tetra-acetyl fisetin* $C_{15}H_6O_6(C_2H_3O)_4$, m.p. 196°–198°, crystallises in colourless needles, and the *benzoyl* derivative $C_{15}H_6O_6(C_7H_5O)_4$ needles, melts at 180°–181° (P. and P.) (Schmid, 184°–185°). Fisetin gives with mineral acids in the presence of acetic acid crystalline salts. *Fisetin sulphate*

$$C_{15}H_{10}O_6 \cdot H_2SO_4,$$

scarlet needles, *fisetin hydrobromide*

$$C_{15}H_{10}O_6 \cdot HBr,$$

orange needles, and *fisetin hydrochloride* have been prepared in this manner (P. and P.). These compounds are readily decomposed by water. *Monopotassium fisetin* $C_{15}H_9O_6K$, yellow needles (Perkin, Chem. Soc. Trans. 1899, 75, 433) is obtained from fisetin by means of alcoholic potassium acetate.

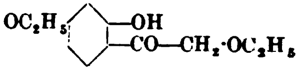
By fusion with alkali or by the oxidation of its alkaline solution by exposure to air fisetin gives *resorcinol* and *protocatechuic acid* (Herzig).

On ethylation with ethyl iodide fisetin is converted into *fisetin tetraethyl ether*

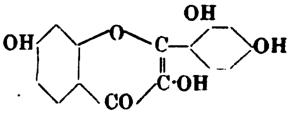
$$C_{15}H_6O_2(OC_2H_5)_4,$$

colourless needles, m.p. 106°–107°; the corresponding methyl derivative $C_{15}H_6O_2(OCH_3)_4$ melts at 152°–153°.

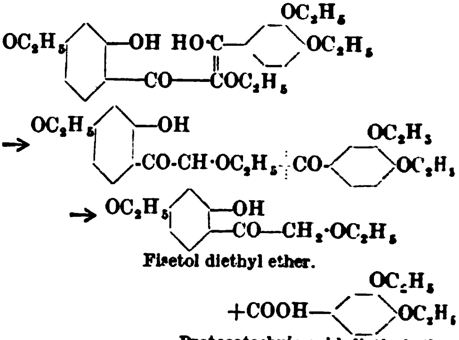
When fisetin tetraethyl ether is submitted to the action of boiling alcoholic potash it gives *protocatechuic acid diethyl ether*, and *fisetol diethyl ether* (Herzig), colourless needles, m.p. 42°–44°. This latter compound, by oxidation with permanganate, is converted into the *monoethyl ether* of *resorcylic acid*, and the *monoethyl ether* of *resorcinolglyoxylic acid*, and consequently fisetol diethyl ether may be thus represented



As a result of his investigation Herzig assigned to fisetin the constitution of a *trihydroxyflavonol*.



The tetraethyl derivative of this compound suffers hydrolysis according to the following scheme—



Fisetol diethyl ether.

Protocatechuic acid diethyl ether.

Fisetin has been synthesised by v. Kostanecki, Lampe, and Tambor (Ber. 1904, 37, 784).

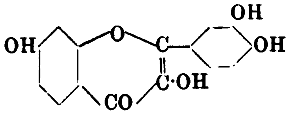
2′-Hydroxy-4′-ethoxy-3:4-dimethoxychalkone (I

I. 
prepared by the condensation of resacetophenone-monoethyl ether with veratric aldehyde, when digested with boiling dilute alcoholic sulphuric acid gives 3-ethoxy-3′:4′-dimethoxyflavanone (II

II. 
and this, when treated with amyl nitrite and strong hydrochloric acid in alcoholic solution, is converted into the *iso*nitroso compound (III)—

III. 
IV. 
When boiled in acetic acid solution with 10 p.c. sulphuric acid this substance gives 3-ethoxy-3′-4′-dimethoxyflavonol (IV). from which fisetin (V) is readily produced by the action of boiling hydriodic acid.

V.



Fisetin is a strong colouring matter and gives shades which are almost identical with those produced by quercetin, rhamnetin, and myricetin. The colours given with wool mordanted with chromium, aluminium, and tin are, respectively, red-brown, brown-orange, and bright red-orange (Perkin and Hummel, Chem. Soc. Trans. 1896, 69, 1290).

The glucoside of fisetin, according to Schmid (*l.c.*), is prepared as follows: A boiling aqueous extract of young fustic is treated with lead acetate, the precipitate removed, the clear liquid freed from lead by means of sulphuretted hydrogen, and saturated with salt. The mixture is filtered, extracted with ethyl acetate, and the extract evaporated. There is thus obtained a residue consisting of the crude fustin-tannide, which is purified by solution in water, precipitation with salt, and extraction with ethyl acetate.

Fustin tannide crystallises in long yellowish-white needles, which are easily soluble in water, alcohol, and ether. When heated it decomposes above 200°. If a solution of fustin tannide in hot acetic acid is treated with water, and allowed to stand for some time, colourless crystals of *fustin* are gradually deposited.

Fustin crystallises from water in yellowish-white needles, m.p. 218°–219°, and when digested with boiling dilute sulphuric acid gives *fisetin* and a sugar, the nature of which has not been determined. The formula given to this glucoside $C_{55}H_{46}O_{23}$ by Schmid cannot be regarded as correct, in view of the fact that the true formula of fisetin is now known to be $C_{15}H_{10}O_6$.

Dyeing properties of young fustic. The colours derived from young fustic are all fugitive to light, hence this dyestuff has lost its importance. In silk dyeing it was formerly used for dyeing brown, the silk being mordanted with alum, and afterwards dyed with a decoction of young fustic, peachwood, and logwood. With the various metallic salts as mordants young fustic yields colours somewhat similar to those obtained from old fustic, the chromium colour is, however, much redder, being a reddish-brown, and the aluminium yellow is much duller; stannous chloride on the contrary gives an incomparably more brilliant orange, not unlike that obtainable from flavin or from Persian berries (Hummel). A. G. P.

YTTERBIUM (*Neoytterbium*). Sym. Yb. At.wt. 172·0. In 1878 Marignac, by the fractional decomposition of the nitrates, isolated from crude erbia the earth *ytterbia*, which has since been resolved by Urbain into two components *neoytterbia* and *lutecia* (Compt. rend. 1907, 145, 759; *cf.* Auer von Welsbach, Monatsh. 1906, 27, 935; 1908, 29, 181; Wenzel, Zeitsch. anorg. Chem. 1909, 64, 119; Urbain, Chem. Zeit. 1908, 32, 730).

Occurrence. Xenotime, ytterbite (gadolinite), monazite.

Separation and purification, v. LUTECIUM (*cf.* Urbain, Congress of Applied Chemistry, 1909, x. 94).

Ytterbium oxide (*Ytterbia*) Yb_2O_3, a colourless mass when free from thulia; it dissolves slowly in cold, and readily in hot, dilute acids. With the exception of scandia and lutecia, ytterbia (neoytterbia) is the weakest base of the yttrium earth series.

Ytterbium hydroxide $Yb(OH)_3$ is a colourless gelatinous precipitate.

Ytterbium chloride $YbCl_3,6H_2O$ (Matignon, Ann. Chim. Phys. 1906, [viii.] 8, 440), prepared by the action of hydrochloric acid on ytterbia, separates in deliquescent crystals, m.p. 150°–155°; it gives rise to the readily soluble **platinichloride** $2YbCl_3,PtCl_4,22H_2O$, and **aurichloride** $YbCl_3,AuCl_3,9H_2O$.

Ytterbium nitrate $Yb(NO_3)_3,4H_2O$ crystallises from strong nitric acid in transparent hygroscopic prisms; a trihydrate separating in colourless plates is obtained from solutions evaporated over strong sulphuric acid.

Ytterbium sulphate $Yb_2(SO_4)_3,8H_2O$, lustrous colourless crystals, the solubility of which diminishes with rise of temperature; this salt is partially hydrolysed in dilute solutions.

Ytterbium orthophosphate $YbPO_4,4\frac{1}{2}H_2O$, a gelatinous precipitate obtained from soluble ytterbium salts and sodium phosphate; the **metaphosphate** $Yb(PO_3)_3$, a crystalline powder, produced by melting together anhydrous ytterbium sulphate and metaphosphoric acid.

Ytterbium borate $YbBO_3$, obtained by fusing together ytterbia and boric anhydride, is a crystalline mass insoluble in dilute hydrochloric acid.

Ytterbium carbonate $Yb_2(CO_3)_3,4H_2O$, a gelatinous precipitate produced by mixing solutions of ytterbium nitrate and ammonium carbonate; the **basic carbonate** $Yb(OH)CO_3,H_2O$ is formed by passing carbon dioxide through freshly-precipitated ytterbium hydroxide.

Ytterbium oxalate $Yb_2(C_2O_4)_3,10H_2O$ is a crystalline powder distinctly more soluble in dilute sulphuric acid than the oxalates of yttrium and gadolinium (Nilson, Compt. rend 1879, 89, 419; 1880, 91, 56, 118). The normal ytterbium salts of the lower fatty acids are very soluble substances.

Spectra. Spark spectrum (i.) visible region (Thalén, *ibid.* 1880, 91, 326); (ii.) ultra-violet (v. Welsbach, Monatsh. 1884, 5, 1; Crookes, Proc. Roy. Soc. 1906, 78, A, 154). Arc spectrum (Exner and Haschek, Die Wellenlängen der Bogenspektra, 1904). G. T. M.

YTTRIUM. Sym. Y. At.wt. 89·0. Yttria, the predominant and most basic constituent of the yttrium earths, was first recognised by Mosander in 1843, and is the most easily purified oxide of this series.

Sources. The yttrium earths from the following minerals: ytterbite, xenotime, fergusonite, yttrotantalite, samarskite, polycrase, euxenite, yttrocrasite (Amer. J. Sci. 1906, [iv.] 22, 515). It also occurs in smaller quantities in the rare earths from cerite and allied minerals (*v.* CERIUM METALS AND EARTHS).

Separation and purification. In its basicity yttria follows the more basic cerite earths and is separated by methods founded on differences in basic strength from the other less basic yttrium earths, erbia, dysprosia, thulia, ytterbia, lutecia, and scandia, the following processes being employed for this purpose: (1) decomposition of nitrates; (2) the basic salt method (*v.* Lanthanum and Scandium); (3) fractional precipitation with alkalis or aniline; (4) successive treatment with ammonium carbonate and acetic acid.

Crystallisation methods are less practicable in the yttrium than in the cerium group, because of the greater solubility of the salts and the instability of the double nitrates, which in the yttrium series are unstable at the ordinary temperatures in aqueous or nitric acid solutions. Nevertheless, the final purification of yttrium from erbium, &c., may be effected by fractionation of the bromates, chromates, formates, acetates, oxalates, acetylacetonates, ethyl-sulphates, and ferrocyanides (*v.* Erbium).

Metallic yttrium has been obtained by the reduction of yttrium chloride or yttrium sodium chloride with sodium or by the electrolysis of the latter salt; it is an iron-grey substance easily oxidisable and decomposing hot water (Cleve, Bull. Soc. chim. 1873, [ii.] 18, 193, 289; 1874, [ii.] 21, 344; *cf.* Winkler, Ber. 1890, 23, 44, 120, 772, 2642).

Yttrium oxide (*Yttria*) Y_2O_3, white powder, sp.gr. 5·353, sp.ht. 0·1173, absorbing carbon dioxide from the atmosphere; obtained crystalline by fusion with calcium chloride (Compt. rend. 1888, 107, 99; J. Russ. Phys. Chem. Soc. 1910, 42, 96).

Yttrium hydroxide $Y(OH)_3$, gelatinous precipitate; the product obtained with ammonia in presence of hydrogen peroxide is a hydrated peroxide Y_4O_9,xH_2O (Cleve, Bull. Soc. chim. 1885, [ii.] 43, 53).

Yttrium carbide YC_2, yellow crystalline mass, sp.gr. 4·13, produced by heating the oxide with carbon in the electric furnace, is decomposed by water evolving acetylene, mixed with hydrogen, methane, and ethylene (Moissan and Étard, Compt. rend. 1896, 122, 573).

The salts of yttrium with colourless acid radicles are devoid of colour, and their solutions show no selective absorption in the visible region of the spectrum.

Yttrium fluoride $YF_3,\frac{1}{2}H_2O$ is obtained in the wet way as a gelatinous precipitate; the anhydrous substance is produced by the action of fluorine on the carbide (Moissan and Étard, *l.c.*).

Yttrium chloride YCl_3 can be produced by the methods generally applicable for the preparation of the anhydrous chlorides of the rare earths (*v.* Cerium). The hexahydrate

$$YCl_3,6H_2O,$$

colourless deliquescent prisms, melts at 160°, and is readily soluble in water or alcohol (Matignon, Ann. Chim. Phys. 1906, [viii.] 8, 433).

Yttrium sulphate $Y_2(SO_4)_3,8H_2O$, monoclinic crystals, isomorphous with the octahydrated sulphates of erbium, neodymium, and praseodymium (Kraus, Zeitsch. Krist. 1901, 34, 307). The **acid sulphate** $Y(SO_4H)_3$ separates from concentrated solutions in sulphuric acid (Brauner and Pičck. Zeitsch. anorg. Chem. 1904, 38, 322). With alkali sulphates, yttrium forms soluble double sulphates, *e.g.* $2Y_2(SO_4)_3,3K_2SO_4$;

$$Y_2(SO_4)_3,Na_2SO_4,2H_2O;$$

$Y_2(SO_4)_3,2(NH_4)_2SO_4,9H_2O$; these salts crystallise on concentrating the aqueous solution of their components.

Yttrium nitrate $Y(NO_3)_3,6H_2O$, very soluble deliquescent crystals; a dihydrate has also been described (Tanatar and Voljanski, J. Russ. Phys. Chem. Soc. 1910, 42, 586); basic nitrates, *e.g.* $3Y_2O_3,4N_2O_5.20H_2O$, are produced by the partial decomposition of the normal salt (James and Pratt, J. Amer. Chem. Soc. 1910, 32, 873).

Yttrium phosphates. The **ortho-phosphate** YPO_4, which occurs native as xenotime (*v. supra*), has been obtained in lustrous needles by melting together yttrium chloride and the amorphous phosphate (Compt. rend. 1875, 80, 304; 1888, 107, 622). When prepared in the wet way the crystalline salt has the composition $YPO_4,2H_2O$. The normal **pyro-** and **metaphosphates** $Y_4(P_2O_7)_3$ and $Y(PO_3)_3$ have been described together with several acid and double phosphates (Cleve, *l.c.*; Johnson, Ber. 1889, 22, 976).

Yttrium carbonate $Y_2(CO_3)_3,3H_2O$, white precipitate obtained either from a soluble yttrium salt and an alkali carbonate, or by passing carbon dioxide into freshly-precipitated yttrium hydroxide; it dissolves in excess of aqueous alkali carbonate forming double carbonates, *e.g.* $Y_2(CO_3)_3,Na_2CO_3,4H_2O$.

Yttrium oxalate $Y_2(C_2O_4)_3,9H_2O$, a white crystalline powder, dissolving in aqueous potassium oxalate to form $Y_2(C_2O_4)_3,3K_2C_2O_4,18H_2O$: it is soluble in dilute sulphuric acid to approximately the same extent as lanthanum oxalate.

Yttrium salts of other organic acids (*v.* Cleve, *l.c.*; Tanatar and Voljansky, *l.c.*; Benner, J. Amer. Chem. Soc. 1911, 33, 50).

Spectra. Spark spectrum; visible region (Thalén, Bull. Soc. chim. 1873, [ii.] 22, 350; Bunsen, Pogg. Ann. 1875, 155, 230, 366; v. Welsbach, Monatsh. 1884, 5, 1): ultra-violet region (Lohse, Ber. Berlin Akad. 1897, 179); Exner and Haschek, Ber. Wien. Akad. 1900, 109, II*a*, 122). Arc spectrum (Exner and Haschek, Die Wellenlängen der Bogenspektra, 1904; Eberhard, Zeitsch. wiss. Photograph. Photophysik. Photochem. 1909, 7, 245). Cathode luminescence (Crookes, Chem. Soc. Trans. 1889, 55, 255; Chem. News, 1889, 60, 27, 39, 51, 63; Muthmann and Baur, Ber. 1900, 33, 1748; Baur and Marc, *ibid.* 1901, 34, 2460).

G. T. M.

YTTROTANTALITE. A complex mineral consisting essentially of yttrium tantalate and crystallising in the orthorhombic system. It is black with a bright, conchoidal fracture, and closely resembles samarskite (*q.v.*) in appearance. Masses several pounds in weight have been found in the felspar quarries at Ytterby and Fahlun in Sweden and in the south of Norway (W. C. Brögger, Die Mineralien der südnorwegischen Granitpegmatitgänge, Vid.-Selsk. Skr. Kristiania, 1906, No. 6, 152). L. J. S.

Z

ZAFFRE. *Cobalt blue v.* Cobalt; also Pigments.

ZALA. A synonym for Borax.

ZANTHOXYLUM. The bark of the prickly ash, *Zanthoxylum americanum* (Mill.), and *Z. carolinianum*, which are rutaceous plants. Is used in medicine in the treatment of rheumatism and to relieve toothache. It contains a volatile oil and resin.

ZEÏN *v.* Maize, art. Cereals.

ZEIODELITE. The name of a mixture obtained by stirring 24 parts of finely-powdered glass into 20 parts of melted sulphur; used as a cement and for taking casts instead of sulphur or plaster.

ZEOLITES. A large group of minerals consisting of hydrated silicates of aluminium with alkalis and alkaline earths. A few of the more important are—

Natrolite (*q.v.*)	$Na_2Al_2Si_3O_{10},2H_2O$
Stilbite	$CaAl_2Si_6O_{16},6H_2O$
Heulandite	$CaAl_2Si_6O_{16},5H_2O$
Chabazite	$CaAl_2Si_4O_{12},6H_2O$
Analcite	$NaAlSi_2O_6,H_2O$
Thomsonite	$CaAl_2Si_2O_8,2\frac{1}{2}H_2O$

Harmotome and edingtonite contain barium; brewsterite contains some strontium; and potassium is present in phillipsite. These minerals hold their water of crystallisation very loosely, and it is replaceable by a variety of substances (*e.g.* ammonia, alcohol, &c.). They fuse readily with intumescence, hence the name zeolite, from ζεῖν, to boil, and λίθος, a stone. They are readily decomposed by acids, usually with the separation of gelatinous silica; and by the action of various reagents several substitution products have been prepared. They are minerals of secondary origin, occurring usually in the steam-cavities of volcanic rocks, and have been derived from the decomposition of felspar and other alkali-bearing minerals (with which they show certain chemical analogies).

The zeolites present many points of mineralogical interest, and they afford beautifully crystallised specimens, but they are of no direct economic importance. They appear, however, to play an important part in soils by retaining in a readily soluble form the alkalis set free on the weathering of felspar. The indefinite zeolitic constituent of soils has been named *geolyte* (Ger. *Bodenzeolith*) (E. A. Wülfing, Jahresh. Ver. Naturk. Württemberg, 1900, 66, 35; R. Gans, Zeolithe und ähnliche Verbindungen ihre Konstitution und Bedeutung für Technik und Landwirtschaft, Jahrb. K. Preuss. Geol. Landesanst, Berlin, for 1905, 1906, 179–211.)

On *permutite*, an artificial zeolite-like substance employed for softening water and for removing manganese and iron from water, and also used in sugar refining, *v.* R. Gans, Chem. Zentr. 1909, i. 2031; also art. Water.

L. J. S.

ZINC. Sym. Zn. At.wt. 64·88.

This metal was mentioned by Albertus Magnus, who died in 1280, the name then employed being 'golden marcasite.' The modern word zinc appears first in the writings of Paracelsus, about 1500.

The metal had, however, been produced at a much earlier date, probably by accident. Zinc bracelets were discovered in the ruins of Cameros, destroyed *circa* 500 B.C. Libavius carefully examined the properties of zinc about 1595.

Ores of zinc were known to the ancients, and were employed by them both for the manufacture of brass by the calamine process, and also in medicine. The working of zinc ores in Europe in modern times dates from the introduction of the use of brass, and there are records extant which show that in 1439 the Vieille Montagne calamine mines had been worked for a considerable time by the men of Aix. Metallic zinc was sometimes produced accidentally during the smelting of copper, but is stated to have been first made directly from calamine by Henckel in 1721 (Percy, Metallurgy, i. 520). A zinc factory was erected at Bristol by Champion in 1743; but the production in this country was small, the greater part of the metal required being imported from China and India, and zinc is stated to have sold in 1731 for £260 per ton, or more than ten times its present value. Other works were erected in the United Kingdom, and the demand gradually increased with the introduction of the direct method for the manufacture of brass. In England the process of distillation *per descensum* in fireclay crucibles was adopted; this has scarcely been used elsewhere, and is now completely abandoned in this country. The important zinc industry of Silesia in Germany was commenced in 1799 by Ruhberg, who had learned the process in England. The Liège (or Belgian) process was invented by Daniel Douy in 1809, and works were immediately erected for carrying out the process at Liège. These works ultimately developed into the Société de la Vieille Montagne in 1837, and this Société is now the largest zinc-producing company in the world. Zinc smelting was not introduced into the United States until 1850. It was not till 1820 that the exports of zinc from England to India about equalled the total imports, and this country could be considered for the first time to supply itself with zinc. Since that time, however, the trade has fluctuated considerably, so that in 1864 the total production of zinc in the United Kingdom did not equal one half of that required in the Birmingham brass trade alone.

In recent years the world's production of zinc (or 'spelter') has steadily increased, though the industry is limited to comparatively few centres. On the continent smelting is conducted in Belgium, Westphalia, and Silesia; in America the centres are Kansas, Illinois, and New Jersey; in the United Kingdom at Swansea and near Birmingham. The world's production of zinc in 1907 was 737,500 metric tons, the chief producers being—

United States . .	226,400 tons
Germany . . .	208,200 „
Belgium . . .	154,470 „
France and Spain .	55,730 „
United Kingdom . .	55,600 „

The greater part of the zinc smelted in the United Kingdom is now obtained from imported ores, the zinc ore raised in 1911 being only 17,652 tons. The Derbyshire mines were once of great importance, but their output now is negligible. Between 1880 and 1910 the British production of zinc increased tenfold. In addition about 100,000 tons of crude spelter are annually imported. At the end of the nineteenth century a very important zinc industry had grown up in Kansas. It depended largely on natural gas for fuel, and with the gradual exhaustion of the gas supply many spelter works were closed, and the industry migrated to the coalfields of Illinois or to Joplin.

Ores of zinc. The most important ores of zinc are the sulphide and carbonate. *Zinc blende* (ZnS) is commonly called 'black jack' by the miner on account of its dead black colour and high lustre. The use of blende for the manufacture of zinc and brass was patented in 1758 by Champion of Bristol. Previously the source of the metal was the carbonate, *calamine* ($ZnCO_3$), and this was the only ore used in Belgium until about 1855, when roasting of blende was adopted. Both these ores are widely distributed and are now extensively employed. Of less importance are the oxide (which usually contains oxide of manganese, and from its colour is called red oxide of zinc), and the silicates.

