---Abstract-----

In Part 1 of this report, we introduced fundamental aspects of the use of artificial light in horticulture, giving an outline of a number of different artificial light sources and discussing recent research trends (such as the use of microwave-powered lamps, light-emitting diode and laser diode devices) in Japan.

Discipline: Agricultural facilities/Crop production/Horticulture

Additional key words: artificial light source, supplemental lighting, plant factory

---Introduction-----

Most terrestrial plants grow by selective absorption of natural light from the sun. In plant factories and indoor living spaces, artificial light is necessary as a source of light energy. Therefore, it is necessary to develop technologies to control the light environment and provide effective and economical irradiation for plants. Part 1 of this report covers basic issues related to plant growth and light.

---Wavelengths for effective plant growth-----

Solar radiation is subject to extensive scattering and absorption by the atmosphere before it reaches the surface of the earth. Direct solar radiation has wavelengths ranging from 300 to 3,000 nm, and is divided into 3 bands: ultraviolet radiation, visible radiation and infrared radiation. The wavelengths of visible radiation for humans are in the range from 380 to 780 nm, and the peak of the visibility curve (photopic vision) is at 555 nm. Similarly, plants have a range of wavelengths that are physiologically effective. There are 2 types of effective radiation for plants: physiologically active radiation and photosynthetically active radiation (PAR). These 2 types of radiation, ranging from 300 to 800 nm, are physiologically effective in photosynthesis, pigment biosynthesis, photoperiodism, phototropism and photomorphogenesis⁸).

Physiologically active radiation is divided into 5 wavebands: near ultraviolet light (UV) 300-400 nm, blue light (B) 400-500 nm, green light (G) 500-600 nm, red light (R) 600-700 nm, and far-red light (FR) 700-800 nm ([Fig. 1\(20KB\)](#)). Photosynthesis, which uses PAR (waveband 400 to 700 nm), requires an energy source with high intensity. The units of PAR radiation are expressed as total photon fluxes in this waveband, since this radiation induces chemical reactions. The total energy emitted from the light source is designated as photosynthetic photon flux (PPF). On the other hand, the energy actually received by plants is designated as photosynthetic photon flux density (PPFD), and its S. I. units are expressed as $\frac{1}{4}\text{mole}\cdot\text{m}^{-2}\cdot\text{sec}^{-1}$. Although quantum sensors are preferable for measuring the photon flux, because of their high cost, radiation is often measured by PPFD with conversion factors for illuminance.

---Light intensity suitable for photosynthesis-----

Light intensity suitable for photosynthesis depends on the light adaptation and acclimation properties of the plants, which in turn depend on the environment of their place of origin. The effect of the light intensity can be estimated to some extent by changes in morphology. Generally, plants which grow in the shade or at low light intensities (shade plants) have large, and thin leaves. Inside their leaves, parenchymatous cells do not adequately develop, resulting in an increase of the development of the grana structure and of the chlorophyll content in chloroplasts. The same morphological changes also occur with exposure to red light. On the other hand, plants which grow at high light intensities (sun plants) have thick leaves. Inside their leaves, parenchymatous cells are remarkably developed, resulting in a lower development of the grana structure. However, many enzymes important for photosynthesis can be observed. The same morphological changes occur with exposure to blue light. These differences in the morphology can also be observed in a single plant. Leaves that grow at low light intensities are referred to as shade leaves, and leaves that grow at high light intensities are referred to as sun leaves. Accordingly, leaves in the upper and lower parts of trees have different photosynthetic capabilities⁹⁾. Morphological adaptation through changes of the light environment is related to the speed of photosynthesis. Plants growing at high light intensities (for example, watermelons, tomatoes, cucumbers, melons and C₄ plants) have high saturation points, and they show a maximum photosynthetic rate at the light saturation point. Therefore, a large amount of light energy is required to cultivate plants that grow better at high light intensities. [Fig.2\(21KB\)](#) was obtained by measuring the absorption and release of carbon dioxide during photosynthesis, and indicates the light adaption capability for photosynthesis. When the light intensity is low, the amount of carbon dioxide released by plant respiration is higher than the amount of that absorbed for photosynthesis, resulting in a net release of carbon dioxide. As the light intensity increases, absorbed and released amounts of carbon dioxide change and reach an equilibrium at point A where a net release of carbon dioxide is no longer observed. This point is referred to as the compensation point. If the light intensity increases further, the amount absorbed reaches point B. This point is the saturation point. A suitable light intensity can be determined somewhere between these points A and B according to the particular requirements. On the other hand, since plants that grow under a low light energy (for example, lettuce, *Cryptotaenia japonica*, herbage crops, and most of the indoor ornamental plants) have low saturation and compensation points, it is relatively easy to cultivate them, to provide them with supplemental lighting and to maintain growth with artificial lighting. [Table 1\(77KB\)](#) shows the saturation and compensation points of major crops, and [Table 2\(109KB\)](#) shows the saturation and compensation points of ornamental plants. Indoor ornamental plants, most of which are derived from jungle undergrowth, can maintain growth at a relatively low light intensity.

In cultivation facilities for plants utilized for salad, and lettuce in closed-system type plant factories in Japan, a light intensity of about 300 to 400 $\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$ is used. Factories where a higher light intensity is needed are hybrid type plant factories where supplemental lighting of 100 to 150 $\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$ is provided. For indoor ornamental plants, supplemental lighting of 10 to 50 $\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$, depending on the variety, has been gradually employed.

---Photosynthesis action spectrum-----

The efficiency of plant photosynthesis is not the same throughout the 400 to 700 nm waveband. Just as human eyes have visual curves, plants have sensitivity curves over a wide range. Plants select effective wavelengths from white light and utilize them. [Fig. 3\(21KB\)](#) shows the photosynthesis action spectra described by Inada(1976)⁷⁾. Curve 1 shows the average values for 26 species of herbaceous plants, and curve 2 shows the average values for arboreous plants. [Fig. 4\(21KB\)](#) shows the photosynthesis action spectra described by McCree(1972)¹⁴⁾. Curve 1 shows the average values for 20 species of plants in chambers, and curve 2 shows the average values for 8 species of plants in fields. The sample plants used are listed in [Table 3](#). Each of these 4 photosynthesis action spectra has a large peak composed of 2 peaks at about 675 and 625 nm in the red light region, and a small peak between 440 and 450 nm. All 4 photosynthesis action spectra show that red light has a strong action and blue light a weak action. [Fig. 5\(18KB\)](#) shows the average values for the 4 photosynthesis action spectra, and is used to evaluate light sources for plant growth.

Table 3. Plant materials used for the determination of photosynthesis action spectra

Plants Species

Inada 1. (26 species of herbaceous plants, 1976)	rice, maize, wheat, barley, oat, soybean, peanut, kidney, bean, pea, cabbage, turnip, radish, tomato, eggplant, cucumber, squash, lettuce, garland, chrysanthemum, spinach, onion, sugar beet, sweet potato, perilla, buckwheat, strawberry
India 2. (7 species of arboreous plants, 1976)	peach, Japanese pear, grape, satsuma mandarin, tea, Japanese black pine, ginkgo
McCree 1. (20 species tested in chamber, 1972)	Maize, sorghum, wheat, oat, barley, secalotricum, sunflower, soybean, tampala, peanut, lettuce, tomato, radish, cabbage, cucumber, oriental melon, squash, clover, sugar beet, castor-oil plant
McCree 2. (8 species tested in field, 1972)	Maize, wheat, oat, secalotricum, rice, sunflower, squash, cotton

----Photomorphogenesis-----

Light acts on plant morphogenesis, including germination, flowering, stem growth, and leaf opening. Light is also a source of stimuli or information in different ways depending on the plant species and the stage of growth. In general, light with blue, red, and far-red components acts on plants. [Table 4\(57KB\)](#) shows the action of each range of wavelengths³¹).