In New Jersey red oxide of zinc occurs together with magnetic oxide of iron in *Franklinite* from which the zinc is first extracted, and the residue is afterwards smelted for spiegel-eisen in the blast furnace. For ores which consist largely of oxide of zinc, but with some iron, magnetic concentration is now employed, the magnetite being removed, and an ore suitable for the zinc smelter obtained. The flue dust from the blast furnace used in the manufacture of iron is also frequently sufficiently rich in zinc to render its extraction advantageous.

Extraction of zinc. It is necessary that the ores used for the extraction of zinc should be as rich and as uniform in character as possible. The ore as purchased by the smelter usually contains at least 50 p.c. of zinc, though 45 or even 40 p.c. ores are used if they contain other valuable materials to replace the decrease in zinc. The ores as they occur are often only poor in zinc, and require to be concentrated by washing; in the case of calamine ores this is usually a simple matter, but with blendes which are frequently associated with other sulphides concentration is a more complicated operation, though with modern appliances, careful sizing, and the necessary attention, a remarkably perfect separation can be effected. The slimes produced during concentration are again treated, 'frue vanners' being now used for this purpose, and such portions as are rich in zinc are dried and smelted in mixture with other materials as afterwards described.

'Complex' ores, *i.e.* ores containing other metals in addition to zinc, have been the cause of considerable loss in times past, and enormous quantities of tailings were accumulated. These are now treated by flotation processes which separate the metallic sulphides from the gangue. In oil separation processes the dry, finely-crushed ore is mixed with a small quantity of oil, and is then washed with water. The metallic particles, or other bodies with smooth surfaces like sulphides, are wetted by the oil, and float upon the water, while the earthy portions sink to the bottom. In the Elmore oil vacuum process separation is assisted by the aid of partial exhaustion of a large metal receiver into which the oiled slimes and water enter. The air films surrounding the oiled particles are thus expanded and the separation much improved. In other cases diluted acid is employed, and with suitable ores gas bubbles are produced which cause the particles rich in metal to rise to the surface of the liquid. These flotation processes are now of such importance that from the Central mine at Broken Hill in Australia one-tenth of the total zinc ore of the world is obtained. The original ore contains 16·5 p.c. lead, 18·5 p.c. zinc, and 13 oz. of silver per ton. The concentrates account for 90 p.c. of the lead present, 85 p.c. of the zinc, and 88 p.c. of the silver (Sulman, Jour. Inst. Min. and Metallurgy, 1911, 47, 20).

When the ores have been thus concentrated, they are calcined or roasted to convert them as completely as possible into zinc oxide. Calamine is readily calcined, and this is frequently conducted in kilns with the waste heat from the smelting furnaces. On the other hand, blende requires much care and experience in roasting, so as to prevent the formation of difficultly decomposable sulphate. Blende is generally roasted in multiple-bedded reverberatory furnaces, sometimes with the waste heat from the smelting furnaces. By the use of multiple-bedded roasting furnaces a considerable economy of fuel and more uniform heating are obtained. It has generally been considered that the presence of any sulphur in roasted blende leads to loss of zinc, owing to sulphide being left in the retort, but, according to A. Voigt (J. Soc. Chem. Ind. 8, 986), the zinc left in the retort is chiefly in the form of oxide, while the sulphur in roasted blende is in the form of sulphates of metals generally other than zinc, and the presence of a small quantity of sulphur in roasted blende does not reduce the yield of zinc.

In roasting blendes a quantity of zinc fume is produced, and may lead to a somewhat considerable loss of zinc. This fume has been utilised by Krause-Cöthen for the manufacture of zinc carbonate (Berg. u. Hütt. Zeit. 1891, 246). The blende roasted at Oberhausen contains 0·02 p.c. of mercury. The dust deposited from the roasting kilns contains about 7 p.c. of mercury, which is extracted, and the sulphur dioxide from the gases is used for the manufacture of sulphuric acid (Chem. Zeit. 10, 1039).

Great advances have been made in recent years in the furnaces used for roasting blende, the object being to economise fuel and labour to obtain a more uniform product, and to utilise the sulphur dioxide evolved. This branch of the subject has been historically treated and fully illustrated by E. Schütz, Metallurgie, 1911, 635. One form of such furnace which has met with considerable favour is known as the Merton. It is multiple-bedded, and mechanically stirred.

After calcination the finely-divided ore is in all cases mixed with a suitable proportion of ground coal (non-caking), or other carbonaceous material, and heated to bright redness in a retort, the form and dimensions of which vary with the locality and the nature of the ore. The carbon unites with the oxygen of the ore to form carbon monoxide, and zinc is set free; the metal at the high temperature employed is converted into vapour, which is caused to pass into suitable receptacles, and condensed. The processes which are, or have been, used for the extraction of zinc differ merely in the form, arrangement, and number of the retorts, and in the methods adopted for supporting and heating them.

As the temperature at which the reaction $ZnO+C=Zn+CO$ takes place under ordinary atmospheric pressure is about 1050°, and nearly as high in a vacuum, the temperature of the retorts is necessarily high. The fuel consumption is therefore high, and the wear and tear of the retorts considerable. The difficulty of condensing the zinc vapour is increased by the fact that it is accompanied by carbon monoxide and other gases.

It is advantageous to thoroughly crush the materials, and to have as large a condensing space as possible. The condensers should be just sufficiently hot to keep the condensed metal in the liquid state, as, if the receivers are too hot, zinc is lost by volatilisation, while if the temperature is too low a coarse crystalline product is obtained. It is necessary that the retorts should be kept filled with carbon monoxide; if carbon dioxide is present, part of the zinc is oxidised and zinc and zinc oxide distil over together. For this reason it is necessary to leave a little of the ore unreduced in the retort at the end of the process (Steger, J. Soc. Chem. Ind. 5, 607).

The following general principles have been laid down for the construction of zinc furnaces by M. F. Laur (Bull. Soc. Indust. Minérale, 1874, 3, 395; Inst. C. E. 41, 317):—

1. That it is not prudent to construct furnaces the internal capacity of which exceeds about 32·5 cubic yards.

2. The thickness of the charge to be reduced in the muffles should not exceed 7 ins., and the vessels should not exceed 20 ins. in height, or 5 ft. in length.

3. The maximum capacity which can be advantageously given to the retorts is about 22 gallons.

4. The total internal volume of the retorts should be about one-third of the volume of the furnace in which they are heated, since experience shows that about two-thirds of the space is required for supports and free circulation.

Four processes for the extraction of zinc have been actually worked on a considerable scale—namely, the English, Carinthian, Belgian, and Silesian.

1. In the *English process*, adopted by Champion at Bristol, large fire-clay crucibles were used, and the method was that known as distillation *per descensum*. The process involved the use of an excessive amount of fuel, and only a comparatively small amount of zinc could be produced. This manufacture forms a very interesting chapter in the metallurgy of zinc, and has been fully treated by Dr. Percy (Metallurgy, i. 550), but as it has been entirely superseded, will not be here described in detail.

2. *The Carinthian process.* The process formerly adopted in Carinthia was in principle similar to the English method, the ore being charged into vertical pipes or retorts of fire-clay, and distillation being effected *per descensum*; a single furnace sometimes contained over 250 such pipes. This process is also now abandoned.

3 and 4. *Belgian and Silesian processes.* The only processes now in extensive operation for the smelting of zinc are the Belgian and Silesian, neither of which is confined to the countries in which it was invented. The two systems are sometimes combined in the same furnace, the retorts in the lower or hotter part being on the Silesian principle, and in the upper part on the Belgian. In each case the retorts are of fire-clay, and are generally made on the premises. In this country they are still frequently moulded by hand, then air-dried for about a fortnight, and afterwards heated to redness in a separate furnace before being set in position. By an improvement, the invention of M. Dor, which has been largely adopted on the Continent, and to some extent in the United Kingdom, the retorts are subjected to a pressure of 3000 lbs. to the square inch during manufacture. Great care is taken in the selection of suitable clays, in the preparation and tempering, and in pressing the retorts. They are thus made very thin, and yet possess great durability. The differences between the Belgian and Silesian systems are in the shape, size, and method of supporting the retorts, in the amount of charge used, and in the arrangement of the retorts in the furnace. In each system direct firing by coal was formerly universal and is still occasionally used, but gas-firing is now very generally employed. In Wales and in the United States regeneration by reversals, on the Siemens' principle, is generally adopted, but in Belgium continuous regeneration is preferred. In this system the gas producers are not separate from the furnace, but are placed in the furnace below the retorts. The products of combustion circulate by a zig-zag course through firebricks. The firebricks are provided with hollow channels, through which is drawn the air used for combustion. Such furnaces appear to work very satisfactorily and to require little attention or repair. The introduction of gas furnaces has led to considerable saving of fuel, which in Silesia was formerly 3·5 tons of coal per ton of ore, and is now about one-third of that quantity; gas firing has also led to the use of larger furnaces and given longer life to the retorts. The result has been that, in Silesia, while the number of works has actually decreased, the production of zinc has greatly increased (*v.* M. Georgi, Zinc Industry of Upper Silesia; Berg. u. Hütt. Zeitung, 36, 71, 78, 97; Inst. C. E. 49, 369).

The retorts used in the *Belgian process* are cylindrical or elliptical in shape, being closed at one end; these retorts are supported at the extremities, and are set in the furnace in tiers, each retort being inclined, and higher at the back than the front. The elliptical retorts are used for the lower tiers, where the temperature is highest, and they are sometimes air-cooled at the bottom. The introduction of the charge involves considerable skill. As the material is finely divided, particularly when fine concentrates are employed, it has been found advantageous to briquette the mixture by pressure, and this improvement is steadily gaining ground. The mouths of the retorts are fitted with condensing tubes of clay in which the zinc collects, partly in the form of metal and partly in the form of more or less oxidised dust, which deposits chiefly in a sheet-iron nozzle fitted to the clay tube. The workman judges of the progress of the operation by the colour of the flame or vapours which are evolved. Brown vapours are first given off, and with these any cadmium passes over; they are succeeded by the characteristic flame of zinc, which continues until the operation is completed. The loss of zinc by the Belgian process is about 10–15 p.c. of that originally present in the ore; while in the Silesian process, in which poorer and more refractory ores are employed, the loss is 5, or even 10, p.c. greater (F. Juretzka, Metallurgie, 1911, viii. 1).

In the *Silesian process* the retorts are ⌒ shaped; the width is the same as that of the Belgian retorts, but the height is greater, and as the retorts are supported in the furnace from beneath, they are made longer than in the Belgian process—consequently the charge is greater. The retorts are usually placed in a single row in the furnace, which occasionally contains as many as forty such retorts, though about thirty-two is stated to give the best results, and a smaller number is frequently employed. At Freiberg the muffles are arranged in two rows one above the other, and each row contains sixteen muffles. In recent years the tendency has been to use a much larger number of retorts than formerly, so that the charge of ore per furnace has been raised from 15 cwt. to 8 or 10 tons.

In the lower part of the front of a Silesian muffle a hole is provided for the purpose of introducing the charge, and removing the residue after the distillation is complete. This method of charging, combined with the underneath support, gives greater durability to the Silesian muffles, so that, though in a given time the Belgian furnace may make more zinc, the annual production is rather in favour of the Silesian (*v.* F. A. Thum. Notes on Zinc Smelting, Eng. and Min. Jour. 1879, 275; Inst. C. E. 58, 407). The cost of calcining the ore, and smelting the zinc, in a modern works in South Wales, averages about £3 per ton of spelter produced (1911).

The zinc works of Prince Hohenlohe in Silesia include three smelting works, with a total of 106 furnaces, and a separate calcining works for the preparation of zinc blende for distillation. The fourteen long double-bedded calcining furnaces employed have each an output of 220 lbs. of roasted ore every 5 hours. Each zinc furnace contains thirty-two muffles, heated by gas from Boetius producers. Every furnace is arranged with sixteen niches, each containing two muffles, while two furnaces are built together so as to form a double furnace. Two spaces are provided at either end of the double furnace, one for tempering the muffles, and the other for calcining the lump calamine. Most of the calamine is charged raw, as the carbon dioxide is driven off long before the temperature of reduction is reached. The charge per muffle weighs 507 lbs., and consists of a mixture of roasted blende, lump calamine, and dried slimes. The daily yield is about 108 lbs. of zinc. The zinc contains 3–4 p.c. of lead, which is reduced by refining to 1·07 p.c. The refining is conducted in a reverberatory furnace with an inclined base, in the well of which the metal collects, the lead at the bottom and the zinc above. Every 12 hours about half a ton of zinc is tapped, and the same amount of raw zinc is charged in; the lead is removed at longer intervals. An exactly similar process is used in Birmingham for refining Continental zinc previous to rolling. The refined zinc contains about 1 p.c. of lead, 0·02 p.c. of iron, and 0·04 p.c. of sulphur (Berg. und Hütt. J. 1889, 389; Inst. C. E. 101, 382).

For full particulars of modern practice in zinc smelting, especially in reference to the United States of America, W. R. Ingall's standard treatise on the Metallurgy of Zinc should be consulted.

The demand for spelter of high chemical purity is now considerable, such metal being required for the production of the ductile brasses. One of the most remarkable advances in connection with the metallurgy of zinc in recent years has been the improvement in the quality of the product when required for special purposes. Formerly 98 or 98·5 p.c. zinc was considered satisfactory, upwards of 1 p.c. of lead and a few tenths p.c. of iron being present. It is now possible to regularly obtain considerable quantities of metal guaranteed to contain over 99·75 p.c. of zinc, and upwards of 99·9 p.c. is also sold at a rather higher price. Such metal is either produced electrolytically, as afterwards mentioned, or by the use of a filter of carbon, firebrick, or other crushed and porous material placed in the mouth of the ordinary zinc retort. This filter retains the lead, while zinc vapour passes through and is condensed (*see* Primrose, Production of Pure Spelter, Inst. of Metals, 1909, ii. 231; Bannister, Carbonaceous Filters in the Smelting of Zinc, Inst. of Metals, 1910, i. 213).

Treatment of zinc ores in the blast furnace. In order to reduce the consumption of fuel and labour in the extraction of zinc a number of attempts have been made to reduce zinc in the blast furnace, but hitherto without much success. The difficulty experienced is due to the fact that the vapour of zinc and the furnace gases must, in such a furnace, pass away together, and during the condensation which ensues a reaction takes place between the zinc and the carbon dioxide of the gases, thus $Zn+CO_2=ZnO+CO$ reproducing oxide of zinc, and the ultimate result of the operation is merely to carry zinc oxide out of the blast furnace into the condensing apparatus. This action has been studied by Lencauchez (Mém. Soc. Ingén. Civils, 1877, 568; Inst. C. E. 51, 332), who found that zinc was still oxidised when the proportion of carbon dioxide was only 0·5 p.c. of the gas employed. Zinc vapour is also oxidised by any water vapour which may be present. By very rapid cooling of the gases Lencauchez succeeded in reducing the oxidation of the zinc to as little as 5 p.c., but after numerous experiments he concluded that this process is not likely to be commercially successful.

In some cases, with relatively poor complex ores containing zinc, a blast furnace smelting is adopted with the deliberate intention of volatilising the zinc as oxide. This is condensed, usually with the aid of bag filtration, and sold to the smelters to be dealt with in the ordinary way.

In 1878 Binon and Grandfils, in Stolberg, made the attempt to use a zinc oven with upright retorts. They aimed at making the old Carinthian method continuous. The materials containing zinc were heated with reducing agents by gas in reduction spaces in the form of shafts, which were filled above and emptied below.

Electric smelting of zinc. Considerable attention has been devoted to this subject during the past few years, and a lengthy list of patents has resulted. In the opinion of competent and disinterested observers the solution of the problem of the blast furnace reduction of zinc ores will come by means of the application of electricity. Two typical processes may be here mentioned. In that of Snyder, adopted in British Columbia, complex ores are calcined to oxides, mixed with fluxes to give a slag melting at about 1050°, and treated in an electric furnace. The current passes through the molten slag, under which the lead is collected in a well. The zinc is volatilised and condensed in suitable chambers. The De Laval process, worked in Sweden, is conducted in an arc furnace into which the roasted ores are charged after mixing with flux and coal. The product is a coarse metal containing zinc, lead, and other impurities. This coarse metal is refined by distillation in another furnace, and zinc of high purity is obtained, together with zinc dust or fume and base lead bullion. One h.p. year is claimed to produce 800–1000 k. of metallic zinc, much of which is, however, in the form of dust. The current cost is about half the total charges. The electric processes depend for their success upon electricity from cheap water power, and are not likely to seriously compete with the old-established reduction centres, at all events for some time to come (*see* Sulman, J. Inst. Min. and Met. 1911. lxi.; Min. Mag. 1911, 310, 389).

Wet methods of extracting zinc. One of the most difficult problems connected with the metallurgy of zinc is that of the treatment of complex ores. These may contain, in the aggregate, very considerable proportions of metallic constituents, but in that a number of metals are present together the ores cannot be treated by ordinary methods. Such ores usually contain about 12–28 p.c. of zinc, and 5–15 p.c. of lead, together with a few p.c. of copper, some ounces of silver per ton, and frequently small proportions of other constituents. Such ores are now frequently treated by oil vacuum or other concentration processes so as to classify the metalliferous portions into separate saleable products whenever possible. Various wet methods of extraction, usually connected with electro-deposition, have from time to time been suggested, and have been worked on a more or less considerable scale, though as yet usually without much commercial success. It was only after many trials that copper-refining by electro-deposition became a commercial success; and yet copper is worth more than double the price of zinc. The electro-motive force required for the deposition of copper is less than that necessary for zinc, and the strength of current that may be used with copper is greater. Thus electrolytic methods of extraction of zinc have to contend with the disadvantages of the comparatively low intrinsic value of the metal, and of comparatively slow deposition.

Where electro-deposition is employed, there are two methods open for extracting the zinc; in the first the ore itself may be used as anode; or, secondly, the ore may be roasted or treated with solvents to convert the zinc into a soluble form.

1. Luckow proposed to mix the ore with coke in order to render it a conductor, and to place it in an open chest in an electrolyte consisting of a somewhat strong and acid solution of common salt or zinc chloride (20–30 p.c. Zn). The metal was deposited either upon a zinc plate or upon a cathode of coke. Higgs (Eng. Pat. 9158, 1886) proposed a similar method, but used magnesium chloride as electrolyte, and adopted special arrangements for collecting the evolved chlorine.

2. Many processes have been proposed for rendering the zinc in complex ores soluble, and in a number of these it is proposed to recover the zinc from solution by electro-deposition.

Lambotte and Doucet proposed to roast blende to oxide, dissolve in crude hydrochloric acid, precipitate the iron with chloride of lime and zinc oxide, and electrolyse the solution.

Parnell calcined complex ores to oxide, dissolved in dilute sulphuric acid, which was obtained as a by-product, precipitated the copper by metallic iron, and evaporated the liquor to a mud. Zinc sulphide was then added, and zinc oxide produced by heating the mixture strongly. The zinc oxide so obtained was sold to the smelters. Maxwell Lyte calcined the ore, and dissolved in hot dilute hydrochloric acid; the lead was allowed to separate as chloride on cooling, the iron precipitated by limestone, the copper with scrap iron, and the zinc as oxide by lime. Létrange was one of the earliest workers in the direction of electro-deposition of zinc; in his process blende was carefully roasted at low temperatures to produce zinc sulphate, which was dissolved with hot water and dilute sulphuric acid. The solution was then electrolysed, using an anode of lead (or carbon) and a cathode of zinc. The current used must have a high electro-motive force owing to the peroxidation of the surface of the lead.

Among other suggestions the following are worthy of notice. In 1886 Lea and Hammond (Eng. Pat. 10868) suggested the use of hydrochloric acid as a solvent for roasted ores previous to electro-deposition, while in the same year Squire and Currie (Eng. Pats. 12249 and 12630) proposed the use of an alkaline solution for the same purpose, and in 1887 Watt patented (Eng. Pat. 6294) the application of dilute vegetable acids for a similar object. Again, Burghardt (Eng. Pats. 8986 and 13182, 1888; 659, 1889) proposed the use of an alkaline solution made by adding the roasted ore, previously mixed with 3–7 p.c. of powdered coal or charcoal, to melted caustic potash or soda. The mass was extracted with water, the zinc electro-deposited, and the alkali recovered to be used over again. Croselmire (Eng. Pat. 4286, 1888) proposed to mix the ground ore with clay, and form into perforated pressed bricks which are roasted into sulphate in kilns. The roasted mass is extracted with hot water and an equivalent of dilute sulphuric acid, air is blown through the liquors to precipitate iron and manganese, and, after settling, the clear liquor is electrolysed, or the zinc may be precipitated by soda ash. In

1889, also, Cunningham (Eng. Pat. 9987) again patented the use of an alkaline solution obtained by fusion with caustic soda.

Among methods of another class proposed for the treatment of complex zinc ores may be mentioned that of Perino (Eng. Pat. 10657, 1888) who fused the blende in clay retorts at 150°–200° with ferric nitrate in the proportion of about 5 parts of nitrate of iron to 1 of zinc. The mass was extracted with water and a solution of zinc sulphate obtained. Arrangements were made for recovering the ferric nitrate. Siemens and Halske also (Eng. Pat. 3533, 1889) use ferric sulphate for extracting zinc from complex ores, while Seegall (Eng. Pat. 4871, 1889) employs a slightly acidified solution of ferric chloride for the same purpose.

The complex ores of Leadville, U.S.A., containing 25 p.c. zinc, 15 p.c. lead, 20 p.c. iron, are roasted to sulphate, extracted with water; the residue chlorinised to complete the extraction of the zinc, and the zinc precipitated from the solutions as oxide (J. Soc. Chem. Ind. 7, 572).

The only process for the electrolytic production of zinc which is at present successfully conducted on a considerable scale in the United Kingdom is a modification of the Höpfner patent, introduced at Northwich by Messrs. Brunner, Mond, Ltd. The primary object is the production of chlorine from the calcium chloride liquors made in the ammonia-soda alkali process. These liquors are treated with zinc oxide (roasted zinc ores) and carbon dioxide, when calcium carbonate is produced and zinc chloride liquors obtained. This solution, after the removal of all the more electro-negative elements, is electrolysed, a current density of as much as 30 amperes per sq. ft. of cathode surface being allowable. The products are zinc and chlorine. The cathode consists of a series of discs of iron which revolve on a horizontal axis; the anodes are of carbon and are enclosed in wooden frames, the sides of which are enclosed with cloth diaphragms. The chlorine evolved is subsequently converted into bleaching powder. The zinc is stripped off the cathode plates, remelted, and cast into ingots. The great difficulty is to obtain a smooth adherent coating of zinc, and to prevent, as far as possible, the formation of spongy zinc. The exact nature of the latter product, and the cause of its formation, are still not thoroughly understood. This is doubtless the reason for the monopoly enjoyed by the above firm, the precise details of the process being kept secret. The zinc obtained is sold with a guaranteed purity of 99·96 p.c., which makes it of great value in the production of ductile brasses, and for other purposes where the presence of lead, &c. would be detrimental.