Among these actions, the red and far-red reversible reaction of phytochrome (a photoreceptor involved in seed germination) is particularly well known. In the reaction, the promotive effect of germination by red light(660 nm) irradiation is cancelled out by far-red light(730 nm) irradiation. That is, the effect of the previously irradiated light appears when red and far-red light is irradiated alternately. High intensity blue light and low intensity red light induce strong control of internodal growth. It is well known that with combined irradiation, far-red light is necessary, and that the ratio of red to far-red light controls internodal growth^{12,15,17}). In addition, blue or high energy light promotes the growth of sun leaves, and red or low energy light promotes the growth of shade leaves. Daylength controls flowerbud formation (photoperiod). Plants are generally divided by daylength into 3 groups in which flowerbud formation is differentiated by specific daytime length: short-day plants, long-day plants, and intermediate-day plants. In flowerbud formation, light acts as a stimulus, with red light, far-red light or blue light being particularly effective, depending on the plant species. Besides photomorphogenesis, blue light with a wavelength of 500 nm or less acts phototropically, and blue light also acts on stomatal movement.

---Artificial light sources for plant growth-----

The artificial light sources shown in [Fig. 6\(40KB\)](#) can be divided into 2 systems: thermal radiation and luminescence. Among these light sources, 6 light sources which are actually used for plant growth are incandescent lamps, high pressure mercury fluorescent lamps, self-ballasted mercury lamps, metal halide lamps, high pressure sodium lamps and fluorescent lamps. Also, xenon lamps and low pressure sodium lamps are used for research. [Fig.7\(56KB\)](#) shows the energy spectrum of each lamp, and [Table 5\(73KB\)](#) shows the radiant energy balance and reduced values of PPF per 1,000 lx in the 400 to 700 nm waveband.

1) Incandescent lamps (IL)

Incandescent lamps radiate visible light by thermal radiation generated from tungsten filaments heated to a high temperature by an electric current. The energy distribution is continuous, but the intensity of red light is higher than that of blue light, which possibly leads to intercalary plant growth. Therefore, these lamps are not suitable for photosynthesis. Furthermore, since they have a low light conversion efficiency of around 10 lm/W, as well as high thermal radiation, they are not used for the cultivation of plants. These lamps are used mainly to control photomorphogenesis, and for example, in some factories they are used to control

the flowering of chrysanthemums under low light intensities, to prevent dormancy of strawberries and to promote germination.

2) *Fluorescent lamps (FL)*

Fluorescent lamps are low-pressure mercury vapor discharge lamps with a hot cathode. Ultraviolet light generated by the discharge is transduced to visible light by phosphor coating on the inside of a glass tube. These lamps easily provide the required radiant energy by use of an appropriately selected phosphor, but cannot provide sufficiently high energy light on their own for cultivation. These lamps are often used to grow seedlings in plant factories. Fluorescent lamps for plants are used not only as supplemental lighting for ornamental plants in flower shops but also for tissue culture, especially for plant growth. In addition, a plant factory system has recently been developed, in which an average value of $650 \frac{1}{4} \text{mole m}^{-2} \text{e sec}^{-1}$ can be achieved by employing a total lamp system where a 110 W 3-band fluorescent lamp irradiates cultivated plants at a distance of 30 cm (6). Furthermore, the compact fluorescent lamp has become popular, and is able to provide local supplemental lighting to indoor ornamental plants by recessed lights.

3) *High pressure mercury fluorescent lamps (HPMVL, phosphor-coated type)*

HPMVLs are based on the principle that the luminous efficiency of sources is enhanced when the vapor pressure of mercury is increased. These lamps are the most stable lamps, and have been used for many years to grow plants. They provide light composed mainly of the radiation line spectrum of mercury, that is, the light lacks the red light component. These lamps therefore enable to control plant growth. To compensate for the lack of red light, a phosphor lamp which provides red light was developed. The efficiency of this lamp is around 60 lm/W. It has been used for many years in foreign countries to provide supplemental lighting and lengthening of daytime. Two types of lamps are available: a clear bulb type and a phosphor-coated type. The phosphor-coated type is a type of fluorescent lamp. The phosphor-coated type is further classified into 2 types: the X type for general use, and the XW type, which compensates for the missing red light component. The range of this lamp is from 50 to 2,000 W. Regarding the outer bulb shape of this lamp, a BT type and an R type are available.

4) *Self-ballasted mercury lamps (SBML)*

In SBMLs, the arc tube is connected in series to the tungsten filament as a ballast. These lamps compensate for the red light component, which high pressure mercury vapor lamps lack. They provide a good spectral distribution, but since the efficiency is as low as 20 to 27 lm/W, they are used as supplemental lighting for ornamental plants. For plants, lamps where the input ratio of the arc tube of mercury lamps to that of the tungsten filament is adjusted are also available. Two types of outer bulbs are available: a clear bulb type and a fluorescent type. A BT type and an R type for the outer bulb form of this lamp are available. The lamps can be selected in the range from 100 to 750 W.

5) *Metal halide lamps (MHL)*

The structure of metal halide lamps is based on that of mercury lamps, but they contain various halide additives. There is a wide selection available, including lamps mainly with line spectra and lamps mainly with continuous spectra. The efficiency of MHLs is around 100 lm/W, and they provide light with a reduced red light component above 600 nm. Therefore they are used in plant factories in combination with high pressure sodium lamps. MHLs on their own are used for supplemental lighting in greenhouses, and high color rendition type MHLs which provide light with a spectrum distribution similar to that of natural daylight are used in hybrid type plants factories and growth chambers. Recently, high color rendering index types (70 to 150 W) have gradually been used for supplemental lighting and display lighting for indoor ornamental plants (20). Murakami et al. (18) carried out research on high color rendering MHLs containing Dy, Nd, Cs, In, Tl, and Na for use in horticulture. Two types of these lamps are available: a high efficiency lamp with a built-in starter and a high color rendition type. BT, T and R types (only for high color rendition lamps) for outer bulb shapes are available. The lamps can be selected in the range from 70 W and 2,000 W. Typical additives are as follows: indium (blue light), thallium (green light), sodium (yellow light), and lithium (red light).

6) *High pressure sodium lamps (HPSL)*

HPSLs use alumina ceramic for the arc tube, and in the arc tube, sodium and mercury from an amalgam acting as a buffer gas are enclosed. Neon-argon penning gas is also sealed in the arc tube to help starting. The efficiency of some of these lamps exceeds 150 lm/W. Since they have a large red light component which can cause intercalary growth, they are used with metal halide lamps which provide compensating blue light. These lamps are used on their own to cultivate herbage crops with green leaves. These lamps are used solely in hybrid type plants factories. Three types are available: a high efficiency type with a built-in starter, an improved color type with a built-in starter, and a high color rendition type. BT type, T type and R type for outer bulb shapes are available. The lamps can be selected in the range from 50 to 940 W. A lamp in which the lack of blue light component is compensated by the addition of sealed mercury has recently

been developed for plants. Inagaki et al.¹⁰⁾ developed a high pressure sodium lamp with an output of 1.2 kW and an efficiency of 180 lm/W. Xenon, an inert gas for starter assistance, was sealed in the double-end type lamp at nearly three times the normal pressure.

7) Research trends

(a) Electrodeless discharge lamps(Microwave-powered lamps)

There are several designs of electrodeless discharge lamps depending on the method of illumination, with the microwave-powered lamp being the most promising future development for use in horticulture. Until now, microwave-powered lamps have solely been used for ultraviolet curing in photoengraving processes. Research is currently being conducted on the application of high intensities(130 lm/W , $1,000 \frac{1}{4} \text{ mol} \cdot \text{m}^{-2} \cdot \text{sec}^{-1}$) which could be achieved by the variation of the sealed gas¹³⁾. The next challenge facing microwave-powered lamps would concern the production cost and the life-span of magnetrons. [Fig. 8\(31KB\)](#) shows the structure of a microwave-powered lamp and emission spectrum.

(b) Light-emitting diode devices(LED)

LEDs are light-emitting semiconductors with uses ranging from simple indicator lamps to more complicated bar and numeric displays, where the development of the blue LED leads to the practical use of full color displays. The LED is a remarkable evolving technical invention. When current flows through the p-n junction of compound semiconductors consisting of GaP(gallium phosphide) or GaAsP(gallium arsenide phosphide), light is emitted as a result of electrons recombining with holes near the p-n junction. The characteristics of LEDs are as follows: low voltage operation, low heat emission, a compact and lightweight design, lack of noise(electron discharge tubes produce noise) and easy control. Horticultural applications are being considered for plant cultivation in space³²⁾. In this application, an irradiation source(surface) consisting of a bundle of LED devices irradiates the plant at a close proximity, moving with the plant as it grows. At a distance of 1 cm, a 5,000 mcd, 660 nm LED is able to produce an intensity of almost 50,000 lx. In addition, a combination of red, green and blue devices together with lighting control can produce a balance that is compatible with photosynthesis. The next challenge facing LEDs concerns the production cost and the heating effects resulting from the concentrated use of LED devices. [Fig. 9\(13KB\)](#) shows the structure of a LED device²³⁾ and Fig. 10((shows the spectral distribution in composite lighting. Table 6 shows the characteristics of red, green and blue LED devices²¹⁾.

Table 6. Characteristics of red, green and blue LED devices (modification of Nakamura, 1995)

Color	Material	Peak wavelength (nm)	Luminous intensity (mcd)	Output power ($\frac{1}{4}w$)	External quantum efficiency(%)
Red	GaAlAs	660	5,000	4,500	12.0
Green	AlInGaP	570	1,000	400	1.0
	GaP	555	100	40	0.1
	ZnTeSe*	512	4,000	1,300	5.3
	InGaN	520	12,000	3,000	6.3
Blue	SiC	470	20	20	0.04
	ZnCdSe*	489	700	327	1.3
	InGaN	450	2,500	5,000	9.1

Under a forward current of 20 mA. . *Under a forward current of 10 mA.

(c) Laser diode devices(LD)

LDs are light-emitting semiconductors like LEDs. LDs are mainly used in bar-code readers, writeable compact disks(CD), mini disks(MD), compact disk read only memory(CDROM), optical communication transmission, and photocopiers or optical printers. The operation principle of an LD is equivalent to that of laser

oscillation. Light emitted from an LED is reflected by a mirror and amplified by stimulated emission. The light is finally emitted through the mirror surface. [Fig. 11\(24KB\)](#) shows a simple LD structure²²⁾. [Table 7](#) shows the wavelengths produced by several kinds of LDs²²⁾. Takatsuji & Yamanaka²⁴⁾ investigated the possibility of using LDs as light sources in greenhouses since the photo-electronic transducer efficiency of LDs is very high. Results showed that irradiation combined with red and blue LD light pulses was a promising future development in view of the production cost. In addition, Takatsuji & Mori²⁵⁾ confirmed the growth of lettuce using mixed light irradiation (PPFD: $50\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$) of red LD (660 nm) and blue LED (450 nm).

Table 7. Wavelengths of various LDs (Shimoda, 1997)

Material	Wavelength (nm)
GaN	440
Zn _x Cd _{1-x} Se	490-530
Ga _{1-x} Al _x As	650-840
In _x Ga _{1-x} Al _y P _{1-y}	660-690
GaAs	840
Inp	910
In _x Ga _{1-x} As _y P _{1-y}	1,350-1,560
In _x Ga _{1-x} As	840-3,100
InAs	3,100
InSb	5,200
Pb _x Sn _{1-x} Te	6,500-32,000

Tsuchiya et al.²⁸⁾ developed an LD6500 with a wavelength of 680 nm and output of 200 nW. A 35% photoelectric transducer efficiency was achieved (theoretical maximum 60%). Results of tests carried out on lettuce at $200\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$ PPFD showed that growth was slow. The leaves were thin, presumably due to the use of monochromatic and coherent light. In the mixed irradiation test using red LDs and blue fluorescent lamps (about 6%), plants showed an increased weight and a normal leaf shape, confirming the effect of blue light²⁹⁾. Mori & Takatsuji.¹⁶⁾ cultivated lettuce by irradiating light from different kinds of LEDs and red LDs (650 nm) alone or in combination (PPFD: $50\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$) and found that the growth was poor in cases where only red LD irradiation was used. This effect was considered to be due to the monochromatic characteristic of red LD light. The following problems in the application of LDs are as follows: sensitivity to electrostatic and current surges, wavelength increase of about 10 nm as the temperature rises, and need for development of a blue light LD.

---Conclusion-----

Two main requirements dominate the utilization of artificial light sources in horticulture in both gardens and commercial greenhouses, the first being efficiency. High pressure sodium lamps are generally adopted to offer the highest efficiency in terms of plant growth rate and economy. However, to remain within current standards of farm products (such as leaf greenness and coloration, internode length, stem diameter, and leaf thickness), combination with metal halide lamps is recommended. The second requirement is related to the esthetic improvement of store or house environments, where the primary concern is not growth but maintenance of a plant's natural appearance. High efficiency is not a prerequisite, but the light quality balance becomes important in order to bring out the essential color characteristics of plants and flowers as well as maintaining plant health. To meet these requirements, high color rendering index type MHLs are recommended. Current horticultural research trends lead to the development of 1.2 kW HPSL, 180 lm/W, LED and LD devices for use in commercial greenhouses and the application of microwave and 400 W MHL lamps in growth chambers.

Effects of Various Radiant Sources on Plant Growth(Part 2)

Shinji TAZAWA

Light Source Division, Iwasaki Electric Co., Ltd.
(Gyoda, Saitama, 361-0021 Japan)

---Abstract-----

In Part 2 of this report, we analyzed the spectrum distribution of several high intensity discharge lamps, in which the spectrum values were multiplied by the average values for 4 different photosynthesis curves developed by McCree(1972) and Inada(1976), and we calculated the photoelectric conversion efficiency expressed as the plant growth radiant efficiency. As a result, we confirmed the high effectiveness of high pressure sodium lamps for plant growth within the PAR range of wavelengths, and concluded that a metal halide lamp 3,500 K(150 W high color rendering index type) was a suitable light source for indoor maintenance of ornamental plants. We also analyzed the light quality balance within the PAR range of different artificial light sources, by using the R/B and R/FR ratios as a reference to photomorphogenesis.

Discipline: Agricultural facilities/Crop production/Horticulture

---Introduction-----

Part 2 of this report deals with an evaluation of various radiant sources for plant growth and the quality of the light balance.

---Evaluation of various radiant sources for plant growth-----

Broadly speaking, 2 aspects must be considered in the evaluation of radiant sources for plant growth. The first is the efficiency of light energy transformation which is expressed by the ratio of the radiant energy of a lamp to the effective light energy for photosynthesis. This efficiency is a measure of how close the spectral distribution of a light source is to the photosynthesis action spectrum of the plants. To obtain this efficiency, the value for spectral distribution of a light source is multiplied by the sensitivity of the photosynthesis action spectrum of the plants, and then divided by the input power of the light source used. However, it is virtually impossible to analyze the photosynthesis action spectra of hundreds of thousands of plants on the earth. Therefore only the main typical species are used to calculate the efficiency. The quantum sensor, in which the sensitivity is close to the photosynthesis action spectrum, is considered to be a suitable device for measuring the efficiency. [Fig. 1\(23KB\)](#) shows the curve of luminous efficiency and quantum sensitivity. The second aspect to be considered is the quality of the light balance. In general, it is recognized that light with a large red light component promotes intercalary growth, and that light with a large blue light component controls plant growth. The ratio of blue, green

and red light components controls plant growth. The ratio of blue, green and red light components in PAR radiation is the key factor determining plant growth. In addition, the ratio of red light and far-red light is an important factor in the elongation of plants.