To avoid the necessity for electrolysis of the zinc solutions obtained from complex ores processes have been introduced to precipitate the zinc in a form suitable for sale to the zinc smelter. A typical process is that in which sulphur dioxide, obtained from blende roasting, is used to extract zinc from roasted ores. With excess of sulphur dioxide the zinc passes into solution as bisulphite, and is separated from the residues. These contain lead, silver, &c., and are sold to the smelters. By the removal of half the sulphur dioxide from the solution insoluble zinc sulphite is thrown down. This sulphite is filtered off, dried, and calcined in a muffle at a low temperature. Zinc oxide is obtained in a form suitable for spelter production, and the sulphur dioxide is added to the calciner gases to enrich them for fresh leaching operations (Eng. Pat. 21759, 1908).

Properties. Zinc is a bluish-white metal, which at ordinary temperatures is brittle, and when pure exhibits a beautifully crystalline fracture. The presence of impurities usually renders the fracture closer in the grain and less brilliant. Zinc melts at 420°, and boils at 930°. It can, however, be readily distilled in glass vessels in a vacuum, under atmospheric pressure. It undergoes two marked changes in electric conductivity, one at 170°, and the second at 340°. It is, therefore, believed by Benedicks to exist in these allotropic modifications (Metallurgie, 1910, 7, 531). Its tensile strength varies greatly according to the mode of preparation; cast zinc has a tenacity of only 1·2 tons per square inch, whilst an annealed rod gave a tenacity of 7·9 tons per square inch, and zinc wire 10 tons per square inch. Its hardness is intermediate between that of tin and copper, being equal to 6 on Turner's Sclerometer and 2½ on Moh's scale.

Though zinc is brittle at ordinary temperatures, and so tender above 200° that it can readily be crushed to powder, it can be rolled into sheet or drawn into wire at an intermediate temperature of about 100°–150°. It is a remarkable fact that the metal when so treated retains its malleability in the cold. Zinc was first rolled early in the present century in Birmingham, and rolled zinc now forms one of the most important applications of the metal, the greater part of the zinc produced in Europe being used for this purpose. Commercial zinc always contains more or less lead and iron, together with traces of cadmium, arsenic, and sulphur, the lead being volatilised with the zinc in the process of manufacture. Kosmann has also found comparatively large quantities of thallium in commercial zinc (Chem. Zeit. 10. 762). The chief technical methods for the assay of zinc have been described and discussed in connection with a paper by Greenwood and Brislee (Inst. of Metals, 1909, 2, 249). The presence of lead, which is objectionable in zinc to be used for the manufacture of the best qualities of strong brass, is an advantage in zinc that is to be rolled. As English zinc is relatively free from lead, it is usual to employ this variety for the production of alloys in which lead would be objectionable, while Continental zinc is imported for rolling. If the state of the market renders it advantageous to roll English zinc, this can be improved by the addition of a small proportion of lead. In addition to what is made here, more than 20,000 tons of sheet zinc is annually imported into the United Kingdom. The density of zinc varies from 6·8 to about 7·2 according to the mode of preparation.

When heated in the air much above its melting-point, zinc readily burns with a brilliant greenish-white flame, producing the oxide (ZnO) which condenses in a bulky flocculent condition formerly known as 'philosopher's wool.' The white fume produced when casting brass or other zinc alloys that melt at a tolerably high temperature consists of zinc oxide. Though zinc is readily volatile, the oxide is fixed at all ordinary furnace temperatures. Zinc is not affected by dry air at ordinary temperatures, but tarnishes superficially in moist air. The metal is also not attacked by mineral lubricating oils, and of ordinary animal oils it is attacked most by sperm oil and least by lard oil (Redwood, J. Soc. Chem. Ind. 5, 362). Zinc, both pure and commercial, dissolves readily in alkalis. Pure zinc is unattacked by water at boiling-point, and is almost unaffected by ordinary acids either diluted or strong. Commercial zinc, on the other hand, decomposes boiling water with the evolution of hydrogen, and is readily attacked by diluted sulphuric acid and by hydrochloric acid either diluted or strong. Impure zinc when amalgamated resists the action of acids exactly like pure zinc, and hence the zinc plates used in electric batteries are amalgamated so as to prevent the loss due to 'local action.'

This difference in the behaviour of pure and impure zinc towards acids has attracted much attention from chemists since the fact was first pointed out by A. de la Rive in 1830. Among the more important observations on the subject are those of Pullinger (Chem. Soc. Trans. 57, 815) and Weeren (Ber. 24, 1785).

Pullinger's conclusions are as follows:—Pure zinc with a perfectly smooth surface is not acted upon by dilute sulphuric acid that has been previously well boiled; pure zinc with a rough surface is readily acted upon, but less by acids that have been boiled than by those which have not. The presence of oxidising agents such as nitric acid, hydrogen peroxide, or electrolysed sulphuric acid, increases the rate of dissolution, while a reducing agent, such as hydriodic acid, almost entirely prevents dissolution; but reducing agents containing sulphur, such as sulphur dioxide, are without effect. It is not improbable that when zinc with a rough surface dissolves in dilute sulphuric acid the cause of dissolution is persulphuric acid, which acts catalytically, and in all probability *pure* dilute sulphuric acid would be without action upon metallic zinc, whether the surface of the latter be rough or smooth.

The solubility of impure zinc in diluted acids has been generally explained on the supposition that local electric currents are set up owing to the presence of the impurities, whilst with pure zinc no such currents are produced. Weeren, however, shows (*l.c.*) that the insolubility of pure zinc is due simply to the formation of a layer of condensed hydrogen on the surface of the metal, and thus the further action of the acid is stopped. Oxidising agents remove this film and assist dissolution; in impure zinc the hydrogen, obeying ordinary electrical laws, is evolved from the surface of the impurities. The fact that dissolution is much promoted by simply brushing the surface of the metal, or by allowing the action to take place in a vacuum, appears to afford strong support of this view, which is also quite in harmony with the fact that pure zinc dissolves much more rapidly in boiling dilute sulphuric acid, when the ebullition of the liquid removes any hydrogen from the surface of the metal, than at 98° where no ebullition occurs. Pure zinc with a rough surface, as Pullinger has shown, dissolves much more readily in diluted sulphuric acid than the same metal when the surface is perfectly smooth. Weeren suggests from the above facts that the difference in the action of diluted sulphuric acid on pure and impure zinc is capable of a simple mechanical explanation.

The question of the corrosion of zinc sheet and pipes, and of articles coated with zinc, when in use, is of great commercial importance. In dry pure air, as for instance in parts far removed from manufactories and towns, zinc roofing, when properly attached, lasts almost indefinitely with only a surface oxidation. But in the neighbourhood of towns, and especially in the vicinity of chemical manufactories, commercial zinc is rapidly corroded and spoiled. The presence of the slightest trace of free sulphuric or hydrochloric acid in the drainage water is very prejudicial. The presence of copper in any form in contact with zinc, should also be carefully avoided. Thus Müller has shown (Dingl. poly. J. 269, 280), that the zinc pipes which carried the drainage water from the copper dome of the royal castle at Brunswick, were rapidly attacked and corroded, while similar pipes on the opposite side of the same building were unaffected. The explanation of this difference probably was that in the presence of ammonia or of acids in the atmosphere some copper was dissolved by the rain water, and this copper being afterwards deposited on the surface of the zinc, set up an electric action resulting in the destruction of the pipes.

The use of galvanised iron tanks for water-cisterns has led to much controversy, particularly in the colonies, as to the effect of such storage on the health of persons who drink the water so stored. According to Bunte, the use of zinc-coated iron water-pipes is not deleterious to health, and this view is supported by Dr. Ehmann, late director of the water supply of Würtemburg, and by Dr. Boardman, of Boston (J. Soc. Chem. Ind. 6, 557). But a strong feeling exists to the contrary, and, after careful inquiry, the use of galvanised tanks for drinking-water was condemned in the British and French Navies. From the well-known properties of zinc it might be anticipated that some waters, which are either slightly acid or alkaline, would attack zinc vessels, while other waters might be almost without action. The presence of chlorides would probably also be prejudicial. It is not unlikely, therefore, that the differences in the action of water on zinc cisterns as noticed by various observers, is due in great measure to the character of the water. It is, however, certain that zinc or galvanised vessels should not be employed with acid waters.

Zinc-dust is employed somewhat largely as a reducing agent, as a precipitant for gold in the cyanide process for the extraction of gold from gold ores, and in the manufacture of fireworks. It is obtained, mixed with more or less oxide, in the distillation of the metal, or can be produced by crushing the metal in a mortar at a temperature somewhat below its melting-point.

In castings zinc takes a very sharp impression of the mould, and, as it melts at a low temperature, it has been used to a considerable extent, especially in France, for the production of statuettes and other objects of great beauty, which are afterwards usually coloured or bronzed. Some of these bronzes contain about 17 p.c. of copper; this alloy expands in the mould, and gives very sharp and clear impressions (*see* Turner and Murray, Inst. of Metals, 1909, ii. 115). The introduction of photo-engraving has also in recent years led to the use of considerable quantities of sheet zinc of special quality.

Galvanising. An important application of zinc, known as galvanising, was patented by Crawfurd in 1837. The object of the process is to coat the surface of iron with a thin layer of zinc, which protects the metal underneath from oxidation. In this respect zinc acts more perfectly than tin, which is negative to iron; in the case of tin plates the protection only lasts so long as the surface of the iron is covered with tin, but as soon as any portion of the iron is exposed to the action of the atmosphere oxidation proceeds more rapidly than in the absence of tin. Zinc, on the contrary, is more positive than iron, and thus, even though the coating of zinc may be removed in places, the protection continues so long as any zinc remains. Galvanised iron, however, cannot be used in contact with acids or alkalis, nor for the canning of fruits, meat, &c., on account of the action of vegetable acids and animal juices on the surface of the zinc.

The operation of galvanising is not in any way an electric process, as might be inferred from its name, but is simply a method of coating clean iron with zinc by immersion in a molten bath of the latter metal. Numerous patents have been obtained for suggested improvements in galvanising since Crawfurd introduced the process, particularly by Mallet and Morewood, but the old process is still almost universally adopted with a few improvements in details for saving of labour and the production of a better surface with a smaller consumption of zinc. Galvanising is conducted largely in the United Kingdom, and particularly in the neighbourhood of Birmingham and Wolverhampton, and in South Wales.

The iron or steel which is to be galvanised is received in the black state, coated with scale from the process of manufacture. Sheets are close annealed (*i.e.* annealed in large iron boxes, while carefully protected from access of air) to render them soft, but many other articles are treated without annealing. The scale is next removed by pickling in hydrochloric acid, which is used cold, or nearly cold, and which is contained in stone troughs. Tanks built of blue brick, set with sulphur joints, are also frequently used for containing the pickling acid. The strength of the acid depends on the character of the work; for wire 12 p.c. of real HCl is sufficient; for tubes, buckets, and general work an intermediate strength is best; while for sheets about 20 p.c. is generally used, and sometimes the undiluted muriatic acid of commerce (26–30 p.c.) is employed. By this method of working, pickling is usually complete in a few minutes; but on the Continent, where acid is dearer and economy is necessary, a dilute pickle is used, the water is heated, and the sheets are allowed to remain in the pickle for about 2 hours. The scale having been thus dissolved or loosened, the iron is washed with water, and, if necessary, rubbed with sand to complete the cleansing. The molten zinc is contained in a wrought-iron pot, the dimensions of which vary according to the character of the work to be done, and which is heated by means of a slow coke fire around the sides and under the bottom of the pot. The surface of the zinc is covered with powdered sal-ammoniac, which acts as a flux, and when best sheets are being treated it is usual to add about 2 or 3 p.c. of tin to the bath so as to assist in the production of a crystalline appearance of 'spangle' on the surface. In other cases re-melted zinc, *i.e.* zinc containing some tin and lead solder, is added to the bath for the same purpose. In galvanising sheets also it is usual to have a pair of rolls in the bath to guide the sheet in its passage through the zinc and to improve the surface. The consumption of zinc can be somewhat reduced, and the surface considerably improved, by the use of rolls or wire brushes as the sheet leaves the bath. Koffler and Breden (Eng. Pat. 12485, 1885; and 16674, 1888) have patented the use of wire brushes for this purpose; whilst Heathfield (Eng. Pat. 10089, 1886; and 1682, 1890) has introduced brushes which press evenly on the surface of the sheet as it leaves the bath, and he also adds fine wire brushes, together with improved rolls for feeding in the sheets. Corrugated sheets form a considerable portion of the trade; these are galvanised plain, and afterwards passed through corrugating machines in the cold. In galvanising wire, it is reeled through the pickle trough and the zinc-bath continuously, while netting is woven in the black, and afterwards reeled like wire. A continuous arrangement for this purpose has been patented by Vibart (Eng. Pat. 14297, 1889). The proportion of zinc taken up by the iron in galvanising varies considerably, being as high as 25 p.c. with moderately small wire, and less than one-fourth of this with many articles such as anchors, chains, and large elbows. In some galvanising works the sheets are pickled with hot diluted sulphuric acid, and the molten zinc is covered with zinc chloride instead of ammonium chloride; but the process above described is in much more general use.

The molten zinc gradually takes up iron during the galvanising process, and forms an alloy which is heavier than zinc, and which sinks to the bottom of the bath. This is removed from time to time and cast in plates, which, when broken, exhibit a close-grained fracture with black spots. This alloy is known as 'hard zinc,' and contains from about 2 to 5 p.c. of metallic iron. It is usually re-melted at a higher temperature, when it separates into two portions, one being tolerably pure zinc. The other portion is much less fusible, and forms a crystalline or granular material of the colour of zinc; it is very friable, and frequently exhibits surface colourations of great beauty. In this form it is generally sold to the smelter, and contains about 7·5 p.c. of iron, though exceptionally compounds are produced which contain upwards of 25 p.c. of iron.

The ammonium chloride used as a flux in galvanising is gradually lost during the process, and fresh additions have to be made as required. This loss is doubtless due in part to volatilisation of the salt itself, but also to a reaction which takes place, whereby zinc chloride is formed and ammonia set free. It has been proposed to collect the fume of ammonium compounds evolved from the galvanising bath by suitable exhausting arrangements and scrubbers in which the gases are washed by diluted acid, and it is stated that such an arrangement not only very much improves the atmosphere of the manufactory, but actually yields a profit in working.

The result of the action of the ammonium chloride and of atmospheric oxygen on the molten zinc during galvanising is the production of a scum which is known as 'flux skimmings,' and which is removed from time to time. This material consists of chloride and oxide of zinc, together with some ammonium chloride and dirt; it is usually sold to the smelters. Heathfield (Eng. Pat. 14411, 1885) proposed to dissolve the chlorides in water and deposit the zinc electrically: Richards (Eng. Pat. 13982, 1885) dissolves the oxide of zinc, together with the chlorides, in the minimum quantity of hydrochloric acid, and after evaporation electrolyses the concentrated solution of zinc chloride (*cf.* Ingalls, Metallurgy of Zinc, and ed. 578).

The electrolytic method has also been applied to the treatment of the zinc scum obtained during desilverising, and Rosing states (Dingl. poly. J. 263, 87) that this method is the most suitable for the purpose of any process at present known. The powdered scum is spread on a lead plate at the bottom of a wooden vat which is filled with a solution of zinc sulphate. The lead plate acts as anode, and when the current is passed, zinc deposits on the cathode, and a corresponding weight of zinc is dissolved from the scum. When the surface zinc has been thus removed, the residual mass is dried and heated to redness in a cupellation furnace and again electrolysed.

The quantity of hydrochloric acid annually used for pickling in the country is very great, as a number of firms engaged in the galvanising trade each require some thousands of tons of commercial muriatic acid (26–30 p.c.) per annum, but no statistics on this point are available. When the works are situated near the sea the waste pickle is readily disposed of, but the Midland manufacturers have during the last few years met with increasing difficulty in getting rid of their waste acid. The nuisance has become intolerable, and costly litigation has been undertaken by the local corporations to enforce some efficient system of treatment. Hitherto the usual system has been that of neutralisation with lime and subsequent filtration, with or without subsequent roasting of the ferrous precipitate, to convert it into red oxide of iron. Turner (Eng. Pat. 1889, 1890) introduced a method of recovering the hydrochloric acid, and the process has been in operation in South Staffordshire for over 20 years. The waste liquor, which consists of an acid solution of ferrous chloride, contains slightly under 10 p.c. of iron and about 15 p.c. of acid, chiefly in combination. The liquor is allowed to trickle slowly into a fire-brick reverberatory furnace of special construction; this is connected with condensers for the acid, which are arranged in the ordinary way. A bath of concentrated ferrous chloride solution is maintained in the furnace and thus prevents leakage, as the saturated solution penetrates any crack, and solidifies in coming in contact with the cool exterior of the furnace. The ferrous chloride is more strongly heated near the firebridge, and decomposes thus:—

$$2FeCl_2+2H_2O+O=4HCl+Fe_2O_3.$$

Hydrochloric acid is thus recovered and used over again, while the ferric oxide is raked out of the furnace and used as fettling in the puddling process. The fuel consumption is about 4 cwt. of gas coke per ton of waste liquor treated.

When sulphuric acid is used for pickling, the solution is evaporated and crystallised to produce copperas (commercial ferrous sulphate), for which there is a limited demand. In a few instances the copperas is afterwards decomposed by heat for the production of rouge, and other varieties of bright-red ferric oxide.

Dry galvanising. In the process known as 'sherardising,' introduced by S. Cowper-Coles, the articles which are to be coated with zinc are carefully cleaned and placed in closed boxes with zinc in a state of fine division. The boxes with their contents are then heated to a temperature insufficient to cause the zinc-dust to melt, and the vapour evolved gradually combines with the surface of the iron, and produces a closely adherent and protective coating of zinc. This process has been applied on a considerable scale, and is specially suited for articles which have sharp patterns upon their surfaces, or crevices which would be obliterated or filled up with zinc in the usual processes of dipping in molten zinc. The surface is somewhat less bright than usual, but is pleasing in appearance, and its wear is quite satisfactory.

Electro-galvanising. Iron or steel articles are now also frequently covered with zinc by deposition, with the electric current, from a neutral solution of zinc sulphate, or from zinc salts dissolved in caustic alkali. This process is not used for the general run of galvanising work, but more particularly for articles which are in a partly finished condition, or which are of such a special size or shape as to render the ordinary process unsuitable. Zinc coatings can thus be obtained which are quite satisfactory in wear and appearance, but they are apt at times to be soft and spongy, and not to adhere firmly to the surface of the iron. They are also more than usually subject to trouble from the development of black spots on the surface when exposed to moist air.

The nature of the zinc coating obtained by various processes has been studied in detail by Guertler, Metallographie, 1911, 353. The most complete account of the various processes of galvanizing is that given by M. A. Sing (Le Zingage du fer et de l'acier, Revue de Metallurgie, 1912, 1, 78, 160).

ALLOYS OF ZINC.

Zinc readily unites with most metals when the temperature is raised sufficiently to insure fusion. The *binary* alloys of zinc are generally white, crystalline, brittle materials, of limited importance. These alloys are usually of uniform composition; with lead and with bismuth, however, zinc unites at a temperature above its melting-point, but the alloys separate on cooling into two distinct layers, the upper layer in each case consisting of nearly pure zinc. The most important series of binary alloys of zinc is the copper-zinc (or brass) series, which is separately described.

With *aluminium* zinc readily unites when the metals are melted together in any proportions. The constitution of the series of alloys has been studied by Heycock and Neville (Chem. Soc. Trans. 1897, 389; Shepherd, J. Phys. Chem. 1905, 9, 504); Ewen and Turner (Jour. Inst. of Metals, 1910, 2, 140); and Rosenhain and Archbutt (Phil. Trans. A, 211, 315; also 10th Report Alloys Research, 1912). The phases which are recognised are α, which is zinc, or a solid solution containing less than 1 p.c. of aluminium; β, which is a definite compound, probably Al_2Zn_3; and γ, which is a solid solution of zinc in aluminium, and may contain as much as 40 p.c. of zinc. There is one eutectic, with 95 p.c. of zinc, melting at 380°, there is also a small break on the freezing-point curve at 85 p.c. of zinc, and an inversion at 256°, when the β-phase on cooling breaks up into α and γ. The commercially interesting alloys are at the aluminium end of the series, and these have assumed very considerable importance in recent years. The so-called aluminium castings used for motor cylinders and many similar purposes usually consist of about 10 p.c. of zinc; not unfrequently a few p.c. of copper or other metal or metals, and the residue aluminium. These alloys are rather more fusible than pure aluminium and are stronger and work better. They are also slightly cheaper. Alloys containing up to 25 p.c. of zinc can be rolled hot, at suitable temperatures, and material with tensile strength up to 34 tons per sq. in. obtained. The strength of these alloys is thus equal to that of mild steel, and as their density is only about 3–3·2 they have found considerable applications where lightness and strength are required. In sand cast alloys the maximum tensile strength is obtained with from 20 to 60 p.c. of aluminium, and the maximum hardness is within the same range. The tensile strength of all these alloys rapidly falls as the temperature rises. They are, therefore, not suitable for use when subjected to the effect of heat.

With *antimony*, zinc readily unites in all proportions; the resulting alloys are brittle, and exhibit a close-grained, dark-grey fracture when much antimony is present; when antimony is in excess, the surface of the alloys readily tarnishes during the process of casting, and the ingot becomes coated with a dark-grey crust of oxide. When the constituent metals are present in about equal proportions, surface colorations of great beauty can be obtained by oxidation, the tints obtainable including yellow, green, red, purple, and blue. A small proportion of antimony renders the surface colour of cast zinc distinctly more blue than usual, and with care the presence of 0·5 p.c. of antimony can be readily detected by this test. The usual colour of the surface of ingots, of equal parts of antimony and zinc, is a bright sky-blue, and the alloy has the peculiar property of marking glass (Turner). Antimony-zinc alloys are readily fusible, and in this respect the influence of antimony is quite different from that of arsenic or phosphorus, both of which raise the melting-point of zinc. Zinc-antimony alloys have met with an application for the production of thermopiles, for which purpose they are well suited.

With *bismuth*, zinc unites when the metals are melted together, but on cooling the alloy separates into two layers, the upper consisting of zinc containing bismuth, while the lower layer consists of bismuth containing zinc. The composition of the two layers varies with the temperature, the solubility of each metal in the other steadily increasing as the temperature rises until at about 850° the whole is of uniform composition (Heycock and Neville, Chem. Soc. Trans. 1897, 71, 390). With *gold*, zinc forms a series of alloys which are pale yellow, with excess of gold, and greenish as the proportion of zinc increases; all these alloys are more or less brittle. In the production of jewellery part of the copper used in the preparation of the gold alloys is often replaced by brass, as the colour of the resulting gold can be thus improved, while the cost of the alloy is slightly reduced. The presence of much zinc renders the gold hard and difficult to work, and as the zinc is volatile at high temperatures this alloy is not suitable for use where the article has to be reheated during manufacture. The compound AuZn, with 75·1 p.c. Au can be obtained by distilling off the excess of zinc from gold zinc alloys, in a vacuum, at 500° (Groves and Turner, Chem. Soc. Trans. 1912, 585).