1) Evaluation of light energy transformation efficiency

To obtain the light energy transformation efficiency, the radiant energy of the light source is multiplied by either the quantum sensitivity or the operational sensitivity of photosynthesis, then divided by the input power of the lamp. Equations used to calculate the light energy transformation efficiency of the light sources are shown below (Eqns. 1 to 3).

Radiant energy of artificial light source;

$$\int_{380}^{780} P(\lambda) d\lambda / P_{in} \dots \dots \dots (1)$$

Radiant energy x quantum sensitivity;

$$\int_{400}^{700} P(\lambda) Q(\lambda) d\lambda / P_{in} \dots \dots \dots (2)$$

Radiant energy x average sensitivity of photosynthesis spectra ;

$$\int_{400}^{700} P(\lambda) S(\lambda) d\lambda / P_{in} \dots \dots \dots (3)$$

0(»): spectrum distribution,

1(»): quantum sensitivity,

3(»): average sensitivity of photosynthesis action spectra,

P_{in} : input power of lamp.

[Table 1\(52KB\)](#) shows the radiant energy and light energy transformation efficiency of various 660 to 1,000 W high intensity discharge lamps (HID lamps) used in closed system plant factories. Line (1) in Table 1 shows the transformation efficiency to visible light from electric energy supplied by actual light sources as radiant energy. Line (2) shows the light transformation efficiency multiplied by the quantum sensitivity for evaluating measurements. Line (3) shows the efficiency of light energy transformation actually used, which is calculated from the efficiency of light energy transformation multiplied by the average sensitivity of the photosynthesis action spectra of 33 plant species examined by Inada(1976)²⁾ and 28 by McCree(1972)⁴⁾. As shown in Table 1, from the standpoint of photosynthesis sensitivity and quantum sensitivity, the most effective lamp for plant growth is the HPSL, in which the red light component is large and the efficiency of light energy transformation is high. However, normal growth cannot be expected with a light with a large red light component only. That is, an adequate balance with blue and green light is also necessary.

[Table 2\(61KB\)](#) shows the efficiency of light energy transformation of 400 W HIDLs used in hybrid type plant factories and in greenhouses for supplemental lighting. Compared with HPMVL, MHL and HPSL show a higher efficiency. In addition, comparison of Tables 1 and 2, shows that high-wattage type HPSLs have a higher efficiency than 400 W HPLSs, and 400 W MHLs have a higher efficiency than high-wattage type MHLs.

[Table 3\(46KB\)](#) shows the efficiency of light energy transformation of compact type HID lamps installed for indoor ornamental plants. All MHLs have a high efficiency of light energy transformation, as shown

in Table 3. In particular, the 150 W 4,500 K lamp shows the highest efficiency, based on the multiplication with the average photosynthesis sensitivity.

2) Evaluation of quality of light balance

Evaluation of the quality of the light balance involves the determination of the relative balance of blue light, green light, and red light in the effective radiation range of photosynthesis. Among these, the balance of red light and blue light (R/B ratio) is a typical factor for consideration. High R/B ratio, depending on the light quantity, is associated with intercalary growth of the internodes, and a low R/B ratio is associated with growth control, i.e. suppression of elongation, and production of thick, strong leaves. [Table 4\(41KB\)](#) shows the quality of the light balance of various kinds of photosynthesis action spectra and quantum sensitivities. Considering quantum sensitivity as an indicator, an effective light balance is represented by an R/B ratio of 1.44, obtained with 27.3% blue light, 33.3% green light and 39.4% red light. The average quality of the light balance of 4 photosynthesis action spectra includes 23.5% blue light, 32.0% green light and 44.5% red light. From these values, the R/B ratio is calculated to be 2.71, indicating that light with a large red light component is effective. However, studies carried out by Inada & Yabumoto³⁾ using lettuce and radish, showed that an R/B ratio of 10 or higher was effective for cultivation. Takatsuji et al.⁵⁾ irradiated lettuce with red LED(660 nm, half wavelength about 30 nm) and blue LED(450 nm, half wavelength about 70 nm) and showed that an R/B ratio of 10 was effective.

Another factor for the evaluation is the photomorphogenesis reaction discussed in Section 5(Part 1). Based on the red light to far-red light ratio (R/FR ratio) it can be determined whether plants will have elongated or controlled growth. High R/FR values indicate controlled growth, and low values indicate elongated growth. The R/FR ratio is calculated by multiplying the light spectrum distribution by the quantum sensitivity. Inada & Yabumoto³⁾ using lettuce and radish, showed that an R/FR ratio between 1.00 to 2.00 was effective for cultivation. Horaguchi et al.¹⁾, who cultivated lettuce and sunflower using irradiation from several 4-band fluorescent lamps where an FR light was added to 3-band fluorescent lamps, showed that an R/FR ratio of 0.78 was effective. In general, the wavelength ranges are broadly defined as 600 to 700 nm for red light and 700 to 800 nm for far-red light. Equation (4) is used for the calculation of the R/FR ratio as follows;

R/FR ratio :

$$\int_{600}^{700} P(\lambda) Q(\lambda) d\lambda / \int_{700}^{800} P(\lambda) Q(\lambda) d\lambda \dots (4)$$

[Table 5\(42KB\)](#) shows the quality of the light balance, R/B ratio and R/FR ratio of various HID lamps(660 to 1,000 W). The light balance is adjusted on the basis of the visibility curve for human eyes, and therefore tends to contain a large green light component(500 to 600 nm). There is no lamp with an R/B ratio in the range of the quantum sensitivity and the average photosynthesis sensitivity(1.44 to 2.71), except for SBML that shows a low efficiency of light energy transformation. HPSLs, which have a large red light component, induce elongated growth, and are therefore used for cultivating herbage crops in plant factories of the closed system type because of their high efficiency. HPMVLs, and MHLs have a large blue light component, and therefore induce growth suppression. However, MHLs are currently the only high wattage lamps that can be used on their own to induce relatively good quality growth.

Table 6(58KB) shows the quality of the light balance of radiant energy, R/B ratio and R/FR ratio of various HID lamps(400 W). SBMLs show the optimum R/B ratio, but their R/FR ratio is associated with elongated growth because of the large FR component. The R/B ratios of HPMVL and MHL are associated with growth control, and that of HPSL with growth elongation. The R/FR ratio of the XW type of HPMVL, the MHL and the high color type of HPSL are all associated with growth elongation.

Table 7(39KB) shows the quality of the light balance, R/B ratio and R/FR ratio of compact type HID lamps for indoor ornamental plants. To achieve adequate growth in indoor shops, MHL 3,500 K may be recommended because of the high R/B ratio, R/FR ratio and light quality balance. For maintenance growth and esthetic displays, MHL 6,500 K can be recommended because it enhances the green color of leaves of ornamental plants. MHL 4,500 K or 6,500 K can be recommended because their R/B ratios are associated with growth control. If HPSL 2,500 K is used, ornamental plants may become overgrown indoors because both the R/B ratio and R/FR ratio lead to the optimum conditions for growth.

---Conclusion-----

To compare different artificial light sources, we determined the spectrum distribution of different light sources and multiplied the values by the average values for the photosynthesis curves derived from 4 sets of data to give an efficiency which we designated as the PGRE(plant growth radiant efficiency). As a result, the PGRE of high pressure mercury fluorescent lamps amounted to 8 to 12%, metal halide lamps(MHL) to 17 to 19% and high pressure sodium lamps to about 18 to 32%, respectively. Metal halide lamps were found to be the most efficient. High color rendition type HPSL and SBML gave excellent light quality balance and high R/B and R/FR ratios, but both exhibited a low basic photoelectric conversion efficiency. For the maintenance of ornamental plants, high color rendition type 4,500 K and 6,500 K lamps show a high PGRE and are effective, but we recommend the 3,500 K lamps due to the high light quality balance and R/B and R/FR ratios. However, if the esthetic effects of a certain store atmosphere are required, we may recommend MHL 4,500 K or 6,500 K in terms of color warmth as well as other factors. The HPSL 2,500 K lamps provide the highest combination of light quality balance, R/B and R/FR ratios, and lead to superior plant growth characteristics. Since many factors relating to plant growth and light irradiation remain unclear, we hope that this report will be a useful point of reference for the research and development of artificial light sources for horticultural applications.

---Abstract-----

Oxygen uptake models for horticultural commodities were constructed based on the Langmuir adsorption theory, mechanism of depression of respiration caused by CO₂ and transition state theory in order to design modified atmosphere packaging (MAP) systems. To examine the usefulness of the models, O₂ uptake rate data for the commodities were applied to the models. The models were found to be suitable for describing the respiration of several kinds of commodities. Mathematical analysis of MAP systems for shredded lettuce and shredded cabbage was conducted using the proposed rate equations and mass balance equations. The simulated results were in agreement with the experimental data. The O₂ uptake models were found to be suitable for the design of the MAP systems.

Discipline: Postharvest technology

Additional key words: lettuce, cabbage, mathematical model, MAP

(Received for publication, December 8, 1998)

---Introduction-----

In the storage and/or the transportation process of horticultural commodities, respiration control plays an important role in prolonging the postharvest life of the commodities. Decrease of O₂ and increase of CO₂ concentrations in the environment surrounding the commodities are effective for the depression of respiration¹¹). A modified atmosphere packaging (MAP) system is generally adopted for controlling the gas environment²⁶). The system creates an optimum composition of O₂ and CO₂ suitable for the storage of the commodities by controlling the respiration and film permeability.

Investigations on the prediction of the dynamics of atmosphere in various MAP systems have been undertaken since the 1960s¹⁰). Respiration models of the commodities used for the prediction were constructed by empirical approaches except for a model by Lee et al.¹⁵). It is thus necessary to develop a respiration model on a theoretical basis.

In the present study, theoretical models were constructed for representing the relationship between O₂ uptake rate in the commodities and O₂, CO₂ and temperature. Suitability of the derived models was

evaluated using respiration data for various kinds of commodities. Mathematical analysis of the MAP systems for shredded lettuce and shredded cabbage was conducted to analyze the suitability of the models.

---Mathematical models-----

1) *Respiration models*

Respiration is controlled by an elaborate interlocking system of feedback control that coordinates the rates of glycolysis, fatty acid breakdown, the citric cycle and electron transport¹). In the biochemical reaction of O₂ uptake in a unit cell, it is assumed that one molecule of O₂ is adsorbed on an active site of the cytochrome oxidase complex buried in the inner membrane of mitochondria, and that the O₂ molecule is desorbed from the site when it accepts 4 electrons, which react with the O₂ molecule, and is transformed to 2 molecules of H₂O²⁵). The cytochrome oxidase reaction is estimated to account for 90% of the total O₂ uptake in most cells¹). To analyze these biochemical reactions mathematically, a very complicated model is required. From a practical point of view, a simplified expression is desirable for predicting the atmospheric conditions within the package. An organism, for example a horticultural commodity, takes up an O₂ molecule by a chemical adsorptive reaction on an active enzyme site²⁵). Cytochrome oxidase complex adsorbs one molecule of O₂ per active site¹). I therefore attempted to construct a practical model for O₂ uptake in horticultural commodities based on the adsorption theory proposed by Langmuir¹⁴).

$$J_o = \frac{abp_o}{1 + ap_o} \dots\dots\dots(1)$$

It is generally assumed that in the respiratory depression by CO₂, the CO₂ molecule induces the metabolic inhibition of organic acids in the TCA cycle which is one of the most important steps in the respiratory process^{4,8,19}). The inhibition decreases the formation of NADH and FADH₂ which are produced from NAD⁺ and FAD. As a result, the desorption of the O₂ molecule in the final step of the electron transport chain is indirectly reduced²). Eq. 1 is modified to rate Eq. 2 for O₂ uptake¹⁷) as follows:

$$J_o = \frac{abp_o}{1 + ap_o + aip_o p_c} \dots\dots\dots(2)$$

On the basis of the transition state theory^{7, 18}), the maximum O₂ uptake rate *b* in Eq. 1 or 2 is expressed as follows:

$$b = \frac{NkT}{Lh} e^{-\frac{\Delta G}{RT}} \dots\dots\dots(3)$$

When the temperature dependence of the rate parameters a and i is assumed to be much lower than the dependence of b , the O_2 uptake rate of a horticultural commodity for storage is calculated using Eqs. 1 (or 2) and 3.

2) Respiration rate parameters

Eq. 1 is modified to a linear form given as follows:

$$\frac{p_O}{J_O} = \frac{1}{ab} + \frac{1}{b} p_O \dots\dots\dots(4)$$

The values of a and b are obtained from the slope b^{-1} and the intercept $(ab)^{-1}$ of $p_O \cdot J_O^{-1}$ vs p_O plots. Eq. 2 can be modified to a linear form as given below:

$$\frac{1}{J_O} = \frac{1}{b} + \frac{1}{abp_O} + \frac{i}{b} p_C \dots\dots\dots(5)$$

Equations for the calculation of the parameters a , b and i are derived from Eq. 5 as follows¹⁷:

$$a = \frac{C_1 p_1 - C_2 p_2}{p_1 p_2 (C_2 - C_1)} \dots\dots\dots(6)$$

$$b = \frac{p_1 - p_2}{C_1 p_1 - C_2 p_2} \dots\dots\dots(7)$$

$$i = \frac{B(p_1 - p_2)}{C_1 p_1 - C_2 p_2} \dots\dots\dots(8)$$

A linear form of Eq. 3 is given as follows:

$$\ln\left(\frac{b}{T}\right) = -\frac{\Delta G}{RT} + \ln\left(\frac{Nk}{Lh}\right) \dots\dots\dots(9)$$

3) Changes in atmosphere in a MAP system

Mass balance equations of O₂, CO₂ and N₂ gases in a MAP system are expressed by the following equations (10):

$$\frac{dv_o}{dt} = \frac{P_o A}{X} (q_o - p_o) - J_o W \quad \dots\dots\dots (10)$$

$$\frac{dv_c}{dt} = \frac{P_c A}{X} (q_c - p_c) + J_c W \quad \dots\dots\dots (11)$$

$$\frac{dv_N}{dt} = \frac{P_N A}{X} (q_N - p_N) \quad \dots\dots\dots (12)$$

Temperature dependence of a gas permeability coefficient of a polymeric film is expressed by the Arrhenius equation as follows (22):

$$P_i = F_i e^{-\frac{E_i}{RT}} \quad \dots\dots\dots (13)$$

Respiratory quotient (*RQ*) is defined as follows:

$$Q = \frac{J_c}{J_o} \quad \dots\dots\dots (14)$$

Atmospheric change with time in a MAP system included in a practical temperature range for storage of horticultural commodities is simulated by solving Eqs. 1 (or 2), 3 and 10-14 simultaneously by the Runge-Kutta method using a microcomputer.