With *iron*, zinc forms a series of alloys which are generally white, hard, and brittle. With not more than 5 p.c. of iron the alloys are close-grained and darker in colour than pure zinc; such alloys are produced in the process of galvanising, and are known as 'hard zinc.' With more iron the character of the alloy varies according to the method of preparation. The ferriferous residue left on liquating 'hard zinc' is very friable, and readily crushes into a coarse dust, consisting of bright flakes or spangles; on the other hand, the material obtained by fusion is compact, white, hard, and brittle. The alloy of zinc and iron obtained by saturating zinc near to its temperature of volatilisation with iron, is not attracted by a magnet; it does not rust, nor give sparks by friction or blows. It is dense in structure, but is only semi-metallic in fracture, and contains about 22 p.c. of iron. These alloys have a somewhat important application in the preparation of 'delta metal,' and also of Aich, sterro, and Gedge's metal, all of which are yellow brasses containing about 60 p.c. of copper and nearly 40 p.c. of zinc. The addition of iron to these brasses, first suggested by Keir in 1779, imparts special hardness, toughness, tenacity, and wearing properties, while the alloy can be rolled either hot or cold, and the constituents of the mixture are relatively cheap. The proportion of iron present usually varies from about ¼ to 4 p.c., according to the purpose for which the alloy is to be applied. The necessary zinc-iron alloy can be prepared by one of the following methods :—

1. By immersing clean iron wire, or sheet, in a bath of molten zinc heated to near its boiling-point. The addition of a little charcoal and some solid ammonium chloride assists the action. Where the presence of a little tin in the alloy is not objectionable (as for stere-metal) a convenient method is to employ clean tin-plate scrap; the coating of tin readily unites

with the zinc and leaves a clean surface of iron exposed to the action of the molten metal.

2. In order to reduce the waste of zinc usually accompanying the production of such alloys, a zinc of high boiling-point may be advantageously used in some cases. Bull (Eng. Pat. 4086, 1888) proposed the addition of phosphorus or arsenic for this purpose, while the addition of a little copper to the zinc assists the action without the introduction of any injurious constituent.

3. Alloys rich in iron can also be obtained by liquating the 'hard zinc' from galvanising works, and strongly heating the ferriferous residue in a closed crucible. The excess of zinc is volatilised, and the percentage of iron increases with the temperature employed. The alloys actually used in practice contain from about 7 to nearly 30 p.c. of metallic iron.

The equilibrium of the iron-zinc series has been studied by V. Vegesack (Zeitsch. anorg. Chem. 52, 1907, 30). The diagram is somewhat complicated. At the iron end there is a series of solid solutions in α, β, and γ iron with a maximum of about 35 p.c. of zinc at 1100°. At the zinc end two compounds are recognised $FeZn_7$ (or perhaps $FeZn_8$) and $FeZn_3$. These compounds undergo decomposition at 777° and 662° respectively. W. Guertler (Metallographie, 1911, 353) has recognised the compound $FeZn_8$ as an intermediate, electro-negative layer in the coating of galvanised iron, and occurring between the iron and the zinc coating. He has also recognised crystals of $FeZn_7$ in the external coating of zinc.

With *lead*, zinc readily combines when the two metals are melted together, but on cooling the mixture, or allowing it to remain at rest, the zinc collects as a layer at the upper surface, while the lead is found at the bottom of the mass. Neither of the metals is, however, quite pure, for the lead on cooling retains 1·6 p.c. of zinc, while the zinc retains 1·2 p.c. of lead (Percy, Metallurgy, 90). These proportions vary according to the method of treatment and the temperature employed. Thus E. Kraut has examined the behaviour of zinc containing lead on remelting (J. Soc. Chem. Ind. 5, 537). The sample was melted, well mixed, and a quantity removed and granulated. The residue was allowed to cool slowly, and the top, middle, and bottom of the mass separately analysed. The top contained 0·943 p.c. of lead, the middle 2·847 p.c., and a small quantity at the bottom as much as 4·121 p.c.; whilst the original zinc contained 1·543 p.c. of lead. In these experiments only 2 kilos. of metal was employed; on the large scale the separation of the two metals is still more complete.

The rolled zinc of commerce is a nearly saturated solution of lead in zinc, and usually contains about 1 p.c. of lead. An excess of lead injuriously affects the rolling properties: hence it is usual when rolling Continental zinc to remelt it in a reverberatory furnace with an inclined bed. The metal is allowed to remain fluid at a temperature a little above its melting-point, and the zinc is ladled off from the top from time to time. The excess of lead separates and collects as a layer in the lower end or 'sump' of the furnace, beneath the zinc, and is removed at suitable intervals.

On strongly heating lead-zinc alloys, the excess of zinc is at first volatilised, but as the temperature rises both lead and zinc distil over together. This curious volatility of lead in the presence of zinc is doubtless the cause of the occurrence of lead in commercial zinc, obtained from ores containing lead. The presence of a small proportion of zinc in commercial lead communicates hardness and allows the lead to receive a good polish without destroying its malleability.

With *mercury*, zinc readily unites to form a series of white brittle amalgams which become pasty when mercury is in excess. Zinc amalgams are easily obtained by mixing mercury with molten zinc, or by adding zinc to mercury heated nearly to its boiling-point. Zinc plates for galvanic batteries are coated with mercury by first cleaning the surface of the zinc with dilute sulphuric acid and then rubbing the mercury over the clean surface. An amalgam of zinc and tin is used on the rubbers of frictional electrical machines. On the literature of zinc-amalgams *v.* J. Soc. Chem. Ind. 9, 512.

With *silver*, zinc does not very rapidly unite at the melting-point of the latter, but at higher temperatures the metals readily combine, forming a series of alloys which are whiter than zinc, and the use of which has been proposed for coinage and other purposes. With 5, 10, or 20 p.c. of zinc, silver forms white ductile alloys, which can be rolled like standard silver, and which are more fusible than the corresponding copper alloys (Percy, Gold and Silver, 169–171).

When lead which contains silver or gold is melted with zinc and allowed to cool, the zinc separates, rises to the top, and solidifies first. This solid crust of zinc contains the precious metals, and this fact was applied by Parkes in the well-known process for desilverising argentiferous lead. The zinc scum is distilled to remove the zinc, much of which is recovered in the metallic state. The silver is melted, refined, and cast into ingots. The separation of the two metals is practically complete at 700° in a vacuum (Groves and Turner).

With *tin*, zinc readily unites in all proportions, the resulting alloys being generally harder than tin but softer than zinc. The colour of the alloys is in all cases white, and the fracture is crystalline, although its appearance varies with the mode of preparation. The alloys of tin and zinc are not quite uniform in composition, as the tin tends to separate and collect at the bottom on cooling. Tin-zinc alloys are used for castings of patterns for ornamental purposes. A detailed description of these alloys, based on the work of Guettier and Rudberg, is given in Hiorns' Mixed Metals, 249–253.

GERMAN SILVER, BRASS, &C.

In addition to the binary and other zinc alloys above mentioned, zinc enters into the composition of a number of alloys containing three or more metals, of which the following are the most important.

German silver (also known as Nickel Silver, Packfong, White Copper, Electrum, Nevada Silver, &c.) consists of copper, zinc, and nickel. It is an alloy of white, or nearly white colour, of high tenacity, and capable of being cast, rolled, spun, and otherwise worked. One of its most important properties is its relative permanence in the air, and this has led to the use of the alloy on a very extensive scale. It usually contains about 56–60 p.c. of copper, the proportions of zinc and nickel varying according to the price and use of the alloy; the zinc is seldom less than 14 or more than 30 p.c. of the whole. For castings a little lead is frequently added. Generally an alloy of about equal weights of zinc, and nickel is first prepared, and to this 'temper' the necessary quantities of copper and brass are added to give the required composition. A good description of the copper-nickel-zinc alloys will be found in Hiorns' Mixed Metals, 235–248.

One of the chief applications of German silver is in the electro-plate trade, for the production of articles of which teapots, forks, and spoons may be taken as examples. The alloys are melted in crucibles, deoxidised usually with manganese, cast into strips in metal moulds, and rolled, with several annealings, to the required gauge. For the production of ductile alloys pure metals must be used, and the temperature and character of the annealings carefully regulated. The character of the silver deposit in such articles has been studied by McWilliam and Barclay (Inst. of Metals, 1911, 1, 212), who conclude that when the proportion of nickel exceeds 14 p.c. the silver is more liable to strip off irregularly in actual use. With more nickel the strength and hardness increase and the alloy more nearly resembles silver in colour. Alloys containing 19–22 p.c. of nickel are specified for best work, and by suitable methods adherent coatings of silver, of excellent quality can be obtained (*ibid.* 226).

Part of the tin in *gun metal* and in *bearing metal* is frequently replaced by zinc, as it is found that the density and wearing properties of the alloy are thereby increased (*v. Bronze*, art. TIN). For the same reason the bronze coinage of this country contains 1 p.c. of zinc. Zinc is also present in some varieties of aluminium bronze and phosphor bronze in manganese bronze, and other similar alloys. The 'Biddery Ware' manufactured in India usually contains about 90 p.c. of zinc together with copper, lead, and tin in different proportions.

Copper alloys—Brass. *History.* Although the word brass frequently occurs in the Old Testament, there is little evidence that an alloy of zinc and copper was known in early times, unless, indeed, the suggestion be accepted that brass was sometimes accidentally produced in the manufacture of copper. The word translated 'brass' might equally well be rendered copper or bronze, both of which were in common use for a considerable period before the introduction of copper-zinc alloys (*v. Bronze*, art. TIN).

There is abundant evidence, however, that brass was known to the Romans about the beginning of the Christian era; that it was used for coinage purposes, and that it formed one of the yellow alloys known as *orichalcum*. The analytical and historical evidence on these points has been summarised by Dr. Percy (Metallurgy, i. 518–528; *cf.* Gowland, Presidential Address, Inst. of Metals, 1912). In the middle ages the Germans were famous for the production of brass, which was imported into this country chiefly in the form of sheet or *latten*, which was employed for the 'brasses' of churches, particularly in the Eastern counties. Over 4000 such brasses are known to exist in various churches &c. in the United Kingdom, which is far richer in this respect than any other country. The first brass manufactory in England is stated to have been erected by a German in Surrey about the middle of the seventeenth century. Brass works were started in Bristol in 1702; whilst the first works for making brass in Birmingham (now the centre of the brass trade) were erected about 1740 by Turner. Up till the middle of last century the only method used in the production of brass was the calamine, or cementation, process, in which copper, in the form of bean shot or sheet, was heated in crucibles in contact with calamine and carbon, with the result that zinc was liberated and volatilised, being afterwards absorbed by the copper. The brass thus produced was then melted down and cast. This process was slow and laborious, and only yielded a brass tolerably rich in copper. In 1781 James Emerson patented the direct production of brass from copper and zinc, although there is evidence that the method had been previously used to a limited extent. The calamine process was gradually superseded by the direct method of production, so that the last calamine brass works in this country were closed about 1850. Some of the most important factors in the development of the brass trade have been the introduction of rolling mills in the early part of last century, with the subsequent application of powerful machinery; the application of the stamp and die in 1769, whereby articles were produced more rapidly, with better finish, and with less metal than by the old process of casting; the introduction of gas fittings in the early part of the nineteenth century; the use of brass and copper tubes in locomotives and marine engines; the introduction of yellow metal sheathing; and the extended use of engineers' brass work and steam and water fittings, and lastly the applications to electric fittings. These and many other circumstances have resulted in an enormous development of the brass trade, so that there are employed in the brass trade of Birmingham alone over 35,000 persons (male and female), while the consumption of metal is valued at 4 millions sterling (v. A Short History of the Brass Trade, J. W. Davis; also Encyc. Brit. art. Brasses; Thomson, Hist. of Chemistry i. 55, 62, &c.; Midland Hardware District. 226–240; Percy, Metallurgy, 504; Holzapffel's Mechanical Manipulations, 312; Useful Metals and their Alloys, 566).

General properties of zinc-copper alloys. Zinc and copper unite in all proportions, the resulting alloys being of remarkably uniform composition throughout the mass (Laurie, Chem. Soc. Trans. 53, 106; 55, 677). The experiments of Tilden (J. Soc. Chem. Ind. 9, 84) also show the great uniformity in composition of commercial sheet brass, although on the other hand Hiorns (Mixed Metals, 107) gives analyses showing the copper to be less at the top than at the bottom of ingots of cast brass. The alloys containing upwards of 80 p.c. of copper are red or red-yellow in colour; those containing less than 48 p.c. of copper are grey or white; the intermediate alloys are yellow. The hardness of the alloys is usually greater, while the melting-point is higher, than that calculated from the mean of the constituents. The addition of zinc to copper produces remarkable alterations in the working properties of the product, varying, however, with the proportion of zinc present. Thus, pure copper can be rolled hot or cold, although in the latter case frequent annealing is necessary, and rolling hot is much cheaper and more expeditious. The addition of only a trace of zinc renders copper 'red short,' although it does not interfere with the malleability of the metal when cold. Hence alloys which contain from about 62 to 100 parts of copper p.c., and the residue zinc, cannot be rolled hot, or if so rolled require special treatment. Usually these alloys are rolled cold, and are annealed and pickled from time to time as the metal becomes hard and brittle from the work put upon it. But alloys with about 60 p.c. of copper can be rolled either hot or cold, and the cost of production is thus reduced. These alloys are, however, less ductile and tough than those which contain more copper. Their tensile strength is greater, but their ductility less than with alloys higher in the series. The alloy of 60 parts of copper and 40 of zinc was patented by Muntz for the production of sheathing for wooden ships, and is now largely prepared under the name of 'yellow metal,' for the production of the cheaper varieties of brass sheet, tubes, and wire. The standard size of yellow metal sheets is 14 by 48 ins., and the thickness is returned according to the Birmingham metal gauge. Alloys containing about 50 p.c. of copper are light yellow in colour; but cannot be rolled either hot or cold. The chief application of alloys containing rather more than half their weight of copper is for the production of 'brazing' solder for use with copper, brass, &c. These alloys form what is usually known as 'hard' solder, in contradistinction to lead-tin alloys or 'soft' solder. But in the brass trade different varieties of solder are used, containing from about 45 to 56 p.c. of copper, according to the temperature to be employed. The brazing solders containing more copper are called 'hard,' and those with more zinc 'soft.' The solder most commonly employed contains about 51 p.c. of copper, and is usually sold in the form of powder, which is prepared by heating a mass of the alloy to a particular temperature below its melting-point, when it is struck a sharp blow with a mallet. At this temperature the alloy is very friable, and readily crumbles into powder when treated as above described. If it is too hot or too cold it cannot be powdered in this way.

With more than 50 p.c. of zinc the alloys lose their yellow colour and become white, brittle, and more fusible. Though all these white alloys are brittle when hot or when cold, they can usually be laminated at some intermediate temperature, and in this respect they resemble zinc. This proper temperature varies according to the proportion of copper present, being as low as 150° in zinc, and at a red heat, probably about 600°, in yellow metal. As the copper increases beyond 60 p.c., as before explained, brass can no longer be rolled hot, but is laminated in the cold with repeated annealing.

According to Mallet (Construction of Artillery, 82), the alloy $CuZn_2$, containing about 33 p.c. copper and 67 p.c. zinc, is used for watchmaker's brass, and possesses the greatest tenacity of the whole series. This statement has been copied into many well-known works on the subject, but it is evidently an error. Laurie has shown by his investigations on the electro-motive force of zinc-copper alloys (*see* above) that only one definite alloy exists in this series. This compound is white, hard, and brittle, and corresponds very closely in composition to Mallet's alloy above mentioned. All other zinc-copper alloys may be considered as solidified solutions of this definite compound in excess of one or other of the constituent metals. Guertler (Zeitsch. anorg. Chem. 1906, 51, 397; 1907, 54, 58) and Murray and Turner (J. Inst. of Metals, 1909, 2, 131) support the view of only one definite compound in the copper-zinc series, viz. Cu_2Zn_3 with 39·36 p.c. Cu. This compound is a brilliant white brittle substance, harder than mild steel. Of itself it is of little or no practical value, but by its union with various proportions of copper, which alone is too soft, a whole series of alloys is obtained which possess most valuable and wonderfully graduated properties.

The equilibrium of the copper-zinc series has been studied by Roberts-Austen (4th Report Alloys Research); Shepherd (J. Phys. Chem. 1904, 8, 421), Tafel (Metallurgie, 5, 13), Hudson (J. Soc. Chem. Ind. 1906, 503), Murray and Turner (J. Inst. of Metals, 1909, 2, 103), and Carpenter and Edwards (*ibid.* 1911, 5, 127). The latest form of the equilibrium diagram of this series has been given and discussed by Rosenhain in the article on METALLOGRAPHY, and will, therefore, only receive brief reference here. The alloys, which are of commercial importance, contain from about 45 to 100 p.c. of copper. Within this range there are three constituents which are respectively designated by the Greek letters α, β, and γ. The α constituent is a solid solution of zinc in copper, the maximum content of zinc being about 36 p.c. at 400°. The γ constituent was regarded by Shepherd as a solid solution, but by Murray and Turner as the compound Cu_2Zn_3, containing about 40 p.c. copper. The β constituent contains about 52 p.c. copper. It has the properties of a solid solution, but is believed by Carpenter (J. Inst. of Metals, 1912) to be an intimate mixture of α and γ below a critical temperature of 470°. This critical temperature is noted with alloys containing from 60 p.c. of zinc down to 28 p.c., and probably less. The α phase is relatively soft and ductile: the β phase is harder and more brittle, while the γ phase is still harder, and practically has no ductility. It can be readily powdered in a mortar. The effect of adding zinc to copper is, therefore, as shown by Charpy, to increase the tenacity and to diminish the ductility. Beyond 40 p.c. the tenacity very rapidly falls away again, whilst the ductility is diminished after 30 p.c. Hence where ductility and strength are required together, as with cold-drawn tubes, or cartridge cases, about 70 p.c. copper is preferred. The chief commercial alloys may be classed as follows (Hudson):—

1. 100–71 p.c. Cu. Consist entirely of α at all temperatures.

2. 71–64 p.c. Cu. Entirely α below 400°; $\alpha+\beta$ above.
3. 64–63 p.c. Cu. Consist of $\alpha+\beta$ at all temperatures.
4. 63–53·5 p.c. Cu. $\alpha+\beta$ at low temperatures; β only at some higher temperature.
5. 53·5–51 p.c. Cu. Consist of β entirely at all temperatures.
6. 51–40 p.c. Cu. $\beta+\gamma$ at low temperatures; β only at a higher temperature.

It will be noted that the proportion of the β constituent increases as the temperature rises, and this fact has important bearings on the heat treatment of brass.

Cast brass. All brass is now made by melting together copper and zinc, but the term 'cast brass' is applied when the article to be made receives its form in the mould, and does not require to be afterwards rolled, drawn, hammered, or spun. For this purpose the charge is melted in graphite or clay crucibles, which usually contain about 90 lbs. of metal, and which are heated in small wind furnaces by coke. Generally each furnace contains but one pot, but sometimes two or four pots are placed in a single furnace, which is made proportionately larger in such cases. In Birmingham clay crucibles were formerly used for brass, and plumbago for bronze castings. Larger crucibles, holding 250 lbs. of metal, are often used in big foundries. Small cranes are then provided. In practice it is necessary to add a quantity of scrap brass to the charge, and this is generally introduced first into the red-hot crucible together with a small quantity of flux, which is added to remove the oxide and dirt adhering to the scrap. When only new metal is used the flux is either much reduced or altogether omitted. The fluxes most commonly employed are ground fluor spar, together with more or less glass, and *sal enixum* or acid potassium sulphate. When the scrap is hot the copper is charged into the crucible, usually in the form of ingots, though occasionally bean shot copper is used. After the copper has thoroughly melted, the zinc is cautiously added in as large pieces as possible. The use of large pieces of zinc reduces the loss, and moderates the violence of the combination. In any case considerable heat is produced by the union of zinc and copper, and some of the zinc burns with a dazzling brilliancy. After allowing the crucible to remain in the furnace a short time to permit the metal to become sufficiently fluid, it is poured into moulds, which for cast brass are generally of 'green' sand. While the brass is hot, zinc gradually volatilises and burns at the mouth of the crucible, forming zinc oxide; this produces the white fume which fills the casting house while the metal is being poured, and as a protection against the deleterious effects of inhaling the fume it is customary for the workman to keep his mouth and nostrils covered with a cloth. Regulations are now in force to ensure the proper ventilation of brass foundries. When the metal has set, the castings are turned out and dipped while warm into water, which detaches most of the adhering sand; the processes of dressing, grinding, polishing, dipping, and burnishing are necessary to give the required surface, while the finished article is lacquered to preserve it against atmospheric influences. The proportion of copper in cast brass varies considerably according to the purpose for which it is required; in some cases cheapness is of prime importance, in others the metal must 'dip' well when immersed in acid, while not unfrequently the shade of colour of the resulting alloy is of the utmost moment. Best cast brass generally contains from 70 to 75 p.c. of copper; ordinary good English brass 66·6 p.c. (*i.e.* 2 of copper to 1 of zinc); while common cast brass contains about 62 p.c. of copper. A little lead is generally added in preparing cast brass; this gives sounder castings and produces a metal which turns much better in the lathe than ordinary brass. Although not unfrequently as much as 2 p.c. of lead is added to the charge, most of this is removed by oxidation and usually only about 0·3–0·5 p.c. remains. The loss of metal in melting and casting is usually about 5 p.c., but this is greater when much small scrap is used. It may be added that in the preparation of cast brass it is not so necessary to ensure the absence of very small quantities of metals such as antimony, bismuth, and silver as is the case when the alloy has afterwards to be rolled or drawn. When special ductility or malleability is required in the final product, it is of the utmost importance that the purest obtainable materials should be employed.

When alloys of the copper-zinc series are cast in bars in sand moulds, and the length of the bars during cooling is observed by means of an extensometer, it is found that in some cases marked expansion occurs, while with other compositions there is little or no expansion. There are three maxima, which in order of magnitude occur with 15, 80, and 50 p.c. of copper respectively. The series has four maxima on the hardness curve, which are with 40, 80, 65, and 10 p.c. respectively. The 40 p.c. alloy is exceptionally hard (Turner and Murray, J. Inst. of Metals, 1909, 2, 98).

Sheet brass. One of the most important applications of brass is for the production of sheets, as sheet brass is not only needed for a multitude of useful and ornamental purposes itself, but it forms the starting-point for the manufacture of the greater part of the brass wire and tubing that is dealt with in commerce.

For the production of 'yellow metal' it is customary to prepare the alloy by melting copper on the bed of a small reverberatory furnace and adding the requisite quantity of zinc. But in preparing other varieties of sheet brass it is usual to employ crucibles heated in coke fires as described for cast brass. Gas- or oil-fired furnaces are also employed. The crucibles generally hold about 120 lbs. of metal. In either case the alloy when melted is cast in iron moulds into flat bars, varying in size, but of which one about 4½ in. × ⅜ in. × 90 in. may be taken as an example. These are known as 'strips' and the operation is known as 'strip casting.'