---Materials and methods-----

1) Horticultural commodities

Head cabbage (variety YR-Aoba), head lettuce (variety Cisco), tomatoes (variety Momotaro) and broccoli (variety Naomidori) were purchased from a wholesale market in Takamatsu (Kagawa Prefecture, Japan).

Head cabbage was shredded into 1 mm wide slices with a cooking cutter (CQ-34R, Toshiba, Inc., Tokyo, Japan). The shredded cabbage was washed twice in a stainless-steel pan and rinsed for 1 min using a water sprinkler. The water adhering to the surface of the cabbage was removed by centrifugation (64.1 m s^{-2} for 30 s). Head lettuce was shredded into $30 \times 30 \text{ mm}$ (900 mm^2) fragments with a kitchen knife. The shredded lettuce was treated by the same method as the shredded cabbage after shredding.

2) Measurement of O_2 uptake and CO_2 production rates

Oxygen uptake and CO_2 production rates of horticultural commodities were measured by the method of Jurin & Karel¹⁰ under gaseous environments including the combination of 5 levels of O_2 [2, 5, 10, 15 and 21% (partial pressures of 2.03, 5.07, 10.1, 15.2 and 21.3 kPa under 101.325 kPa)] and 3 levels of CO_2 [0, 3, and 9% (partial pressures of 0, 3.04 and 9.12 kPa under 101.325 kPa)] balanced with N_2 .

3) Measurement of O_2 and CO_2 concentrations in a MAP system

A low density polyethylene (LDPE) pouch (thickness 0.025 mm, effective area 0.072 m^2) was used for the MAP test with shredded cabbage or shredded lettuce. Oxygen, CO_2 and N_2 permeability coefficients of LDPE were determined by the method of Makino & Hirata¹⁶ at 5, 15, 20 or 30. The data of the permeability coefficients were analyzed by linear regression using the linear form of Eq. 13

$$[\ln(P_i) = -E_i \cdot (RT)^{-1} + \ln(F_i)].$$

The prepared shredded cabbage (0.06 kg) and shredded lettuce (0.08 kg) were enclosed in LDPE pouches. When shredded lettuce was enclosed, a small package of CO_2 scrubber (Ageless C[®], Mitsubishi Gas Kagaku, Inc., Tokyo, Japan) was also enclosed in the pouch because it is desirable that lettuce be stored under 0% CO_2 ⁵. The pouch was stored for 3 d (shredded cabbage) or 6 d (shredded lettuce) at 10. The void volume of the pouch was determined based on water displacement. Oxygen and CO_2 concentrations within the pouch were periodically measured during storage by gas chromatography.

Data for the changes in the gas concentrations in the LDPE pouch over time were compared with the simulated values to estimate the practical effectiveness of the model equations proposed in the present study.

---Results and discussion-----

1) Suitability of the O_2 uptake model for respiration in horticultural commodities

Fig. 1(26KB) shows the relationship between $p_O \cdot J_O^{-1}$ and p_O of the experimental data of O_2 uptake for shredded lettuce, tomatoes and broccoli, and of the published data for apples⁶, broccoli¹⁵, bananas¹³, and blueberries³ with linear regression lines. The correlation coefficients were found to be in the range of 0.94 to 1.00, which were significant at 99.9% level of Fisher's z-transformation method, suggesting that Eq. 1 may be applied for the prediction of the O_2 uptake rate of many kinds of commodities. Eq. 1 is a simplified mathematical form of the enzyme kinetic model proposed by Lee et al.¹⁵. The validity of this mathematical form has already been demonstrated by Lee et al.¹⁵. In this study, I observed that the same mathematical equation form can be derived using either the enzyme kinetic theory or the adsorption theory, as the control mechanism.

Fig. 2(29KB) shows the relationship between J_O^{-1} and p_C in the experimental data of O_2 uptake for shredded cabbage, tomatoes, and broccoli in this study, and those in the published data for broccoli¹⁵. The value of J_O^{-1} for broccoli obtained in this study was larger than that obtained in the literature¹⁵, presumably due to the difference in the experimental temperature: 16°C in this experiment, and 24°C in the literature. Kader et al.¹¹ reported that temperature and/or cutting treatment affect(s) the respiration rate of horticultural commodities. The correlation coefficients between the experimental data and the straight fit lines were found to be in the range of 0.587 to 0.902, values significant at 95% level of the Fisher's z-transformation except for one coefficient. These findings suggest that Eq. 2 may be applied for the prediction of the O_2 uptake rates of the 3 kinds of horticultural commodities. The O_2 uptake data from the literature¹⁵ for broccoli at 12.7 kPa of O_2 partial pressure resulted in a correlation coefficient which was not significant at the 95% level. However, the experimental data substituted in Eq. 5 were obviously linear as shown in Fig. 2.

The validity of Eq. 2 as a rate equation was demonstrated in the present study as shown in Fig. 2. Eq. 2 is a simplified mathematical form of the enzyme kinetic model with uncompetitive inhibition. The validity of this mathematical form has already been demonstrated by Lee et al.¹⁵ for the aerobic respiration of horticultural commodities. In this study, I observed that the same mathematical form equation describing the control mechanism can be derived using either the enzyme kinetic theory or the adsorption theory. The uncompetitive inhibition is

defined as the direct inhibition of the enzymic activity where an inhibitor binds to the enzyme-substrate complex but does not bind to the free enzyme²⁴). Lee et al.¹⁵) approximated the respiration rate of horticultural commodities with an uncompetitive inhibition model. However, many authors concluded that the mechanism for CO₂ inhibition of O₂ uptake in some way interferes with organic acid metabolism, which is an indirect effect¹⁹). Such indirect effects are not compatible with mathematical modeling of respiration rate equations at a mechanistic level. The macroscopic approach, such as adsorption theory, which was applied to derive Eq. 2 may be more suitable for expressing complex biochemical reactions.

The O₂ uptake rate data for shredded cabbage and shredded lettuce obtained in this study and for blueberries and raspberries obtained from the literature^{3,9}) are shown in [Figs. 3 and 4\(68KB\)](#) with calculated linear regression lines. The uptake rate rose with the increase of O₂ partial pressure, decrease of CO₂ partial pressure, and rise of temperature in the environment surrounding the commodities. The trend was in agreement with that described in the previous report¹²), supporting the assumption that the O₂ uptake rate data obtained in this study are suitable for the analysis of the temperature dependence of the O₂ uptake rate of the commodities.

Values of $\ln(b \cdot T^{-1})$ calculated from the values of the maximum O₂ uptake rate parameter b for various products are shown in [Fig. 5\(18KB\)](#). The results indicate that the values of $\ln(b \cdot T^{-1})$ were linearly correlated with the reciprocal of absolute temperature. These observations suggest that Eqs. 3 and 9 can be used for the analysis of the temperature dependence of the O₂ uptake rate of horticultural commodities. In the previous reports, Karel and Go¹³) and Song et al.²³), applied the Arrhenius equation to express the respiration rates of pre-climacteric hard green bananas, cut broccoli and blueberries, respectively. I applied Eq. 3 derived from the transition state theory. The correlation coefficients in Fig. 5 indicate that the proposed Eq. 3 is suitable for the O₂ uptake rate. The proposed Eq. 3 is composed of Boltzmann's constant k , Planck's constant h , Avogadro's constant L and gas constant R which are generally adopted in the physicochemical field except for the symbol N . These findings suggest that Eq. 3 is more suitable than the Arrhenius equation for describing the temperature dependence of the O₂ uptake rate from a theoretical viewpoint.

2) Simulation of dynamic changes in atmosphere in MAP systems for horticultural commodities

Experimental data and simulation results for the changes in the O₂ and CO₂ concentrations over time in the MAP systems for shredded cabbage and shredded lettuce are shown in [Fig. 6\(21KB\)](#). The simulation results obtained by using the parameters presented in Tables 1 and 2, indicated by the full lines, were in good agreement with the experimental data. These facts suggest that the model derived from the Langmuir adsorption theory, mechanism of the depression of respiration caused by CO₂ and the transition state theory is suitable for expressing the O₂ uptake rate of horticultural commodities as well as for the evaluation of the parameters, gas permeability coefficients and RQ .

Table 1. Oxygen uptake rate parameters for horticultural commodities

Commodity	βG	N	a^a	i^a	Q^a
Shredded cabbage	8.81x10 ⁸	7.74x10 ¹⁸	3.09	0.0691	0.853
Shredded lettuce	7.28x10 ⁸	3.50x10 ¹⁶	0.0532	0.0838	0.962

a): Average in the range of 5 to 30.

Table 2. Gas permeability parameters for a low density polyethylene film

Gas	E_i	F_i
O ₂	4.74 x 10 ⁸	5.42
CO ₂	4.81 x 10 ⁸	44.8
N ₂	3.74 x 10 ⁸	0.126

Morales-Castro et al.^{20,21}) calculated the changes in the O₂ and CO₂ concentrations over time in the MAP systems for sweet corn and head lettuce using respiration models suitable for changes in temperature. The respiration models were constructed by the non-linear regression analysis which is an empirical approach. Deviation of the experimental results from the simulated results was larger than that in this study. It is suggested that the simplified model proposed in this study is more effective for the design of the MAP systems than the model(s) reported in the literature.

---Conclusions-----

An O₂ uptake model based on Langmuir adsorption theory was found to be suitable for the analysis of the actual data of O₂ uptake of shredded lettuce, tomatoes and broccoli obtained in this study and of apples, broccoli, bananas and blueberries obtained in the literature. An O₂ uptake model under an atmosphere with CO₂ based on the assumption that CO₂ gas inhibits the oxidation of the organic acids in the TCA cycle predicted well the actual rates for shredded cabbage, tomatoes and broccoli. The validity of the transition state theory for explaining the temperature dependence of the O₂ uptake rate of shredded cabbage, shredded lettuce, blueberries and raspberries was demonstrated in this study. Simulation of changes in O₂ and CO₂ concentrations over time in a MAP system for shredded cabbage or shredded lettuce was in good agreement with the experimental data. The model equations proposed in this study can thus be used for the design of MAP systems.

Notations

- a*: O₂ uptake rate parameter (kPa⁻¹)
A: effective area of a packaging film (m²)
b: maximum O₂ uptake rate (mmol kg⁻¹ h⁻¹)
B: constant (kg h mmol⁻¹ kPa⁻¹)
C: constant (kg h mmol⁻¹)
E: energy of activation for gas permeation (m² kg h⁻² mmol⁻¹)
F: frequency constant (mmol m⁻¹ h⁻¹ kPa⁻¹)
h: Planck's constant 3.976 x 10⁻³² m² kg h⁻¹
i: O₂ uptake rate parameter (kPa⁻¹)
J: uptake or production rate of a gas in a horticultural commodity (mmol kg⁻¹ h⁻¹)
k: Boltzmann's constant 4.97 x 10⁻²⁰ m² kg h⁻² K⁻¹
L: Avogadro's constant 6.022 x 10²⁰ molecules mmol⁻¹
N: total number of active sites for O₂ uptake in a horticultural commodity (molecules kg⁻¹)
p: partial pressure of a gas in the environment surrounding a horticultural commodity (kPa)
P: permeability coefficient of a gas through a plastic film (mmol m⁻¹ h⁻¹ kPa⁻¹)
q: partial pressure of a gas outside of a MAP system (kPa)
Q: respiratory quotient (RQ)
R: universal gas constant 1.08 x 10⁵ m² kg h⁻² mmol⁻¹ K⁻¹
t: storage time (h)
T: absolute temperature (K)
v: amount of a gas in a MAP system (mmol)
W: mass of fresh produce (kg)
X: thickness of a packaging film (m)
³*G*: Gibbs energy of activation for O₂ uptake (m² kg h⁻² mmol⁻¹)

Subscripts

- C, N, O*: CO₂, N₂, O₂

---Abstract-----

To demonstrate the infection of pigs with helminths in the Mekong Delta, an investigation into the actual conditions was carried out in the area. A total of 87 pigs from 38 farms were examined for the presence of the helminths. Eggs of common nematodes, (*Ascaris suum*, *Metastrongylus* spp., *Oesophagostomum* spp., *Trichuris suis* and *Strongyloides ransomi*) present in Japan, were detected. Especially, since the morbidity rate of *A. suum* infection was very high, the effect of the *Ascaris* infection on pig growth was investigated. As a result, economic loss was estimated at US\$2.0/head. In addition, infection with *Fasciolopsis buski*, which does not occur in Japan, was detected in 4 pigs from 4 small farms. These 4 pigs were give water spinach as a supplemental feed. It was suggested that this vegetable played an important role in *F. buski* infection and that the fluke infection was one of the zoonoses. Infection with this fluke in human can be anticipated, because most of the inhabitants ate this vegetable in the Mekong Delta.

Discipline: Animal health

Additional key words: *Ascaris suum*, zoonosis, anthelmintic, economic loss

---Introduction-----

The Mekong Delta is an important region for the pig production industry in Vietnam¹¹). The pig production is conducted in small farms in integrated farming systems or in the *Vuon-Ao-Chung* (VAC) system combining agriculture, animal husbandry and fisheries for feed from agricultural by-products. The economic efficiency of these farms is very low and the income of the farmers is also low⁶). To increase the productivity of pigs and farmers' income, it is important to prevent the occurrence of various problems relating to feeds and diseases¹⁸). It is considered that helminthic diseases are associated with the low productivity and cause economic loss in the VAC system⁸).

On the other hand, helminthiasis may be an important zoonosis in the VAC system, because many intermediate hosts of helminths, such as snails, crabs or small fishes, occur in this area in which marshlands, small rivers, ponds and rice fields are located.

The objective of the present studies was to identify the swine helminthiasis including zoonotic trematodes in the VAC system. Therefore, we investigated *Ascaris suum* infection and *Fasciolopsis buski* infection in the Mekong Delta.

---Materials and methods-----

1) Surveys of helminths

Sampling sites: Eighty seven fecal samples were collected from pigs in 38 farms in the VAC systems ([Fig. 1\(29KB\)](#)) in the Mekong Delta area. Feces (50-100g each) were packed in plastic bags and stored in a refrigerator until the examination. We also determined which feeds were given as supplement in the farms.

Detection of eggs: The Watanabe sedimentation method¹⁹) was applied to detect eggs. Counts of eggs per gram (EPG) were carried out to estimate the degree of parasitism by using Dennis method⁵) for *F. buski*. The effect of anthelmintics on *A. suum* was estimated using McMaster EPG counting plate, if necessary.

2) Use of scanning electronmicroscope (SEM) for morphological studies of *F. buski*

Several flukes collected from slaughterhouses were fixed in 10% phosphate-buffered formalin and washed 3 times in 0.1 M phosphate buffer. After dehydration in ethanol, the fluke materials were subjected to isoamyl acetate immersion, critical point drying and coating with gold. The fluke specimens were observed with a scanning electronmicroscope (SEM, JEOL, JSM-5300).

3) Experiment on effect of *Ascaris* infection on pig growth

Pigs: Six pigs weighing approximately 40 kg were used. They were littermates and crossbreds of *Ba Xuyen* and Yorkshire from the Experimental Animal Farm of Can Tho University. They were positive for the *A. suum* eggs.