The strips are then 'broken down' by being passed cold through a pair of rolls, the operation being repeated as often as the metal will allow. The work done upon the metal soon causes it to become hard, and if the rolling were continued the strip would readily develop cracks. To obviate this the metal is annealed at a red heat and the surface is cleaned from oxide by pickling in dilute sulphuric acid. After washing with water, the operations of rolling, annealing, pickling, and washing are repeated, in order, until the desired shape and thickness are obtained. During the process of rolling the original crystalline structure of the alloy is largely broken down and an amorphous hard matrix is produced. This subject has been fully dealt with by Beilby (Hard and Soft States in Metals, J. Inst. of Metals, 1911, 6, 5). On annealing, the first effect is to restore the crystalline structure of the alloys. At the same time it becomes soft and ductile. If, however, the temperature of annealing be too high, or the time unduly prolonged, the crystals increase in size, and ultimately become so large that the material is quite weak, brittle, and worthless for practical purposes. The proper annealing temperature varies with the composition of the alloy, and the whole question has been studied by Hudson and Bengough (J. Inst. of Metals, 4, 1910, 92), and by Bengough (*ibid.* 7, 1912). With 70·30 p.c. brass the best annealing temperature is between 600° and 700°, but brass may become coarsely crystallised or 'burnt' at 100° below the solidus line if maintained for sufficient time, while it may safely be heated to within a few degrees of the solidus if the time does not exceed half an hour. Turner has shown (Chem. News, 63, 227, 64, 143) that the use of impure washing water containing chlorides leads to the production of copper-red stains and smears, on the surface of the finished brass, which is a cause of frequent loss and trouble. As sheet brass is used for so many purposes, its composition varies over a wide range, extending in fact from a mere trace to 40 p.c. of zinc.

Since the ductility of the alloy increases with the proportion of copper, alloys such as best red brass, gilding metal, and percussion-cap metal contain from 80 to 96 p.c. of copper. Dutch metal contains 80–85 p.c.; Prince's metal, 75 p.c.; best English sheet brass, 70–72 p.c.; ordinary, 66·6 p.c.; common, 63 p.c.; and yellow metal, 60 p.c. As already explained, this last alloy, though somewhat deficient in ductility, is strong and possesses the great advantage that it can be rolled either hot or cold. White metal alloys are used in the form of sheet to a limited extent, and these contain less than 50 p.c. of copper. The cheaper yellow alloys, rich in zinc, do not 'stand the fire' so well in soldering, and it is not usual to solder anything containing less than 60 p.c. copper. Even with this composition a special soft solder has to be employed, whilst red brass stands the fire best, and can be used with the hardest solder.

Brass wire is made from sheet brass, the sheet of suitable thickness being slit into thin strips by cutters, and the strips are then drawn into wire at the draw bench. The chief varieties of wire arranged in order of ductility are as follows:—Red metal, Prince's metal, ordinary, common, and yellow metal. The first two of these were formerly used in the button trade, as in soldering on the shanks with hard solder they 'stood the fire' well. The other varieties can all be soldered with suitable solder of low melting-point, but the difficulty of soldering increases with the proportion of zinc.

Brass tubes. There are two principal methods of producing brass tubes. By the original process, which is still largely employed, sheet brass of the required composition and thickness is cut into strips of the necessary length; the strips are then drawn through a die, which imparts a circular shape, and the edges are soldered together by the use of powdered solder and borax made into a cream with water. Small tubes are soldered by being drawn through a small furnace fired with small coal or coke, but large tubes are now generally united by the use of a gas blowpipe, which gives a local and easily regulated heat. In the second and more modern method of manufacture brass tubes are solid-drawn, and thus the operation of soldering is dispensed with. This process is chiefly employed for large tubes and for tubes of special quality, as the soldered joint in tubes made in the ordinary way is always more brittle than the rest of the material. The soldered joint is also frequently a cause of corrosion in tubes exposed to steam or salt water. For solid-drawn brass tubes a short hollow cylinder of metal is cast in suitable moulds, and by drawing on a mandril, with frequent annealings, this hollow cylinder is gradually elongated to the required dimensions.

Condenser tubes are generally made of 70 p.c. copper, 30 p.c. zinc; or, according to the Admiralty specification, in which 1 p.c. of the zinc is replaced by tin. The corrosion of condenser tubes is a source of considerable loss and trouble, especially in the mercantile marine. The causes which lead to such corrosion have been studied by Bengough (J. Inst. of Metals, 1911, 5, 28) and Brühl (*ibid.* 6, 279).

Ornamental patterns on brass tubes when parallel with the length of the tube are produced by passing the plain tubes through a set of suitably arranged rolls, on the surface of which the desired pattern is cut. But when the pattern is of a spiral form it is usual to draw the plain tube through a die of the requisite shape, arrangements being made for either the tube or the die to rotate during the operation. Best drawn tubes for locomotives and similar purposes contain 70–72 p.c. of copper; the composition of other tubes varies according to the quality of the sheet brass used in the process of manufacture.

Colouring of brass. A considerable proportion of the goods originally made of brass are so coloured before passing into commerce that the tint of the metal itself is no longer to be recognised. The most important applications of colouring are the following:—Bronzing in various shades, such as black, grey, red, green, &c.; lacquering in many shades; and bright colouring with highly coloured, transparent lacquers. These processes of colouring may be divided into two classes according as to whether they are conducted before or during the operation of lacquering.

As has been pointed out by Löwenherz, a variety of shades of colour can be obtained by carefully heating bright clean brass to definite and regulated temperatures. These colours so produced are formed in the following order:

1. Orange yellow.
2. Clear golden yellow.
3. Orange gold.
4. Dark gold.
5. Brown gold.
6. Rose-red gold.
7. Violet-rose red.
8. Clear rose.
9. Steel white.

Some of the colours are of great firmness and beauty, and the process if full of promise for special purposes, but has not hitherto been successfully adopted on any considerable scale.

The methods of bronzing, applied before lacquering, include the following:

Copper bronzing. To develop a copper-coloured surface on brass the metal may be cautiously rubbed with hydrochloric acid, or, still better, it may be immersed in a slightly acid dilute solution of copper nitrate until the desired depth of colour is obtained. To produce a dark copper-bronze colour, treat as above, and blacken the surface with plumbago before lacquering.

Grey bronze. A cheap grey bronze is produced by rubbing with plumbago and using a nearly colourless lacquer. A more permanent grey bronze is produced by the use of a solution of arsenic trioxide in hydrochloric acid; the addition of iron salts improves the effect. For common work, which is *not soldered*, an aqueous solution of mercuric chloride rendered acid with vinegar is frequently used.

Black bronze. The very beautiful and permanent black bronze used for mathematical and scientific instruments is produced by the application of a dilute aqueous solution of platinum tetrachloride which was introduced for this purpose about the year 1860.

Green bronze. A cheap green bronze which was formerly much in favour was obtained by the use of plumbago followed by a transparent yellow lacquer.

Ordinary lacquer is a solution of shellac in proof spirit, but other gums and solvents are also used. A colourless 'dip' lacquer (*i.e.* one in which the articles may be dipped, instead of the lacquer being applied by means of a brush to the warm surface as usual) is made by dissolving nitrocellulose in amylacetate. For ordinary purposes many shades of lacquer from colourless, through yellow, to brown are regularly employed. For the cheaper kinds of bronzing special bronze lacquers of a variety of colours are used; and in addition richly coloured transparent lacquers of numerous shades are produced for the manufacture of brightly coloured thin sheet metal for ornamental purposes. In this branch of manufacture the use of aniline derivatives has led to numerous improvements.

T. T.

Compounds of Zinc.

Zinc oxide ZnO. This substance, the *nix alba*, 'philosophical wool,' or 'flowers of zinc' of the alchemists, the *tutia* or *pompholyx* of the ancients, occurs as the mineral zincite or red zinc ore which is a mixture of zinc oxide and 7–12 p.c. red manganese oxide. It is often found in red or orange-yellow hexagonal crystals or in granular masses. Zinc oxide is occasionally found crystalline in zinc and brass melting furnaces.

Zinc oxide is known in commerce as zinc white, and is generally prepared on the large scale by burning zinc or its ores in retorts, or in an electric furnace, the zinc fumes being led into chambers where they meet a current of air and the oxide thus formed is led into a second chamber and allowed to condense; or the ore may be heated with anthracite or charcoal, and the resulting hot fumes treated with air (*see* Eng. Pats. 16129, 1891; 11233, 1894; 4310, 1894; 12274, 1901; 18015, 1903; 4058, 1904; 21787, 19839, 1906; U.S. Pat. 902260, 1908; Fr. Pat. 403681, 1909; amongst others; J. Soc. Chem. Ind. 1894, 401; *ibid.* 1901, 911; *ibid.* 1903, 1138; *ibid.* 1906, 1056; *ibid.* 1907, 1150; *ibid.* 1910, 88; Schnabel, Eng. and Mining J. 1892, 9, 26295).

Zinc oxide may also be prepared by heating zinc sulphate with carbon for about 2 hours at about 650° (Eng. Pat. 3906; D. R. P. 93315).

A hot solution of sodium sulphate or other alkali salt is electrolysed with zinc electrodes; zinc sulphate is formed at the anode, and sodium hydroxide at the cathode. These react forming zinc hydroxide, which is then calcined (Fr. Pats. 328491, 1903; 348294, 1904; U.S. Pat. 771025, 1903; Ind. Elektrochem. 1904, 8, 20).

The zinc oxide of pharmacy is prepared either by burning the metal or by precipitating very pure zinc sulphate with a hot solution of sodium, magnesium, or other carbonate, and heating the dried carbonate to expel carbon dioxide (Jansen, Mag. Pharm. 26, 74; Dulk, Berl. Jahrb. Pharm. 24, 2, 74; 29, i. 59; D. R. P. 21987, 151022; Rigg, Eng. Min. J. 75, 626).

Crystalline zinc oxide of sp.gr. 5·782 may be obtained by igniting the nitrate (Brügelmann, Zeitsch. anal. Chem. 29, 126); by heating zinc chloride in a stream of water vapour (Daubrée, Compt. rend. 1854, 39, 153); and by a number of other methods (Sidot, *ibid.* 1869, 69, 202; Gorgeu, *ibid.* 1887, 104, 120).

A large number of patents have been taken out for the preparation of the oxide by various methods, of which the following may be mentioned (Fr. Pats. 338977, 1903; 373027, 373953, 1906; 406150, 1908; 404840, 1909; 412214, 411672, 1910; Eng. Pats. 2532, 1905; 24526, 1906; U.S. Pats. 815516, 1906; 899322, 900088, 1908; 919375, 919376, 920336, 920337, 1909; J. Soc. Chem. Ind. 1897, 812; 1899, 1033; 1904, 1034; 1906, 325, 374; 1907, 477; 1910, 223, 425, 1016).

Zinc oxide is a white powder of sp.gr. 5·6 (*see* Fuchs and Schiff, *ibid.* 1896, 363), which, on heating, becomes lemon-yellow, but on cooling again becomes white.

According to Schüpphaus, the yellow colour is due to the formation of a suboxide (*ibid.* 1899, 987). Zinc oxide volatilises in the electric furnace, the vapours condensing in long, transparent crystals (Moissan, Compt. rend. 1892, 115, 1034). In a current of air it commences to volatilise at 1100° (Doeltz, Metallurgie, 1906, 3, 212). At a bright red heat the oxide is probably polymerised to some extent (de Forcrand, Compt. rend. 1902, 134, 1426; *ibid.* 135, 36; Ann. Chim. Phys. 1902, [vii.] 27, 26). Zinc oxide commences to be reduced by carbon in an atmosphere of nitrogen at 800°, by carbon dioxide at 600°, reduction in both cases increasing rapidly with rise in temperature (Doeltz and Graumann, Metallurgie, 1907, 4, 290). By magnesium it is reduced with explosive violence (Winkler, Ber. 1890, 23, 120).

When strongly heated in the oxyhydrogen flame it emits an intense white light, and is seen to phosphoresce when cooled in the dark. The character of the light emitted by incandescent zinc oxide has been examined by E. L. Nichols and B. W. Snow (Phil. Mag. [v.] 32, 420; and [5] 33, 19; *see* also Schmidt, Ann. Physik. 1904, [iv.] 13, 622; Tafel, *ibid.* 14, 206), who have studied the behaviour of zinc oxide under the action of canal rays.

One part of the oxide dissolves in 236,000 of water (Dupré and Bialas, Zeitsch. angew. Chem. 1903, 16, 54). If quite pure it dissolves completely in ammonia. It is readily soluble in acids, forming the corresponding zinc salts which are colourless substances having a disagreeable taste, are often poisonous to plants and animals, act as emetics, and are employed in medicine, chiefly for external application.

Zinc white has been recommended as a useful, efficient, and more healthy substitute for white lead for oil painting, and in the preparation of varnishes (Livache, Compt. rend. 1901, 132, 1230; Bull. Soc. d'Encouragement, 1908, 110, 516; 1902, 103, 690; Lenoble, J. Soc. Chem. Ind. 1904, 829). For this purpose zinc white, alone, or mixed with finely-ground silica and calcium carbonate, is made into an emulsion with linseed or a similar oil (Eng. Pat. 4870, 1893; Fr. Pat. 366465, 1906; D. R. PP. 175402, 178983; J. Soc. Chem. Ind. 1894, 262; *ibid.* 1906, 1056).

A mixture of zinc hydroxide and hydrocarbonate, used as a white pigment, is prepared by intimately pulverising zinc ore with quicklime, then extracting the mixture with liquid ammonia. After removing foreign metals by ordinary methods the ammoniacal liquid is distilled in a vacuum with or without the application of heat (Fr. Pats. 309079, 2001, 1903).

A mixture of ground zinc white and hydrated oxide of zinc precipitated in the cold or at 50°–80°, is said to be a useful enamel pigment when used in the proportions represented by the formula $2ZnO+Zn(OH)_2$, whilst for matt-surface paints the proportion should be $6ZnO+Zn(OH)_2$. As a second coat for enamelling, zinc carbonate may be substituted for a part or the whole of the zinc oxide (Joannis, J. Soc. Chem. Ind. 1906, 486).

Zinc soaps are manufactured by thoroughly mixing about 0·25 p.c. oleic or other aliphatic acid with zinc oxide and a little water. The resulting zinc soap can now be mixed into an emulsion with raw or boiled oil, a thick paste thus being formed, the constituents of which do not separate even on prolonged standing (Fr. Pat. 368755, 1906).

Zinc lead pigment consists of zinc oxide and sulphate, lead oxide and sulphate, some sulphur dioxide and water (Buskett, Eng. and Ming. J. 1907, 83, 760).

Zinc oxide is used in the manufacture of cements (D. R. P. 56958; Fr. Pats. 332788, 333671, 1903). When mixed with aluminium phosphate it is used as a dental cement (Grenet, Chem. Zeit. 1909, 33, 610).

It is also employed in the glass industry (J. 1894, 151, 354; Zschimmer, Chem. Zentr. 1907, ii. 1461; Walker, J. Amer. Chem. Soc. 1905, 27, 865); and in the preparation of crystalline glazes (Holdcroft, Trans. Eng. Ceramic Soc. 1909–10, 9, 37).

Crystalline zinc glazes are formed by the separation of zinc silicate on slow cooling of the glaze. It has a smaller coefficient of expansion than other glazes, and when melted on to pottery or stoneware is less liable to 'craze' than lead glaze.

By addition of different oxides, characteristic colour effects can be obtained with zinc glazes. Zinc oxide may also be used in place of the more costly tin oxide for producing opalescent glazes (Petrik, Chem. Zeit. 1908, 32, Rep. 490).

Crystalline zinc glazes are prepared by mixing 27·389 parts by weight of zinc oxide with 7·382 potassium nitrate, 13·770 borax, 7·200 whiting, 4·466 flaky boric acid, 0·600 cupric oxide, and 39·693 flint. The glaze should be ground as finely as possible and applied to the surface to be glazed with dextrin as an adhesive (Riddle, Trans. Amer. Ceramic Soc. 1906, 8, 336; Minton, *ibid.* 1907, 9, 782). It is also used for the production of white and colour resists employed in printing processes (Lauber, Zeitsch. Farben. and Textil Ind. 1904, 3, 417); for the preparation of certain sizing materials (D. R. P. 194726; J. Soc. Chem. Ind. 1908, 634); and to some extent in analytical processes in the laboratory (Meineke, Zeitsch. angew. Chem. 1888, 252; Koninck, Chem. Zeit. 1905, 29, Rep. 5).

For the estimation of zinc oxide in zinc paints and lithopones, *see* J. Soc. Chem. Ind. 1907, 977; Stromeyer, Arch. Pharm. 27, 549.

Zinc grey is obtained as a by-product in the manufacture of zinc white. Made into a paste with wood oil it is used as a cement for steam joints (Livache, Bull. Soc. d'Encouragement, 1905, 107, 568). It also forms a good, silver grey oil paint.

Zinc hydroxide $Zn(OH)_2$ is obtained as a white powder by adding caustic potash or soda or ammonia to a solution of a zinc salt. It may be obtained crystalline by allowing zinc to remain in contact with iron or copper under a layer of ammonia or by allowing its saturated solution in caustic potash to stand, or by the action of water on zinc oxide (de Forcrand, *l.c.*). It is stable in air up to 85°, loses nearly all its water at 130°–140°, is readily soluble in excess of ammonia and alkalis towards which it behaves as the weak acid, H_2ZnO. (Herz, Zeitsch. anorg. Chem. 1901, 26, 90; Rubenbauer, *ibid.* 1902, 30, 331; Hantzsch, *ibid.* 289; Bonsdorff, *ibid.* 1904, 41, 132; Moir, Chem. Soc. Proc. 1905, 310; Dawson and McCrae, Chem. Soc. Trans. 1900, 1239; Euler, Ber. 1903, 36, 3400; Kuriloff, Zeitsch. Elektrochem. 1906, 12, 209; Bull. Acad. St. Petersburg, 1901, 1, 95). A mixture of zinc ammonium hydroxide and copper ammonium hydroxide has been used for pectinising cellulose and similar substances to produce a kind of vegetable parchment (J. Soc. Chem. Ind. 1884, 122).

Zinc peroxide ZnO_2, also known under the trade names *Zinkonal*, *Dermogen*, *Ektogan*, and *Zinc perhydrol*, is formed by the action of hydrogen peroxide on zinc oxide or hydroxide (Kuriloff, J. Russ. Phys. Chem. Soc. 1890, 22, 171; de Forcrand, Compt. rend. 1902, 134, 601; *ibid.* 135, 103; D. R. P. 171372). It has also been formed by subjecting an aqueous solution of barium peroxide to the action of a zinc salt, the acid radicle of which forms a soluble salt with barium (U.S. Pats. 709086, 1902; 740832, 1903), or better, by the electrolysis of a zinc chloride solution contained in a vessel with a porous diaphragm, hydrogen peroxide being added to the cathode compartment and platinum or carbon being used as anodes and platinum or tin as cathodes (D. R. P. 151129; for another method *see* J. Soc. Chem. Ind. 1905, 947; also Fr. Pat. 364825, 1906). A number of peroxides have been described, but, according to Kuriloff (Compt. rend. 1903, 137, 618; *see* also de Forcrand, *ibid.* 1904, 138, 129), the only one which is a definite chemical compound has the composition $ZnO_2,Zn(OH)_2$, the others all being mixtures of varying quantities of zinc peroxide with zinc oxide or zinc hydroxide (Lemaire, Rép. Pharm. 1910, 22, 1; Foregger and Philipp, J. Soc. Chem. Ind. 1906, 298).

Zinc peroxide is a yellowish-white, tasteless, odourless, non-hygroscopic, antiseptic, non-irritant powder. It is stable in the autoclave to 130°, and at a dry heat to 150°, is insoluble in water, and gives all the ordinary reactions of a peroxide.

Mixed with tartaric acid it is applied as a dressing to wounds, chronic ulcers, &c. It thus liberates hydrogen peroxide *in situ*, and is therefore more active than the same quantity of the latter applied in the usual way. For eczema and other skin diseases it is applied, mixed with half its weight of potassium iodide and some tartaric acid (Chem. Zentr. 1906, ii. 548; D. R. PP. 14821, 157737; Homeyer, Apoth. Zeit. 1902, 17, 697; J. Soc. Chem. Ind. 1905, 947).

Zinc chloride $ZnCl_2$, the *oleum lapidis calaminaris* of Glauber, who first described it in 1648, may be prepared in the anhydrous state by distilling zinc oxide with sal-ammoniac, forming the ‘butter of zinc’ of Hellot; by distilling zinc with corrosive sublimate (Pott); by the action of chlorine on the metal (Westrumb), or by heating dehydrated zinc sulphate with calcium chloride (Persoz) (Eng. Pat. 982, 1892; 15813, 1895; D. R. PP. 154518, 158089).

On the large scale it is usually obtained by placing scrap zinc in a stone, cast iron, or wooden vessel containing hydrochloric acid. The solution is neutralised with sodium carbonate, warmed to 40° or 50°, and mixed with bleaching powder to precipitate iron and manganese. The clear zinc chloride solution is siphoned off and boiled down in enamelled iron pots. The evaporation is continued until the temperature of the liquor is 230° or 240°, a little potassium chlorate is added to oxidise any organic matter, and some pure hydrochloric acid carefully poured into the hot solution to dissolve any basic salt. The mass is then allowed to solidify, the agitation being kept up all the time, and while still warm it is packed in iron drums of 30–50 kilos. capacity, which are at once closed air-tight.

According to a more recent patent (Fr. Pat. 385448, 1907), zinc-bearing material is intimately mixed with sawdust or similar substance containing cellulose in earthenware or cast-iron twin tubular retorts, which are used alternately. The first retort is heated to 120°–130°, and chlorine is passed in at the base, hydrochloric acid is thus generated *in situ*, and the temperature rises spontaneously to 230°–250°. The products of combustion pass from the upper part of the retort to a receptacle where the tar is deposited and thence to the base of the second retort where the excess chlorine is fixed and the products then pass out into a second receptacle, where the tar is again fixed, and thence into a coil and receiver cooled by water. The mass thus obtained is lixiviated with water. Iron and manganese are then oxidised with chlorine and calcium hypochlorite, the iron is precipitated by zinc oxide, the manganese, if necessary, by lead peroxide (D. R. PP. 154085; 136521), and the other metals by agitation with zinc. The remaining liquor is then finally evaporated to obtain pure zinc chloride.

It may also be obtained almost pure by treating zinc compounds with ferrous chloride (D. R. P. 136521); by heating zinc ore to 550°, passing hydrogen chloride over it, and finally lixiviating the mass so obtained (D. R. P. 158087). A large number of patents exist for the preparation and purification of zinc chloride by the above and other methods (Eng. Pats. 22826, 22827, 1894; 5662, 8449, 7561, 1895; 24573, 1896, 19878, 1900; D. R. PP. 155065. 172460; U.S. Pats. 845868, 1907; 883426, 1908; Mallet and Guye, Chem. Zeit. 1904, 28, 763; J. Soc. Chem. Ind. 1893, 276; *ibid.* 1895, 450, 595; *ibid.* 1896, 198, 356; *ibid.* 1897, 1015; *ibid.* 1900, 146; *ibid.* 1905, 497).

Pure anhydrous zinc chloride can be prepared by dissolving 40 grms. of the chloride in 20 c.c. of hydrochloric acid (sp.gr. 1·19), and evaporating the solution in a tube of refractory glass through which a stream of hydrogen chloride is passed. The temperature is gradually raised, and after some time the mass solidifies with evolution of hydrogen chloride. The solid chloride is fused again rapidly in a current of the same gas. The dehydration is complete in 75 mins. (Grünauer, Zeitsch. anorg. Chem. 1904, 39, 389; *see* Vogel, Faraday Soc. Trans. 1906, May 5; *see* also D. R. P. 120970).

Zinc chloride is a white or greyish-white mass or powder, of sp.gr. 2·907 at 25°/4° (Baxter and Lamb, Amer. Chem. J. 1904, 31, 229). Its m.p. is variously given as 100° (Davy), 250° (Lorenz), 262° (Braun, Mylius, and Dietz), 290°–300° (Schulze). According to Grünauer the completely anhydrous chloride has m.p. 365°. It is very hygroscopic and deliquescent, odourless, poisonous, with a metallic astringent taste. It melts to a clear, mobile, highly refractive liquid, b.p. 730°–732°; in a current of chlorine it sublimes, forming acicular crystals. It forms hydrates with 1, 1·5, 2·5, 3, and 4 molecules of water (Dietz, Ber. 1899, 32, 90; Mylius and Dietz, *ibid.* 1905, 38, 921). Its aqueous solution dissolves paper and cotton, and it should therefore be filtered through asbestos or glass, not paper. When evaporated or boiled with zinc oxide, oxychlorides are formed (Perrot, Bull. Soc. chim. 1895, [iii.] 13, 975; Driot, Compt. rend. 1910, 150, 426), whilst if a solution of sp.gr. 1·7 be boiled with an excess of zinc oxide, the resulting liquid dissolves silk, and can be employed for separating the latter from wool, cotton, or linen. Zinc oxychloride is sometimes also used in the preparation of some dental cements, and as a pigment.

When zinc chloride is electrolysed, chlorine is evolved and crystalline zinc is deposited (Saposhnikoff, J. Russ. Phys. Chem. Soc. 1905, 37, 153; *see* also Schultze, Zeitsch. anorg. Chem. 1899, 20, 323; Grünauer, *l.c.*).

Zinc chloride comes into pharmacy in the form of rods or tablets. It is a powerful caustic, distinguished by its property of burning deeply and not spreading sidewise. It is applied in substance, or made into a paste with starch or gypsum, to cancers, sloughing or unhealthy sores, and nævi (Lauder Brunton).

In dilute solution it is also used as an astringent, an antiseptic, a disinfectant, and as a deodorant.

A solution of zinc chloride, in the proportion of 1 lb. of the salt to 5 gallons of water, was patented by Sir W. Burnett (Eng. Pat. 7747, 1838) for the preservation of timber, and such a solution is still occasionally used for disinfecting and deodorising.

For the preservation of wood it has been recommended to employ an emulsion of aqueous zinc chloride, and wood-tar oil (D. R. PP. 139441, 152179; Chem. Zentr. 1903, i. 749; *ibid.* 1904, ii. 379); or a 15 p.c. solution of a mixture of ammonium sulphate and a soluble zinc salt (D. R. P. 109324).

Zinc chloride is employed for weighting cotton goods (Furth, Färber Zeit. 1901, 12, 1; D. R. P. 214372, 215702; Chem. Zentr. 1909, ii. 1508, 1905), and for crimping cotton, wool, and silk (Bull. Soc. Ind. Mulhouse, 1898, 68, 350, 348; *see* also Flintoff, J. Soc. Dyers, 1899, 15, 151).

Solutions of zinc chloride were also employed by Mercer for treating cotton in the operation of 'mercerising' (*v.* CELLULOSE).

Zinc chloride dissolves casein and these solutions have been employed for preparing artificial silk and hair. Zinc chloride has also been used in the production of hydrochloric acid from hydrogen and chlorine (Fr. Pat. 352419; Chem. Zeit. 1905, 29, 993); for the prevention of the rusting of iron (Reed, Trans. Amer. Electrochem. Soc. 1903, 3, 149); in the preparation of glass etching liquids (J. 1894, 354), and in the laboratory as an analytical, dehydrating and condensing agent and in the synthesis of a large number of organic compounds (Kondakoff, J. Russ. Phys. Chem. Soc. 1892, 24, 114, 309; J. pr. Chem. [ii.] 48, 467; Dott, Pharm. J. 1905, [iv.] 21, 136; among others).

Zinc chloride forms double chlorides with the alkali and other metals (Wells and Campbell, Zeitsch. anorg. Chem. 1894, 5, 273; Ephraim, *ibid.* 1908, 59, 756; Ephraim and Model, *ibid.* 1910, 67, 376, 379; Baxter and Lamb, *l.c.*; Gewecke, Annalen, 1909, 366, 217), with copper oxide (Mailhe, Compt. rend. 1901, 133, 226), an *iodo chloride* $ZnCl_2 2ICl_3,8H_2O$ (Weinland and Schlegelmilch, Zeitsch. anorg. Chem. 1902, 30, 134), a *chlorobromate* (Löwenthal, *ibid.* 1894, 6, 355), and a *chloroborate* $6ZnO,8B_2O_3,ZnCl_2$ (Rousseau and Allaire, Compt. rend. 1894, 118, 1255). Zinc chloride also forms double compounds with ammonia, such as $ZnCl_2{\cdot}NH_3$, $ZnCl_2{\cdot}2NH_3$ (Thoms, Chem. Zentr. 1889, ii. 965; Kwasnick, Arch. Pharm. 229, 310; Jaeger, Ber. 1902, 35, 3405), and with ammonium chloride (Curtius and Schrader, J. pr. Chem. 1894, [ii.] 50, 311; Meerburg, Zietsch. anorg. Chem. 1903, 37, 199).

A solution of zinc ammonium chloride is used in soldering for the purpose of removing oxide from the surface of the metals.

Zinc bromide $ZnBr_2$ is readily made by digesting granulated zinc with bromine water. It resembles the chloride, and is used to a small extent in medicine in the treatment of epilepsy.

Zinc iodide ZnI_2 is also employed in medicine, as an application to enlarged tonsils and in the form of ointment to reduce swellings. It is also administered internally in cases of scrofula, chorea, and hysteria. It has found a limited application in photography.

For a number of double compounds of the bromide and iodide with other metallic compounds, *see* Ephraim, *l.c.*; Ephraim and Model, *l.c.*; Rousseau and Allaire, Compt. rend. 1893, 116, 1445; *ibid.* 119, 71; Tassiliy, *ibid.* 1896, 123, 323; Duboin, *ibid.* 1906, 143, 40; Chrétien, Ann. Chim. Phys. 1898, [vii.] 15, 358; Mosnier, *ibid.* 1897, [vii.] 374.

Zinc fluoride ZnF_2 is formed by the action of hydrofluoric acid on zinc or on zinc oxide at a red heat, or on zinc chloride at 800°–900° (Poulenc, Compt. rend. 1893, 116, 581). It forms slender, colourless, transparent needles, sp.gr. 4·84 at 15°, sparingly soluble in cold water, soluble in boiling mineral acids. It is reduced by hydrogen at a red heat; when heated in air it forms zinc oxide. When dissolved in hydrofluoric acid, or when zinc is dissolved in excess of hydrofluoric acid, it forms the compound ZnF_2,HF, which has been recommended for use in the preservation of wood, particularly of telegraph poles (Nowotny, Chem. Zentr. 1908, ii. 355). Like the other halides, zinc fluoride yields a number of double salts (Helmolt, Zeitsch. anorg. Chem. 1893, 3, 115; Weinland and Köppen, *ibid.* 1899, 22, 266; Giorgis, Gazz. chim. ital. 22, i. 55; Higley, J. Amer. Chem. Soc. 1904, 26, 613; Rimbach and Kilian, Annalen, 1909, 368, 101).

Zinc sulphate $ZnSO_4$. This salt has long been known under the name which it still bears, of 'white vitriol.' It was obtained, on a manufacturing scale, as far back as the sixteenth century, by lixiviating roasted zinc sulphide by means of water, and crystallising the solution—a method still practised, with certain modifications (U.S. Pat. 851639, 1907; J. Soc. Chem. Ind. 1907, 608).

In some processes the zinc pyrites is previously treated with sulphuric acid, after which it is roasted (D. R. P. 154518). It is then sometimes further treated with oxidising agents. In some cases again the ore is treated with a mixture of dilute sulphuric acid, ferric sulphate, and a little sodium chloride (D. R. P. 197044), or with ferric sulphate alone (D. R. P. 200613). According to D. R. P. 135056, after converting the sulphide ore into the sulphate in the ordinary way, the product is roasted with calcium hydroxide and sodium nitrate in a muffle furnace in order to drive off the impurities, or to convert them into insoluble compounds. When the process is finished, the zinc sulphate is lixiviated out (*see* also D. R. PP. 120822, 135182; Knokloch, Pharm. Zeit. 40, 472; Hofmann, Amer. Inst. Mining Eng. Trans. 1905, 117; Fr. Pat. 384904, 1907).

Native zinc sulphate or *goslarite* is occasionally found in zinc mines, being probably formed by the oxidation of zinc sulphide.

Zinc sulphate separates from its solution at the ordinary temperature in right rhombic prisms, isomorphous with magnesium sulphate, and of the composition $ZnSO_4,7H_2O$; sp.gr. 1·95; 2·036 (Mohs). It has a strong metallic styptic taste, and effloresces slightly in dry air. According to Poggiale, 100 parts of water dissolve the following amounts of zinc sulphate at different temperatures (*see* also Callendar and Barnes, J. Phys. Chem. 1897, 2, 536, who give slightly different figures):—

	$ZnSO_4,7H_2O$	Anhydrous salt
10° . .	138·2 . .	48·3
20° . .	161·5 . .	53·1
30° . .	191·0 . .	58·5
50° . .	263·8 . .	68·7
100° . .	653·6 . .	95·6

The solution has an acid reaction and is poisonous. The salt is insoluble in absolute alcohol.

Solutions of zinc sulphate keep clearer in the light than in dark (Verda, Chem. Zentr. 1907, i. 1392).

A hexahydrated salt $ZnSO_4,6H_2O$ is obtained by crystallising the solution at 40°; sp.gr. 2·072 (Thorpe and Watts); a pentahydrated salt $ZnSO_4,5H_2O$ by boiling the salt with alcohol of sp.gr. 0·825 (sp.gr. 2·206, Thorpe and Watts), and a dihydrated salt by pouring a cold saturated solution of zinc sulphate into strong sulphuric acid, and washing the precipitate with absolute alcohol until free from uncombined acid; sp.gr. 2·958 (Thorpe and Watts). The monohydrated salt is formed by heating the heptahydrated salt to 110° until it ceases to lose weight; sp.gr. 3·284 (Thorpe and Watts). The anhydrous salt is obtained by heating the heptahydrate to 300°; sp.gr. 3·4. At a red heat all the sulphates are decomposed, yielding a residue of zinc oxide.

Zinc sulphate is used in dyeing and calico-printing, in the manufacture of varnishes and drying oils for painting.

Coloured zinc pigments are prepared by intimately mixing together zinc sulphate with 6–30 p.c. of the sulphate of other metals which yield a coloured oxide, such as nickel, iron, cobalt, or manganese. The mixture is dried, finely divided carbon is added, and the whole ignited carefully at 650°. To produce a more delicately-tinted pigment, the zinc sulphate should first be purified by stirring zinc oxide into its solution and passing a current of chlorine through it, whereby the impurities are thrown down (Eng. Pat. 17031, 1896; Fr. Pat. 366517, 1908; J. Soc. Chem. Ind. 1908, 1074).

It is also used for the preparation of zinc white and other zinc compounds, and in pharmacy as an astringent, and in lotions, washes, and gargles. It is also occasionally employed as an emetic, and in the treatment of convulsive diseases. A number of basic sulphates, formed by digesting the oxide or hydroxide with strong solutions of zinc vitriol, or precipitating such solutions with varying quantities of potash, can be formed.

Zinc sulphate combines with ammonia and with other sulphates to form double salts (Curtius and Schrader, *l.c.*; Tröger and Ewers, Arch. Pharm. 235, 644; Mallet, Chem. Soc. Trans. 1900, 220; Tutton, *ibid.* 1905, 1123; Koppel, Zeitsch. physikal. Chem. 1905, 52, 385).

The compound $ZnSO_4,3H_2SO_4$ has been separated from the acid in the first chambers in the manufacture of sulphuric acid from zinc blende (Hoffmann, Zeitsch. angew. Chem. **1910**, 23, 1672).

Zinc hydro- or **hyposulphite** ZnS_2O_4 is obtained by passing a current of sulphur dioxide into a mixture of zinc-dust and alcohol or water at a temperature above 40°. On stirring, a crystalline paste of the hydrosulphite is formed, which is washed with methylated spirits and dried *in vacuô* below 70° (Eng. Pat. 3811, 1907; D. R. PP. 184564, 103403, 137494, 144281; Fr. Pat. 331095, 1903; Brunck, Annalen, 1903, 327, 240; Bazlen, Ber. 1905, 38, 1061).

Soluble double salts of zinc hydrosulphite with ammonium salts are obtained by the action of zinc-dust on alkali disulphite in the presence of acid and an ammonium salt (D. R. P. 203846, 1907).

Zinc hydrosulphite forms microscopic rhombic crystals, very soluble in water, giving, very readily, supersaturated solutions. It is employed as a reducing agent in the indigo dyeing industry.

Zinc sulphite $ZnSO_3$ is formed by the action of sodium sulphite on zinc sulphate (Denigès, Bull. Soc. chim. 1892, [iii.] 7, 569). It forms a number of hydrates, double salts and basic salts (Seubert, Arch. Pharm. 1891, 229, 316; Seubert and Elten, Zeitsch. anorg. Chem. 1893, 4, 61; Rammelsberg, Pogg. Ann. 67, 255).

It is used to a very limited extent in medicine.

Zinc sulphide ZnS, as blende, is one of the most important ores of zinc (Robertson, Amer. J. Sci. 40, 160). Its value as an ore of zinc was first demonstrated by Brandt in 1735, it being formerly regarded as a worthless lead ore, *galena inanis*. It is found crystallised in forms derived from the regular system, usually of a red, brown, or black colour, due to the presence of foreign metals. Occasionally it is met with of a light-yellow colour; sp.gr. 3·5–4·2.

It is obtained artificially as a white amorphous precipitate by adding an alkaline sulphide or sulphuretted hydrogen to a solution of a zinc salt (Eng. Pats. 396541, 25965, 1908).

It may also be obtained by dissolving zinc in an alkali hydroxide and then adding just sufficient alkali sulphide to precipitate the zinc (Fr. Pats. 353496, 353480); or by passing zinc chloride vapour over barium or stannous sulphide (Fr. Pat. 338322, 1903; Viard, Compt. rend. 1903, 136, 892).

A mixture of zinc sulphate (230 lbs.), water (90 gallons), ammonia of sp.gr. 0·91 (230 lbs.) is introduced into an enamelled digester and about 60 lbs. of carbon disulphide are added. The vessel is closed and heated to 100° with constant stirring, until the pressure is about 60 lbs. After 4 hours the pressure begins to fall, and in 10 hours it will have fallen to about 22 lbs., when the process is complete. The zinc sulphide is collected, washed, and dried. It is very finely divided and is suitable for use as a pigment (Eng. Pat. 11108, 1900).

Zinc sulphide is sometimes separated from its ores by immersing the crushed ore in a solution of sodium sulphate, disulphate or nitrate, and skimming off the sulphide which rises to the surface (Eng. Pat. 26279, 1902; 27132, 1903; 20160, 20169, 1904; U.S. Pat. 780281; Fr. Pat. 326866, 326867, 1902). For other methods of preparing the sulphide, *see* Eng. Pat. 16272, 1902; Fr. Pats. 397631, 396541, 1908; 415605, 1910; D. R. PP. 132916, 137801, 149557, 167172, 167498, 171872, 179022).

Zinc sulphide is soluble in dilute mineral acids, but is insoluble in acetic acid. When heated in a stream of sulphuretted hydrogen, or in an electric furnace, it forms hexagonal crystals identical in form with a naturally occurring variety known as *wurtzite* (Mourlot, Compt. rend. 1896, 123, 54; Traube, Jahrb. Min. 9, 147). This is also formed when zinc oxide is ignited in sulphuretted hydrogen. For other methods of converting the amorphous sulphide into the crystalline variety, *see* Villiers, Compt. rend. 1895, 120, 97, 149, 322, 498; Viard, *ibid. l.c.*; Spring, Zeitsch. physikal. Chem. 1895, 18, 553; Staněk Zeitsch. anorg. Chem. Chem. 1898, 17, 124.

Pure zinc sulphide melts at 1600°–1700°, and is distinctly volatile at higher temperatures (Friedrich, Metallurgie, 1908, 5, 114). According to Krutwig (J. Soc. Chem. Ind. 1906, 267) the precipitated sulphide decomposes much more readily than natural zinc blende. When treated with hot concentrated sulphuric acid, zinc sulphide evolves sulphur dioxide, whilst with the cold dilute acid, sulphuretted hydrogen is formed (Berthelot, Ann. Chim. Phys. 1898, [vii.] 14 176). Zinc sulphide may be completely reduced by heating it with spongy metallic iron at 1300° (Graumann, Metallurgie, 1907, 4, 69). Freshly precipitated zinc sulphide dissolves in potassium cyanide forming a double salt which is precipitated on boiling (Berthelot, Compt. rend. 1899, 128, 711).

When zinc sulphide is heated with carbon in nitrogen at 1300°–1400°, a volatile compound is formed, which, if the containing vessel is of quartz, reacts with the silicon forming a volatile compound $ZnSSi$, which may also be obtained by heating zinc sulphide with silicon at 1300°. The compound $ZnSSi$ forms hard brown crusts of homogeneous structure. It may be polished like a metal, has an electrical conductivity less than silicon, reacts with acids forming sulphuretted hydrogen and with alkalis with evolution of hydrogen (Fraenkel, Metallurgie, 1909, 6, 682).

Natural zinc sulphide crystals have the property of phosphorescing after exposure to light (Mourelo, Compt. rend, 1899, 128, 557; Verneuil, *ibid.* 1888, 106, 1104), and the phosphorescent sulphide may be prepared artificially by heating precipitated zinc sulphide to redness in the presence of alkali chlorides or the sulphides of other metals (Eng. Pat. 385096, 1907; D. R. P. 163648; Henry, Compt. rend. 1892, 115, 505; Grüne, Ber. 1904, 37, 3076; Hofmann and Ducca, *ibid.* 3407; Jorissen and Ringer, *ibid.* 3983; Chem. Zentr. 1906, i. 644; *see* also D. R. P. 200998). The pure sulphide, however, shows no phosphorescence. It has been proposed to use this property of zinc sulphide in the construction of an actinometer and for photometric purposes (Henry, Compt. rend. 1899, 128, 94). The phosphorescent sulphide glows when exposed to X- or to Becquerel rays; to the α- radiation from radium (Chem. News, 1903, 157; Becquerel, Compt. rend. 1904, 137, 629; Bumstead, Phil. Mag. 1908, [vi.] 15, 432), and under the influence of ozonised oxygen (Schenck and Mihr, Ber. 1904, 37, 3464). When zinc sulphide is heated with manganese nitrate and a number of other substances at 1200°, the product exhibits triboluminescence (Karl, Compt. rend. 1907, 144, 841).

Zinc sulphide may be obtained in a colloidal form by allowing it to remain in contact with water (Donnini, Gazz. chim. ital. 1894, 24, i. 219; Hausmann, Zeitsch. anorg. Chem. 1904, 40, 110); or by allowing a mixture of zinc sulphate, glycerol, and ammonium sulphide to stand for 3 days (Müller, Chem. Zeit. 1904, 28, 357), and in other ways.

Zinc sulphide, or a mixture of zinc sulphide and oxide, is used as a pigment. Griffiths' 'patent zinc white' is obtained by the addition of a soluble sulphide to zinc chloride or sulphate solution, drying the precipitate, and calcining it. It is raked out whilst hot into cold water, and levigated (J. Soc. Chem. Ind. 1885, 563).

A light-proof and weather-proof pigment may be obtained by precipitating zinc as a hydrated sulphide from an alkaline solution. The precipitate is then dehydrated at 300° until $ZnS : H_2O = 5 : 1$ (U.S. Pat. 884874, 1908; *see* also Griffiths' Eng. Pat. 750, 1883; Knight, Eng. Pat. 16220, 1884; J. B. Spence, Eng. Pats. 13462, 1885; 14128, 1885; 27426, 1907; Fr. Pat. 373027, 1906; Cowley, Chem. News, 1891, 63, 88; J. Soc. Chem. Ind. 1910, 99, 166).

A mixture of zinc sulphide and barium sulphate with some zinc oxide is known as *lithopone* or *zincolith.* It is obtained by precipitating hot concentrated zinc sulphate solution with barium sulphide. Rather less than 1 p.c. freshly-precipitated magnesium hydroxide and common salt are added and the precipitate is then washed, dried, crushed, mixed with 3 p.c. ammonium chloride, and heated. The mass, while still hot, is thrown into cold water, after which it is again dried and ground (Leyfert, Zeitsch. angew. Chem. 1902, 15, 802). It comes into commerce in different grades: yellow seal contains 11–18 p.c. ZnS, blue seal 22–30 p.c. ZnS, and green seal, 32–42 p.c. ZnS (Fr. Pats. 335115, 1903; 335358; U.S. Pat. 740072, 1903; Eng. Pats, 1836, 1837, 3768, 3769, 6521, 1903; D. R. PP. 199493, 202420, 163455, 167772, 202253. 202709; Riederer, J. Soc. Chem. Ind. 1909, 403).

Zinc carbonate $ZnCO_3$ occurs native as *smithsonite, calamine* or *zinc spar.* It can be formed artificially by adding zinc sulphate solution to a solution of sodium hydrogen carbonate (Kraut, Zeitsch. anorg. Chem. 1896, 13, 1; Eng. Pat. 6752, 1902; Fr. Pats, 325587, 1902; 329079, 1903; 315888, 1901; J. Soc. Chem. Ind. 1902, 1457; *ibid.* 1903, 214, 752, 1007; Feist, Arch. Pharm. 1909, 247, 439). When the normal carbonate is employed, basic zinc carbonates are formed, the proportion of zinc oxide varying with the temperature and dilution of the solutions. The *zinci carbonas* of the British Pharmacopœia has the approximate composition $ZnCO_3(ZnO)_2,3H_2O$. At a red heat it loses carbon dioxide and forms zinc oxide.

According to Barbier basic zinc carbonate can be effectively employed as a pigment instead of white lead (Fr. Pat. 339151, 1903). It is prepared for this purpose by the electrolysis of a calcium carbonate solution with zinc as anode and carbon as cathode.

Zinc carbonate is a mild astringent to the skin, and is employed in dusting powders and lotion with, or instead of, zinc oxide.

According to Mikusch (Zeitsch. anorg. Chem. 1908, 56, 365) the only basic carbonate of zinc which exists is $5ZnO,2CO_2,4H_2O$. All the others that have been described are solid solutions of zinc oxide and carbonate.

Zinc trithiocarbonate ammonia $CS_3Zn(NH_3)_2$ (Hofmann, Zeitsch. anorg. Chem. 1897, 14, 263); and **dihydroxylamine carbonate**

$$Zn(NH_3O)_2CO_3$$

(Goldschmidt and Syngros, *ibid.* 1894, 5, 129) have been described.

Zinc cyanide $Zn(CN)_2$ is prepared by precipitating zinc acetate with aqueous hydrocyanic acid or by heating zinc-dust with an organic substance containing nitrogen (Aufschläger, Monatsh. 1892, 13, 268). It is a white powder insoluble in alcohol and water, and has been used in the manufacture of alkali cyanides (D. R. P. 132294; Chem. Zentr. 1902, ii. 80). It forms double salts such as $M_2Zn(CN)_4$ and $MZn(CN)_3$ (Berthelot, Ann. Chim. Phys. 1899, 17, [vii.] 458; Sharwood, J. Amer. Chem. Soc. 1903, 25, 570; *see* also Miller and Danziger, *ibid.* 1902, 24, 823; Fischer and Cuntze, Chem. Zeit. 1902, 26, 872). It also combines with ammonia (Varet, Compt. rend. 1887, 105, 1070; *ibid.* 1888, 106, 1080; Ann. Chim. Phys. 1897, [vii.] 10, 5).

Zinc nitrate is formed by dissolving zinc in nitric acid. It is said to crystallise with 2, 3, 4, 6, and 9 molecules of water (Funk, Zeitsch. anorg. Chem. 1899, 20, 400; Vasilieff, J. Russ. Phys. Chem. Soc. 1909, 41, 744, 748). When heated for some time at 100° it forms basic salts (Athanasescu, Bull. Soc. chim. 1896, [iii.] 15, 1078; Terreil, *ibid.* 7, 553; Riban, Compt. rend. 1892, 114, 1357). It also forms double salts (Urbain and Lacombe, *ibid.* 1903, 137, 568).

Zinc nitrite forms fine unstable needles (Matuschek, J. Soc. Chem. Ind. 1902, 705), and also gives double salts (Rosenheim and Oppenheim, Zeitsch. anorg. Chem. 1901, 28, 171).

Zinc nitride Zn_3N_2 is formed by heating zincamide to dull redness, or zinc in a current of ammonia at 600° (White and Kirschbraun, J. Amer. Chem. Soc. 1906, 28, 1343). It is a green powder which becomes incandescent when moistened with water.

Zincamide or **zinc diamine** $Zn(NH_2)_2$ is a white amorphous powder readily decomposed by water, thus:

$$Zn(NH_2)_2+2H_2O=Zn(OH)_2+2NH_3.$$

It is formed by the action of dry ammonia on zinc ethyl (Frankland, Phil. Mag. [iv.] 15, 149).

Zinc hydroxylamine $Zn(O{\cdot}NH_2)_2,3NH_2OH$ is prepared by the action of anhydrous hydroxylamine on finely-divided pure zinc and treating the product with absolute alcohol. It forms glistening crystals which detonate and evolve ammonia when heated rapidly (Ebler and Schott, J. pr. Chem. 1908, [ii.] 78, 289).

Basic **Zinc azoimide** N_3ZnOH (?), *see* Curtius and Rissom, J. pr. Chem. 1898, [ii.] 58, 261.

Zinc borate or **hydroxyborate** $Zn_3(B_4O_7)_2(OH)_2$ is prepared by precipitating an aqueous solution of zinc sulphate (500 grms. salt to 5–10 litres water) by the gradual addition, with constant stirring, of 443·6 grms. of borax solution, and 309 grms. 15 p.c. sodium hydroxide solution. The precipitate is then washed and dried (Holdermann, Arch. Pharm. 1904, 242, 567; *see* also Ouvrard, Compt. rend. 1900, 130, 335; Chatelier, *ibid.* 1891, 113, 1034; Borchers, Zeitsch. anorg. Chem. 1910, 68, 269). It is employed in the preparation of zinc powder for wounds.

Zinc perborate is obtained by the action of sodium peroxide or its hydrate and boric acid, or sodium perborate on a zinc salt or from basic acid and zinc peroxide hydrate. It is a white, amorphous powder applicable to dermatology (D. R. PP. 165278, 165279).

Zinc boracite $6ZnO,8B_2O_3ZnI_2$ is formed by passing a stream of carbon dioxide laden with iodine over a heated mixture of zinc and zinc borate (Allaire, Compt. rend. 1898, 127, 555).

Zinc phosphide Zn_3P_2 is obtained as a crystalline friable mass with metallic lustre, by heating zinc in phosphorus vapour in an atmosphere of dry hydrogen; or by passing a mixture of hydrogen phosphide and nitrogen over zinc heated to redness. It is insoluble in water and in alcohol, soluble in acids with evolution of hydrogen phosphide. Zinc phosphide possesses all the properties of free phosphorus, but is very stable and is used in medicine in place of the latter.

Jolibois (Compt. rend. 1908, 147, 801) has also prepared the phosphide ZnP_2 (*see* also Renault, *ibid.* 1873, 76, 283). For zinc phosphates and other compounds of zinc and phosphorus, *see* Bansa, Zeitsch. anorg. Chem. 1894, 6, 128. 143; Schwarz, *ibid.* 9, 249; Schulten, Bull. Soc. chim. [iii.] 2, 300; Ferrand, *ibid.* 1895, [iii.] 13, 115; Compt. rend. 1896, 122, 621, 886; Friedel, *ibid.* 1894, 119, 260).

Some natural zinc phosphates, viz. *hopeite* $Zn_3P_2O_8,4H_2O$; *parahopeite*, same formula; and *tarbuttite* $Zn_3P_2O_8Zn(OH)_2$ are described by Spencer (Min. Mag. 1908, 15, 1).

Zinc permanganate $Zn(MnO_4)_2,6H_2O$ may be prepared by adding a concentrated solution of zinc sulphate to a similar solution of barium permanganate so long as barium sulphate is precipitated. The solution is filtered, and the filtrate evaporated to crystallisation at a low temperature, or *in vacuô* over sulphuric acid, and the crystals finally dried at about 40°.

Zinc permanganate forms crystalline granules of a violet-brown colour, and is very soluble in water. In very dilute solutions it has been used successfully in the treatment of urethritis. It has no irritating action, but, like the potassium salt, it should never be compounded with alcohol, glycerol, sugar, or dry or fluid vegetable extracts as there may be danger of explosion owing to the readiness with which it is reduced and evolves oxygen (Merck, J. Soc. Chem. Ind. 1890. 409; Klobb, Bull. Soc. chim. [iii.] 9, 105).

Zinc orthosilicate Zn_2SiO_4 occurs native as *Willemite*. *Silicious calamine*, used to some extent as an ore of zinc, is a hydrated orthosilicate Zn_2SiO_4,H_2O. It is found in unsymmetrically-terminated rhombic prisms, and, like tourmalin, boracite, sugar, and other unsymmetrical crystals, it is pyro-electric—that is, on warming, one end becomes positively, the other negatively, electrified.

Amorphous zinc silicate is prepared by precipitating a solution of zinc sulphate with sodium silicate. When heated with boric acid for 10 days at a high temperature it forms a white crystalline powder of $ZnSiO_3$ insoluble in acids and isomorphous with the mineral *enstatite* (Traube, Ber. 1893, 26, 2735).

For some double zinc silicates, *see* Wyrouboff, Bull. Soc. Franc. Min. 1896, 19, 219; Wolff, Zeitsch. Kryst. Min. 1900, 33, 147; Duboin, Compt. rend. 1905, 141, 254.

Zinc sulphide *v. supra.*

Zinc chromate *v. Chromium.*

Zinc also forms *arsenates, thioarsenates*, and *arsenites* (Reichard, Ber. 1894, 21, 1019; *ibid.* 1898, 31, 2163; Lefèvre, Compt. rend. 1890, 110, 405; Preis, Annalen, 1890, 257, 178; Avery, J. Amer. Chem. Soc. 1906, 28, 1155); *antimonates* and *thioantimonates* (Senderens, Bull. Soc. chim. 1899, [iii.] 21, 47; Pouget, Ann. Chim. Phys. 1899, [vii.] 18, 508); *tellurates* (Gutbier, Zeitsch. anorg. Chem. 1902, 31, 340); *selenides* (Fonzes-Diacon, Compt. rend. 1900, 130, 832); *plumbates* (Hoehnel, Arch. Pharm. 1896, 234, 397); *ferrocyanides* (Stone and Ingen, J. Amer. Chem. Soc. 1897, 19, 542; Miller and Matthews, *ibid.* 547); and other compounds.

ORGANIC COMPOUNDS OF ZINC.

Zinc acetate $Zn(C_2H_3O_2)_2,2H_2O$ is prepared by neutralising acetic acid with zinc carbonate or oxide. It forms thin, soft, white, glistening, translucent plates, or monoclinic crystals of a pearly lustre soluble in water and in alcohol (Ley, Zeitsch. physikal. Chem. 1899, 30, 243). It closely resembles the sulphate in its action and uses.

Zinc oleate (*shoemaker's zinc oleate*) is prepared by dissolving 32 grms. of hard soap shavings in 480 c.c. of distilled water, heating, if necessary; 64 grms. of zinc sulphate are dissolved in 64 c.c. of boiling water and added to the former solution; after stirring, the oleate is separated, washed with hot water until free from sulphate, cooled, dried, and powdered (Naylor, Pharm. J. 1901, 66, 392). It is used in medicine as a mild astringent ointment and as an absorbent dusting powder to retain perspiration.

Zinc stearate is formed by the interaction of zinc acetate and sodium stearate. It is a fine white, tasteless powder, used for similar purposes as the oleate.

Zinc valerate $Zn(C_5H_9O_2)_2$ is prepared by mixing zinc sulphate with sodium valerate. It forms white, lustrous, pearly scales, or a white powder having the odour of valeric acid and a sweet, astringent metallic taste. It is also employed in medicine.

Zinc oxalate, propianate, tartrate, salicylate, and **lactate** have also been prepared. The last of these has been recommended for use in mordanting cotton and other vegetable fibres (Eng. Pat. 372, 1896; J. Soc. Chem. Ind. 1896, 804).

For the preparation of *zinc tannate, see* Villon, Bull, Soc. chim. 1890, [iii.] 3, 784.

Zinc antipyrine salicylate is formed when a dilute solution of sodium salicylate and antipyrine is mixed with a solution of zinc chloride or sulphate. It forms colourless needles, m.p. 75°–76° (decomp.), sparingly soluble in cold, and more so in warm, water, alcohol, and ether (Schuyten, Chem. Zentr. 1898, ii. 704).

Zinc boropicrate (*Chrysyl*) is obtained by the saturation of boropicric acid (prepared by boiling together 349 grms. picric acid, 62 grms. boric acid, and about 4 grms. of water) with 82 grms. of zinc oxide. It is a yellow powder used as a medicinal antiseptic (Monteil, J. Soc. Chem. Ind. 1908, 354).

Zinc boro-diorthohydroxybenzoate

$$\left(HO{\cdot}B{<}\begin{matrix}O{\cdot}C_6H_4{\cdot}CO_2\\O{\cdot}C_6H_4{\cdot}COOH\end{matrix}\right)_2Zn,10H_2O,$$

m.p. 100° (decomp.), is obtained by mixing 1 part boric acid with 1 of zinc carbonate, and 3 of salicylic acid, and adding the mixture in small portions to 10 times the weight of water at 65°. The mixture is agitated until no more carbon dioxide is evolved, when it is filtered and allowed to crystallise (Fr. Pat. 411614, 1910; J. Soc. Chem. Ind. 1910, 976).

Zinc compounds of 2-hydroxynaphthalenesulphonic acid-1-azo-β-naphthols have been prepared by treating 1-amino-2-naphthalsulphonic acids in concentrated aqueous solution, or in suspension, with alkali nitrite and an equivalent amount of zinc sulphate. The product so obtained is then made to react with a concentrated alkali solution of β-naphthol. The products dye wool in acid solution, bluish-red to violet shades, which turn bluish-black on subsequent treatment with a dichromate (U. S. Pat. 807422, 1905).

Basic zinc formaldehyde hydrosulphite is formed by adding 1 molecule of zinc to a mixture of 2 molecules of sulphurous acid and 2 of formaldehyde and then reducing the mixture by another molecule of zinc (U.S. Pats. 814032, 812124, 1906; J. Soc. Chem. Ind. 1906, 311, 217).

By the interaction of zinc-dust, sulphur dioxide, and aqueous formaldehyde, a difficultly soluble *zinc formaldehydesulphoxylate*, or a readily-soluble *zinc formaldehyde hydrosulphite* is formed, according to the conditions of the experiment (Eng. Pat. 81, 1906; J. Soc. Chem. Ind. 1906, 260; *see* also *ibid.* 1908, 1058; Becker, Ber. 1910, 43, 856; Fromm and Palma, *ibid.* 1906, 39, 3317; D. R. PP. 214041, 172217).

Zinc indigo white $C_{16}H_{10}O_2N_2Zn$ (?) is produced by the action of zinc chloride on calcium indigo white; of zinc oxide on indigo white in boiling naphthalene, and of zinc dust on indigotin in boiling naphthalene. It crystallises in lustrous leaflets (Binz, J. pr. Chem. 1901, [ii.] 63, 497).

Zinc gelatose is obtained by dissolving gelatose (formed by the action of superheated steam on gelatin) in dilute alcohol, adding a solution of a zinc salt and precipitating with alcohol. It is an amorphous powder, soluble in water, but insoluble in ether, benzene, and chloroform. It is said to be a valuable astringent without any irritating action on the mucous membrane (U.S. Pat. 698694, 1902).

Zinc chlorophyll is obtained by the action of zinc hydroxide and carbon dioxide on an alcoholic solution of chlorophyll. It closely resembles chlorophyll in properties. When treated with alkalis it yields a substance closely analogous with alkachlorophyl, but containing zinc instead of magnesium (Marchlewski, Biochem. Zeitsch. 1909, 16, 3).

Zinc *p*-**haemoglobin** $C_{758}H_{1139}Zn_2S_3FeO_{218}$ formed by shaking blood with zinc-dust or by the action of zinc salts on crystalline blood pigment, is a non-toxic compound, which has been recommended for use in the treatment of chlorosis (Grahe, Chem. Zentr. 1894, i. 636).

Zinc chloride forms stable double salts with diazo or tetrazo compounds of amino-azo or diamino-azo bodies which can be employed in dyeing (Eng. Pat. 1645; J. Soc. Chem. Ind. 1897, 40).

The diazo solution is prepared in aluminium or enamelled iron vessels, the requisite amount of zinc chloride is then added gradually with continual stirring. The double salt is formed as a voluminous precipitate, which, after settling, is filtered. When mixed with cold tragacanth thickening these double salts may be preserved unchanged for several days.

The goods prepared with sodium β-naphthol, to which sodium acetate is added, are printed with this paste, and then passed through a weak hydrochloric acid bath, washed, and soaped. The most satisfactory results have been obtained with α-naphthylamine hydrochloride, which yields a bright cardinal of a yellowish tone (Smirnoff and Rosenthal, Färber-Zeit. 7, 442).

Zinc chloride also forms double compounds, with fatty acids, with aliphatic compounds having a basic character, with aromatic bases containing one benzene nucleus, and with such compounds as piperidine, pyridine, and picoline (Lachowicz and Bandrowski, Monatsh. 1888, 9, 510; Bose, Amer. Chem. J. 1898, 20, 246; Bömer, Zeitsch. Nahr. Genussm. 1898, [viii.] 541).

The *zinc alkyl compounds* are formed, for the most part, by the action of the required alkyl iodide on zinc (Frankland and Duppa, Annalen, 1864, 130, 118; Gladstone and Tribe, Chem. Soc. Trans. 1879, 569; Fileti and Cantalupo, Gazz. chim. ital. 22, ii. 387; Ipatieff, J. pr. Chem. 1896, [ii.] 53, 257; Simonowitsch, Chem. Zentr. 1899, i. 1066; Worobéeff, *ibid.* 1067; Bohm, *ibid.* 1067; Ragosin, J. Russ. Phys. Chem. Soc. 1892, 24, 549; Lachman, Amer. Chem. J. 1900, 24, 31; J. Amer. Chem. Soc. 1901, 23, 897; Granichstädten and Werner, Monatsh. 1901, 32, 315; Haase, Ber. 1893, 26, 1052).

Zinc methyl is a colourless liquid, b.p. 46°, m.p. −40°, sp.gr. 1·386 at 10·5°, inflammable in air and decomposed by water.

Zinc ethyl is a colourless liquid, b.p. 118°, m.p. −28°, sp.gr. 1·182 at 18°; it has similar properties to the methyl compound.

The zinc alkyl compounds are employed in the synthesis of many organic compounds (Grigorovitch and Pawloff, J. Russ. Phys. Chem. Soc. 1891, 23, 159; Bewad, *ibid.* 1900, 32, 420; Tichwinsky, *ibid.* 1903, 35, 155; Gwosdoff, *ibid.* 339; Saytzeff, *ibid.* 1907, 39, 1232; Lachman, Amer. Chem. J. 1896, 18, 372; Bamberger and Tichwinsky, Ber. 1902, 35, 4179; Menschikoff, J. pr. Chem. [ii.] 36, 347; Bewad, *ibid.* 1907, [ii.] 76, 62; Saytzeff, *ibid.* 98; Blaise and Maire, Ann. Chim. Phys. 1908, [viii.] 15, 556; Compt. rend. 1907, 145, 73; *ibid.* 1909, 148, 489; Blaise, *ibid.* 1907, 145, 1285; Blaise and Herman, *ibid.* 1908, 146, 479; Delacre, Bull. Soc. chim. [ii.] 48, 784; Wagner, *ibid.* [ii.] 42, 330).

Zinc ethoxide $Zn(OEt)_2$ is formed by the action of zinc methyl on ethyl alcohol in an atmosphere of carbon dioxide, or, better, nitrogen or hydrogen. It is a white powder which cannot be distilled, is insoluble in ordinary solvents and readily absorbs moisture from the air. Zinc *iso*butyl oxide is similarly prepared by employing the corresponding alcohol (Tolkatscheff, J. Russ. Phys. Chem. Soc. 1901, 33, 469).

Other zinc organic compounds have been described by Moitessier (Bull. Soc. chim. 1899. iii. 21, 336); Werner (Zeitsch. anorg. Chem. 1899, 21, 201); Rosenheim and Meyer (*ibid.* 1906, 49, 13); Grossmann and Schück (*ibid.* 50, 1, 21); Ebler and Schott (J. pr. Chem. 1909, [ii.] 79, 72); also in D. R. P. 86148.

For methods of detecting and estimating zinc *v.* Analysis.

ZINC BLENDE *v.* Blende.

ZINC-DUST (VALUATION OF). Klemp has devised a process for the above purpose which depends on the power of zinc to reduce potassium iodate to potassium iodide in an alkaline solution. When the solution is afterwards acidified, iodine is liberated by the interaction of the iodic and hydriodic acids, and is distilled off from the mixture into potassium iodide solution, and titrated with thiosulphate. The details of the method are as follows:—

0·5–1 grm. of the well-mixed zinc-dust is weighed in a tube, and poured into a 200 c.c. stoppered flask, the tube being again weighed. For every 0·1 grm. of zinc present, 10 c.c. of a solution of alkali (containing 370 grms. of potassium hydroxide, or 300 grms. of sodium hydroxide per litre), and 3 c.c. of a solution of potassium iodate (containing 15·25 grms. of potassium iodate per 300 c.c.) are measured into a beaker, and then poured into the flask. Some glass beads are added, and the flask stoppered and shaken for 5 mins. in the cold, no advantage being gained by heating it. Its contents are then washed into a 250 or 500 c.c. flask, and made up to the mark with water. 100 c.c. are now pipetted into the retort of a Topf's apparatus (Zeitsch. anal. Chem. 26, 293), dilute sulphuric acid is added, and the apparatus filled with carbon dioxide. A solution of potassium iodide is placed in the receiver, and the retort heated, at first gently, and then more strongly till the contents are perfectly colourless. The stream of carbon dioxide is continued throughout the distillation, which generally occupies about 20 mins. The solution of iodine in potassium iodide is then transferred from the receiver into a flask, a standard solution of sodium thiosulphate added in slight excess, and the excess titrated back with weak standard iodine solution, starch being used as an indicator. After correcting for the excess, the quantity of zinc is calculated from the amount of thiosulphate used.

Klemp finds that the addition of powdered lead and iron to the zinc makes very little difference in the quantity of zinc found by this process, the results being a little lower in the presence of these metals.

The results by this method agree well with those obtained by Fresenius's method, but are generally higher than those obtained by Drewson's and lower than those obtained by Topf's method (G. Klemp, Zeitsch. anal. Chem. 29, 253–266; J. Soc. Chem. Ind. 9, 968). For a volumetric method, depending on the amount of hydrogen evolved by the action of an acid on zinc-dust, v. *ibid.* 5, 145, 1886.

ZINC FLOWERS. Zinc oxide produced by combustion; *v.* Zinc.

ZINC GREEN, *Cobalt green,* or *Rinmann's green*; *v.* Cobalt; also Pigments. This term is also applied to a mixture of zinc yellow and Prussian blue.

ZINCITE. Native zinc oxide ZnO, crystallising in the hexagonal system. The crystals, which are of rare occurrence, possess the same degree of symmetry (hemimorphic-hemihedral) and very nearly the same angles as those of wurtzite (ZnS) (*q.v.*). The mineral is usually found as lamellar cleavage masses (there being a perfect basal cleavage), which are opaque to translucent and deep-red, rarely orange-yellow, in colour. The streak is orange-yellow; sp.gr. 5·6. Manganous oxide (3–6 p.c.) replaces part of the zinc, and there is often a little ferric oxide present. Zincite is known only from the zinc mines at Franklin Furnace and Sterling Hill in Sussex Co., New Jersey, but it occurs there in considerable abundance, and is mined, together with franklinite and willemite, as an ore of zinc. Fragments of the mineral have also been used in the wave detectors of wireless telegraphy installations. White or yellowish crystals of hexagonal zinc oxide have often been observed in zinc furnaces, and sometimes in iron furnaces. L. J. S.

ZINCOPYRIN. Trade name for phenyldimethyl-pyrazolone zinc chloride

$$(C_{11}H_{12}N_2O)_2\cdot ZnCl_2$$

first obtained by Schuyten. Shining scales, m.p. 156°. Readily soluble in water, alcohol, and chloroform. Used in the treatment of inoperable carcinoma of the uterus.

ZINC SPAR. Syn. with calamine; *v.* Zinc.

ZINC VITRIOL. *Zinc sulphate v.* Zinc.

ZINC WHITE *v.* Zinc.

ZINC YELLOW, or *Buttercup yellow* and *Zinc chromate, v.* Chromium.

ZINKENITE or **ZINCKENITE.** *Lead sulphantimonite v.* Antimony.

ZINNWALDITE *v.* Mica.

ZINOL *v.* Synthetic drugs.

ZIRCON. Native zirconium silicate $ZrSiO_4$, crystallising in the tetragonal system and homœomorphous with cassiterite and rutile. A little ferric oxide (0–3 p.c.) and sometimes thoria are present. The mineral varies considerably in its characters and appearance; and further, several altered and hydrated forms are distinguished by special names (*malacon, cyrtolite, oerstedite,* &c.). The transparent gem-varieties show a wide range in colour; brownish-yellow and red specimens are known as *hyacinth* (or jacinth), and yellowish and green as *jargon* (or jargoon). The colour can usually be changed by heat, and some brownish-yellow stones are completely decolorised. With their brilliant adamantine lustre, these artificially decolorised stones ('Matura diamonds,' from Matura in Ceylon) may be mistaken for diamond. The hardness is 7½. The mineral is remarkable in showing a wide range in sp.gr. (4·0–4·7), and in optical characters, and these sometimes undergo a marked change when the crystals are heated to redness. These differences and changes suggest the existence of three modifications of zircon, which may occur as intergrowths in the zoned crystals (L. J. Spencer, Min. Mag. 1904, 14, 48).

Zircon occurs as a primary constituent of many igneous rocks, but, as a rule, only as minute crystals. Being heavy, hard, and resistant to weathering agencies, it collects in the beds of streams. Most of the gem material is obtained from gem-gravels in Ceylon and Australia. Rough and opaque zircon has been mined in considerable quantity in Henderson and Buncombe counties, North Carolina, and in Brazil. It is employed as a source of zirconia, used in incandescent gas-lighting and in electric arc-lamps. L. J. S.

ZIRCONIUM. Sym. Zr. At.wt. 90·6. Zirconia, the oxide of this metal, was identified in 1879 by Klaproth, who obtained it from the zircon of Ceylon, and this observation was confirmed by Guyton and Vauquelin. Zirconium is sometimes included in the group of rare earth metals, although in its quadrivalency, and in the amphoteric nature of its oxide, it is distinctly unlike the typical members of this series.

Occurrence.—As the main constituent in zircon and malacon, which are found as accessory minerals in many metamorphic and igneous rocks (granites, syenites, elæolite-syenites, basalts, amphibolites), and in baddeleyite (brazilite). Large deposits of zirconia earth have been found in São Paulo, Brazil (*cf.* Fletcher, Min. Mag. and J. Min. Soc. 1893, 10, 148; Hussak and Reitinger, Zeitsch. Krist. 1903, 37, 567; Wedekind, Zeitsch. angew. Chem. 1908, 21, 2270; Ber. 1910, 43, 290). Brazilian zirconia deposits are feebly radioactive, and on ignition evolve a gas containing argon and helium (Zeitsch. Elektrochem. 1908, 14, 585; Ann. Chim. Phys. 1898, [vii.] 13, 433; Chem. Soc. Trans. 1906, 89, 1568; 1908, 93, 350). The following minerals contain a high percentage of zirconium: *zirkelite* (zirconium titanate with thoria and rare earths), *eudialite* (*eukolite*), *elpidite, katapleite* (zirconium double silicates of sodium and calcium), *polymignite* (Norway, a complex zircono-silicate, with titanium and tantalum oxides, columbium oxide, thoria, and the rare earths). Zirconium is a minor constituent of all rare-earth minerals (*v.* Cerite earths), and is found also in *pitchblende, columbite,* and *tantalite.*

Separation and purification of zirconia.

1. *Fusion with sodium carbonate or hydroxide.* The native silicate (zircon) disintegrated by heating and dropping into water, is extracted with hydrochloric acid to remove metallic impurities (iron, &c.) and fused with sodium carbonate or hydroxide (4 parts) containing 10 p.c. of sodium fluoride. When extracted with water the fused mass leaves an insoluble crystalline precipitate of sodium zirconate, which is dissolved in hydrochloric or sulphuric acid, and the zirconium hydroxide precipitated by ammonia (Monatsh. 1885, 6, 531; Chem. Soc. Trans. 1889, 58, 705; Amer. Chem. J. 1892, 5, 551).

2. *Decomposition with hydrofluoric or sulphuric acid, or their acid salts.* Zircon is exposed to the vapour of hydrogen fluoride or heated with potassium hydrogen fluoride, and,

in the latter case, the product, when boiled with hydrofluoric acid, leaves a deposit of potassium silicofluoride, whilst the more soluble potassium zirconofluoride crystallises out on concentrating the solution (J. 1859, 677; Ann. Chim. Phys. 1860, [iii.] 60, 257). Zircon can also be decomposed with hot concentrated sulphuric acid, or with fused potassium hydrogen sulphate (Ber. 1870, 3, 58; Annalen, 1876, 181, 232).

3. *Reduction with carbon or calcium carbide.* Crude zirconium carbide obtained by heating an intimate mixture of zircon and carbon in the electric furnace is heated in chlorine, and the resulting chloride dissolved in concentrated hydrochloric acid; the crystalline oxychloride, which separates from this solution, is decomposed by ammonia. A mixture of zircon, calcium oxide, and carbon is heated in the electric furnace (1030 ampères, 50 volts for 7 mins.); the product, when extracted with water and dilute hydrochloric acid, is decomposed by chlorine at 300°, yielding zirconium chloride (Compt. rend. 1893, 116, 1428; 1896, 122, 651; Zeitsch. anorg. Chem. 1902, 33, 81; Ber. 1902, 35, 3929; Chem. Zeit. 1907, 31, 654).

4. *Other methods of purification.* Zirconia is freed from silica by heating with potassium hydrogen fluoride when the latter oxide is eliminated as volatile silicon fluoride. Crude zirconia is rendered soluble by heating with strong sulphuric acid or by fusion with sodium hydrogen sulphate. Treatment of the product with warm water leads to the separation of crystalline basic sulphate (Ber. 1904, 37, 2024; *cf.* Zeitsch. anorg. Chem. 1905, 45, 155). Zirconia is freed from iron by crystallising the oxychloride from strong hydrochloric acid (Chem. Soc. Trans. 1889, 58, 705; Amer. Chem. J. 1891, 5, 551; J. Amer. Chem. Soc. 1894, 16, 469). Ferruginous zirconium hydroxide, when dissolved in hydrochloric acid and boiled with sodium thiosulphate, gives the pure hydroxide mixed with sulphur. The addition of ammonia and ammonium sulphide to an iron and zirconium solution precipitates zirconium hydroxide, and ferrous sulphide, the latter being dissolved out with sulphurous acid. In the presence of tartaric acid the foregoing solution yields ferrous sulphide alone on adding ammonium sulphide; the concentrated filtrate, when mixed with excess of hydrogen peroxide, furnishes pure hydrated zirconium peroxide (Zeitsch. anorg. Chem. 1902, 33, 81). Brazilian zirconia earth (74–94 p.c. ZrO_2) is dissolved in mineral acid, and the iron and titanium removed from the dilute solution with ammonia and ammonium carbonate, the liquid being warmed until it gives no coloration with sulphuric acid and hydrogen peroxide. The acidified filtrate is boiled to expel carbon dioxide and the zirconium hydroxide precipitated with ammonia. The mineral may also be heated with magnesium in an atmosphere of hydrogen; the product extracted successively with ammonium chloride, hydrochloric acid, and potassium hydroxide to remove magnesium, iron, and silicon; the residue is heated in hydrogen, and then in chlorine or bromine, when zirconium chloride or bromide sublimes (Wedekind, Ber. 1910, 43, 290).

Zirconium is isolated only with difficulty owing to the readiness with which it combines with oxygen, nitrogen, carbon, silicon, &c. When reduced with carbon in the electric furnace zirconia yields zirconium containing either oxide or carbide, depending on the proportion of the reagents (Troost, Compt. rend. 1893, 116, 1227; Moissan, *ibid.* 1222; Greenwood, Chem. Soc. Trans. 1908, 93, 1483). Boron or silicon reacts with zirconia in the electric furnace, but the product is contaminated with boride Zr_3B_4 or silicide. Amorphous zirconium (95–96 p.c. Zr) is obtained by heating potassium zirconofluoride with sodium under fused potassium chloride in closed iron vessels, the product being extracted with alcohol and then with hydrochloric acid. By reducing the double fluoride with aluminium at the temperature of melting iron impure metallic zirconium (98 p.c.) is produced, but in the electric furnace an alloy of this element and aluminium is formed. Reduction of the double fluoride with magnesium in the electric furnace gives crystalline zirconium (94 p.c.), but sometimes contaminated with nitride. The product, containing 97–98 p.c. of zirconium, is pressed into rods, and then used as the terminals of an electric arc operating in hydrogen under diminished pressure; fusion takes place, and 99·8 p.c. zirconium is obtained. This resembles white cast iron, and has a hardness 7–8, sp.gr. 6·40 at 18°, sp.ht. 0·0804, and heat of combustion (1 grm.)=1958·7 cals. The amorphous variety, which is a black powder, and a bad conductor of electricity, is readily oxidisable, whereas the crystalline modification yields zirconia only at white heat. An intermediate oxide Zr_2O_3 has been recognised, which is slowly oxidised to the dioxide. Zirconium is attacked by hydrogen fluoride or by *aqua regia*, and at red heat by hydrogen chloride or chlorine, but is not appreciably affected by sulphuric, hydrochloric, or nitric acid; it is oxidised by fused potassium hydroxide or nitrate (Zeitsch. anorg. Chem. 1905, 45, 385; 1910, 65, 248; Zeitsch. Elektrochem. 1904, 10, 331; Annalen, 1910, 371, 367). Zirconium has also been prepared by reducing zirconia with metallic calcium (Eng. Pat. 23215, 1909).

Zirconia (*Zirconium dioxide*) ZrO_2 occurs native as *baddeleyite* in monoclinic forms, not isomorphous with cassiterite or rutile. When crystallised from borax a quadratic form of zirconia is produced isomorphous with rutile. Ignition of zirconium hydroxide, sulphate, oxalate, or nitrate yields the dioxide as a hard white powder. The density varies with the mode of preparation, unfused specimens having sp.gr. 5·4824 at 18·5°, whilst fused rods vary from 5·48–5·75. Zirconia is extremely infusible and non-volatile, although it has been melted and vaporised in the electric furnace (360 ampères, 70 volts). The vapour condenses to a fine powder which scratches glass. The sp.ht. of zirconia is 0·1076; it is a bad conductor of heat, and has a linear coefficient of expansion=0·00000084, near to that of fused quartz (Nilson and Petterson, Compt. rend. 1880, 91, 232; Moissan, *ibid.* 1893, 116, 1222; Lehman, Dissert. Techn. Hochsch. München. 1908; Zeitsch. anorg. Chem. 1909, 65, 178).

The solubility of zirconia in mineral acids depends on the temperature of ignition; after slight ignition it dissolves readily, but after strong ignition it becomes practically insoluble.

although it is attacked by hydrofluoric and concentrated sulphuric acids.

When heated in the oxy- coal gas flame zirconia becomes brilliantly incandescent, so that it may replace for certain special purposes the lime of the Drummond light, and it has been thus employed by Linnemann and others in spectroscopy and microphotography. It has received an important technical application in the Nernst lamp in which the incandescent body is composed chiefly of zirconia (85 p.c.), together with oxides (15 p.c.) of the yttrium series. This material conducts only at high temperatures, so that it requires to be first heated before the electric current can be transmitted.

Strongly ignited zirconia is very stable towards acids and alkalis, and as it is not fractured by sudden changes of temperature, it may be employed for crucibles in which platinum and quartz can be melted. Refractory vessels have also been made from zirconia mixed with 10 p.c. of magnesia or clay, phosphoric acid being employed as a binding material (Zeitsch. anorg. Chem. 1909, 65, 178).

Zirconia crucibles are moulded from the plastic mass made by kneading together gelatinous zirconium hydroxide and artificial or purified native zirconia, a little starch being added to keep the mass firm while drying. After 2 days the crucibles are gently heated at 50°–100°, and the temperature then raised gradually to 2000°–2300°. These crucibles are not affected by fused alkalis or alkaline bisulphates (Bayer, Zeitsch. angew. Chem. 1910, 23, 488).

Zirconium hydroxide behaves as an amphoteric hydroxide, its compounds with the alkalis undergoing considerable hydrolysis in aqueous solution. The zirconates are produced either by adding zirconium salts (*e.g.* nitrate) to concentrated alkali solution, or by fusing zirconia with the alkaline hydroxides or oxides. The substances obtained by the wet process are probably adsorption products rather than definite chemical compounds, for prolonged washing gradually removes the alkali from the colloidal mass. The fusion process leads to *meta*zirconates $CaZrO_3$, Na_2ZrO_3, and Li_2ZrO_3, but even these products vary somewhat in composition. Other types, such as $Li_2Zr_2O_5$ have been described. When zircon (zirconium silicate) is fused with alkalis the crystalline silicozirconates are obtained, *e.g.* $K_2O(SiO_2,ZrO_2)$ and $CaO(SiO_2,ZrO_2)$, the latter being isomorphous with titanite (Ouvrard, Compt. rend. 1891, 112, 1444; 113, 80).

Colloidal insoluble zirconium hydroxide (hydrogel) is produced by boiling solutions of zirconium oxychloride (Ruer, Zeitsch. anorg. Chem. 1905, 43, 282; van Bemmelen, *ibid.* 1906, 49, 125). The hydrosol modification is prepared by adding ammonia to aqueous zirconium nitrate or by dissolving freshly-precipitated zirconium hydroxide in this solution (Müller, *ibid.* 1907, 52, 316).

Zirconium peroxide is produced as a gelatinous precipitate by adding ammonia to aqueous zirconium sulphate containing hydrogen peroxide; or by the electrolysis of an alkaline sodium chloride solution in which zirconium hydroxide is suspended. The product is probably $Zr(OH)_3{\cdot}O_2H$, a hydrated form of ZrO_3 (Pissarjewski, Zeitsch. anorg. Chem. 1899, 25, 378; 1900, 31, 359; *v.* Bailey, Chem. Soc. Trans. 1886, 49, 149, 481; 1889, 58, 705).

The alkali *perzirconates* $Na_4Zr_2O_{11},9H_2O$ and $K_4Zr_2O_{11},9H_2O$ are precipitated by alcohol, from cold aqueous alkaline solutions of the hydrated peroxide and hydrogen peroxide.

Zirconium hydride ZrH_2, black powder, produced from metallic zirconium and hydrogen at red heat, burns in oxygen under ordinary pressure to the sesquioxide Zr_2O_3, and in the compressed gas to zirconia.

Zirconium fluoride ZrF_4, anhydrous, sp.gr. 4·4333 at 16°, sparingly soluble in cold water, hydrolysed on warming, prepared by heating zirconia with ammonium hydrogen fluoride. The hydrate $ZrF_4,3H_2O$, triclinic crystals, obtained by dissolving zirconia in hydrofluoric acid.

Zirconofluorides. These double fluorides are of especial interest because of their use in the purification of zirconium compounds and in the isolation of the element itself, and also because they illustrate the family relationship subsisting between zirconium and the other elements (silicon, titanium, and tin) of the fourth periodic group. Moreover, the existence of these well-defined crystallisable double salts distinguishes zirconium from the rare earth metals. They are produced by dissolving zirconium fluoride or oxide together with a metallic oxide or carbonate in aqueous hydrogen fluoride. The zirconofluorides corresponding with the general formula $R^I_2ZrF_6$ are the most stable, although other forms exist (Marignac, Compt. rend. 1860, 50, 952; Wells and Foote, Zeitsch. anorg. Chem. 1896, 10, 434; Amer. J. Sci. 1897, [iv.] 3, 466).

Potassium zirconofluoride K_2ZrF_6, rhombic prisms, is the most important compound of this series; 100 parts of water dissolve 0·78 part of the salt at 2°, and 25·0 parts at 100°.

Zirconium chloride $ZrCl_4$ can only be obtained pure by dry processes owing to its great tendency to undergo partial hydrolysis. The following methods have been employed.

(i.) The action of chlorine and sulphur chloride on heated zircon (Matignon and Bourrion, Compt. rend. 1904, 138, 631). Formerly carbon was used as the reducing agent instead of sulphur chloride. The chlorides of silicon and titanium are also produced in this process, but are readily separated owing to their greater volatility.

(ii.) The interaction at 300° of zirconium carbide, and chlorine (Wedekind, Zeitsch. anorg. Chem. 1902, 33, 81).

(iii.) Sublimation in chlorine of the product obtained by heating zirconia and phosphorus pentachloride in sealed tubes at 190° (Smith and Harris, J. Amer. Chem. Soc. 1895, 17, 448; *v.* Venable, *ibid.* 1894, 16, 469; Annalen, 1887, 239, 253; Compt. rend. 1865, 61, 109; 1872, 75, 1819; 1887, 104, 113; Ber. 1887, 20, 683).

The anhydrous chloride is a white crystalline sublimate fuming in moist air, reacting energetically with water, and combining with 1–8 molecules of dry ammonia (J. Amer. Chem. Soc. 1898, 20, 815, 839, 843; Ber. 1905, 38, 2611). It forms additive compounds with phosphorus pentachloride and sulphur tetrachloride, and forms double chlorides $B_2H_2ZrCl_6$ with alcoholi pyridine and quinoline hydrochlorides (Ber. 1905, 38, 812).

Zirconium oxychloride $ZrOCl_2,8H_2O$, colourless tetragonal prisms, the most characteristic product of hydrolysis of the preceding compound, is somewhat sparingly soluble in concentrated hydrochloric acid, and is on this account utilised in the separation of zirconium. The addition of ether to an alcoholic solution of this oxy-salt produces a precipitation of *metazirconium chloride* $Zr_2O_3Cl_2$, corresponding with metastannic chloride. This product, which is practically insoluble in strong hydrochloric or nitric acid, dissolves in water to an opalescent colloidal solution, and this liquid on dialysis furnishes *metazirconic acid* (J. pr. Chem. 1875, [ii.] 2, 219; Ber. 1907, 40, 803; Zeitsch. anorg. Chem. 1904, 42, 87; 1905, 43, 282; 46, 456).

Zirconium bromide $ZrBr_4$, crystalline white powder, and **zirconium iodide** ZrI_4, yellowish-brown powder, are prepared by passing over heated zirconium or its carbide a stream of bromine vapour or hydrogen iodide respectively (Ber. 1904, 37, 1135; 1905, 38, 2611). The corresponding oxy-salts $ZrOBr_2,8H_2O$ and $ZrOI_2,8H_2O$ are produced by hydrolysing the foregoing bromides.

Zirconium carbide ZrC, hard metallic mass, scratching quartz but not ruby, is obtained by heating an intimate mixture of zirconia and carbon in the electric furnace (Moissan and Lengfeld, Compt. rend. 1896, 122, 651). A mixture of calcium carbonate, carbon, and zircon gives a similar result after extracting the fused mass with water and dilute hydrochloric acid. The carbide is also produced by heating native zirconia with carbon, using a current of 600 ampères (Wedekind, Ber. 1902, 35, 3929; Chem. Zeit. 1907, 31, 654). The carbide is an excellent conductor of electricity, and a mixture of 90 parts with 10 parts of ruthenium made into filaments has been suggested for use in incandescent lamps. When heated in nitrogen the carbide furnishes *zirconium nitride* Zr_2N_3 (*v.* Zeitsch. anorg. Chem. 1905, 45, 385).

Zirconium silicide $ZrSi_2$, iron-grey rhombic crystals, sp.gr. 4·88 at 22°, is prepared by the aluminothermic process (200 parts aluminium, 250 parts sulphur, 180 parts sand, and 40 parts potassium zirconofluoride covered with a thin layer of magnesium as priming). It is not attacked by acids except hydrofluoric acid, and is only decomposed by caustic potash at moderately high temperatures (Compt. rend. 1906, 143, 224; *v.* Ber. 1902, 35, 3929). A colloidal variety of zirconium silicide has been observed (Zeitsch. Chem. Ind. Kolloide, 1910, 7, 249).

Zirconium sulphates (1) '*neutral*' *sulphate* $Zr(SO_4)_2.4H_2O$ or *zirconylsulphuric acid*

$$ZrO(SO_4)_2H_2,3H_2O,$$

rhombic crystals from sulphuric acid solution, differs considerably in its properties from the oxychloride. The zirconium present is not precipitated as oxalate by oxalic acid or its soluble salts, and the precipitation which occurs with the aqueous chloride is prevented by the addition to this solution of sulphuric acid or an alkali sulphate. In hydrochloric acid solutions of the chloride the zirconium ion passes to the cathode on electrolysis, but in solutions of the sulphate the zirconium passes to the anode in the complex anion $(ZrOSO_4,SO_4)^{II}$ (*v.* Hauser, Zeitsch. anorg. Chem. 1905, 45, 185; 1907, 53, 74; 54, 196; J. pr. Chem. 1907, [ii.] 76, 363; Ruer, Zeitsch. anorg. Chem. 1904, 42, 87; 1905, 46, 449).

(2) *Basic sulphates* (i.) 4:3-*Basic sulphate* $4ZrO_2,3SO_3,14H_2O$, microscopic birefringent needles, separates at 39·5° from a solution of 10·2 molecules of $Zr(SO_4)_2$ in 1000 molecules of water. When dried at 300° the anhydrous compound $4ZrO_2,3SO_3$ is obtained (Ber. 1904, 37, 2024; Zeitsch. anorg. Chem. 1910, 67, 369).

(ii.) 2:3-*Basic sulphate* $2ZrO_2,3SO_3,5H_2O$ is obtained in a crystalline form by boiling concentrated solutions of zirconium sulphate; in cold water it gradually changes into the preceding basic salt.

(3) *Acid sulphate* $Zr(SO_4)_2,H_2SO_4,3H_2O$, monoclinic prisms or needles, is a very hygroscopic salt produced by adding strong sulphuric acid to an aqueous solution of zirconylsulphuric acid (Zeitsch. anorg. Chem. 1907, 54, 196).

(4) *Complex sulphates.* These are of two types $Zr_2O_3(SO_4R')_2,xH_2O$ and $Zr(SO_4R')_4,xH_2O$, where R is an alkali metal; the former are produced by adding an alkali sulphate to a solution of zirconium oxide in aqueous alkali disulphate and the latter by dissolving zirconium hydroxide in a boiling saturated solution of alkali disulphate (Ber. 1907, 40, 803, 810).

Zirconium nitrate $Zr(NO_3)_4,5H_2O$, colourless hygroscopic crystals, which may also be regarded as *zirconylnitric acid* $ZrO(NO_3)_4H_2,4H_2O$. Aqueous solutions of this compound yield on evaporation *basic nitrates* $ZrO(NO_3)_2,2H_2O$ and $Zr_2O_3(NO_3)_2,5H_2O$.

Zirconium oxalate is a basic salt, *zirconyl oxalate* $ZrO(C_2O_4),H_2O$ or $4H_2O$, white powder, hydrolysed by water. By saturating aqueous oxalic acid with zirconium hydroxide an *acid oxalate* $Zr(OH)(C_2O_4H)_3,7H_2O$ is obtained in large prisms. Double oxalates are produced by dissolving zirconium hydroxide in solutions of the alkali hydrogen oxalates (Mandl, Zeitsch. anorg. Chem. 1903, 37, 252; *v.* Venable and Baskerville, J. Amer. Chem. Soc. 1897, 19, 12).

Zirconium acetylacetonate

$$Zr[CH(CO{\cdot}CH_3)_2]_4,10H_2O$$

crystallises from an aqueous solution of zirconium nitrate and acetylacetone to which sodium carbonate is cautiously added; it is dehydrated by repeated crystallisation from absolute alcohol when it separates in needles. G. T. M.

ZYMASE *v.* FERMENTATION.

ZYMIN *v.* SYNTHETIC DRUGS.

ZYMURGY. A term used to denote that section of applied chemistry which treats of the scientific principles of those arts in which fermentation is employed—*e.g.* preparation of yeast, vinegar, wine, beer, alcohol.

THE END