Experimental design: Group 1 consisted of 3 pigs treated with 1 mL per 15 kg of Polystrongle (injectable

form Tetramizole hydrochloride, France). Group 2 consisted of 3 untreated pigs. Their body weight was checked biweekly for 12 weeks. EPG count was carried out every day using McMaster egg counting plate for 10 days after treatment. *A. suum* eggs were also checked by the sedimentation method every week. All the animals were raised under the standard management applied in the animal farm of the university.

Pathological examination: Pigs from the 2 groups were necropsied 12 weeks after the onset of the experiment. At necropsy, middle parts of the small intestine were fixed in 10% formalin. For histological examination the tissue samples were embedded in paraffin wax, sectioned and stained with hematoxylin and eosin (HE).

4) Ovicidal effect of biodigester

Samples containing *F. buski* eggs were collected from the inlet and outlet of the biodigester (Fig. 1). Each sample of the fluke eggs was washed in tap water and vibrated to remove the debris around the eggs. Then, the egg samples were transferred into Petri dishes with water and incubated at 29 for 15 days. After the incubation, the eggs which did not develop to the next stage (or miracidium) were considered to be dead eggs. The eggs of *A. suum* were also incubated by the same method to examine their activity.

---Result-----

1) Surveys of helminths in the Mekong Delta

Eggs of *A. summ* were detected in 51% (44) of 87 pigs, *Metastrongylus* spp. in 14% (12), *Trichuris suis* in 26% (23), *Oesophagostomum* spp. in 14% (12), *Strongyloides ransomi* in 5% (4) and *F. buski* in 5% (4). There were distinct differences between the regions surveyed in the infective rate of *A. summ*. The rate of this nematode in the pigs from 12 farms near Can Tho University was 100%, whereas about 30% in other regions.

Eggs of *F. buski* (Fig. 2(23KB)) were detected in the feces of 4 pigs from 4 farms. All the pigs infected with this fluke had eaten water spinach (*Ipomoea aquatica*) as supplemental feed (Fig. 3(21KB)). In 3 pigs, the EPG count was 10 or less. However, a sow with severe constipation had an EPG count of more than 1,000 in the feces. The snails which were intermediate hosts of the flukes (*Gyraula* sp. and *Indoplanorbis* sp.) were detected in marshlands, ponds, small rivers and rice fields near the pig pens in the VAC systems. Furthermore, other snails (*Lymnaea* sp. and *Pila* sp.) also occurred in the same areas (Fig. 4(20KB)).

2) Morphology of F. buski

The eggs of *F. buski* were yellowish ellipsoidal and 130-140 x 80-85 μ m in size. They were very similar to the eggs of *Fasciola gigantica* (Japanese type). The *F. buski* flukes in pigs from slaughterhouses were 2.0-4.4 x 0.5-2.0 cm in size. Several adult flukes were detected in the intestine (Fig. 5(30KB)). Under the scanning electronmicroscope an oral sucker, genital atrium and ventral sucker were observed (Fig. 6(43KB)). The middle part of the of the ventral surface of the body showed a crocodile skin appearance (Fig. 7(68KB)). In the tail of the fluke, the excretory bladder opened near the posterior extremity of the body (Fig. 8(68KB)).

3) Effect of A. summ infection on pig growth

In 6 pigs of the 2 groups, only *A. summ* eggs were detected in the feces. In 3 pigs of the treated group, adults of *A. summ* were eliminated within a few days after treatment with Tetramizole, and the EPG of this nematode reached a zero value (Table 1). However, since *A. summ* eggs were found again 6 weeks later, treatment was resumed. While the growth rate of the untreated pigs was low, the growth rate of the treated pigs improved (Fig. 9(22KB)). In the untreated group, the small intestine of an emaciated animal contained 12 *Ascaris* (Fig. 10(25KB)). The pig infected with *A. summ* showed a low weight gain (Table 2). The growth of the untreated pigs which reached a weight of 80 kg was delayed by 2 weeks compared with the treated pigs. Anorexia and diarrhea were not observed in pigs of both groups during the examination.

Table 1. Change in egg counts in feces of pigs after Tetramizole treatment

Group	Pig No.	Days after treatment									
		1	2	3	4	5	6	7	8	9	10
Treatment	1	800a)	0	0	0	0	0	0	0	0	0
	2	900	0	0	0	0	0	0	0	0	0
	3	300	100	0	0	0	0	0	0	0	0
-----	----	----	----	----	----	----	----	----	----	----	----
Control	4	700	800	900	800	800	1,000	900	1,100	900	1,100
No treatment	5	800	900	800	800	800	800	800	900	1,000	1,000
	6	400	400	400	400	400	400	400	400	400	600

a): Number of eggs per g in feces.

Table 2. Body weight of treated and untreated pigs (Unit: Kg)

Group	Pig No.	Weeks after treatment						
		0	2	4	6	8	10	12
Treatment	1	37	44	51	60	79	81	89
	2	40	45	52	60	70	82	89
	3	39	44	51	58	68	80	90
-----	----	----	----	----	----	----	----	----
Control	4	41	46	52	59	66	74	82
No treatment	5	39	44	50	57	64	72	81
	6	42	46	51	58	66	69	72

Macroscopically, there were a few petechial hemorrhage on the pulmonary pleura and white spots on the liver's capsule in the untreated pigs. These changes were less conspicuous in pigs of the treated group. One (No. 4), two (No. 5) and four (No. 6) adult worms were found in the middle part of the duodenum from untreated pigs and the lumen of the intestine become enlarged due to the presence of *A. summ* (Fig. 11(14KB)). Microscopically, the intestinal villi were depressed by *A. summ* infection and epithelial cells desquamated in the duodenum where the worms occurred. Eosinophils infiltrated the lamina propria (Fig. 12(37KB)).

4) Ovicidal effect of biodigester

After processing by the biodigester, eggs of *A. summ* which were collected from the outlet of the biodigester survived in the incubator. On the other hand, all the eggs of *F. buski* were inactivated by biodigester processing and they were not hatched.

---Discussion-----

Survey of the helminths disclosed that various eggs of helminths were detected in the Mekong Delta. Results of the investigation showed that the infection rate of lung worms (*Metastrongylus* spp.) was low. However, swine metastrongylosis is an important cause of swine pneumonia and disturbs their growth⁹). Therefore, it is very important to control this disease in order to increase the productivity of pigs and farmers' income in this area.

Although there are many studies on the biology of *F. buski* in Asian countries, the actual condition of this trematode in Vietnam has not been determined¹⁰). We observed this fluke under SEM and the morphological characteristics of *F. buski* were demonstrated. It is interesting to note that 4 pigs which ate water spinach given as a supplemental feed were infected with *F. buski*. This vegetable may thus play an important role in *F. buski* infection. Since many people eat water spinach in the Mekong Delta, human may possibly become infected with the fluke. In the small VAC system, a snail of *Pila* sp. which is the intermediate host of *Angiostrongylus cantonensis* and a snail of *Lymnaea* sp. which is the intermediate host of *Fasciola* sp. were detected¹⁶). Judging from the disappearance of fluke eggs in the outlet of a biodigester in VAC systems, it is likely that the biodigester contributes to the control of zoonoses, such as fasciolopsiosis, paragonimiosis or fascioliosis. It was considered that the inactivation of *F. buski* eggs may be due to the temperature and also to the effect of ammonia in the biodigester, since fluke eggs were susceptible to a low concentration of ammonia^{12,22}). The highest temperature in the tube type of biodigester was approximately 45 °C²) and *F. buski* eggs were killed at 50 after 4 hours in an experiment²¹).

As *A. summ* eggs were detected again at 6 weeks after Tetramizole treatment, the treatment was resumed. After ingestion of *A. summ* eggs, about 9 weeks were required for the development of the adult stage¹³). Therefore, it is considered that this anthelmintic was effective in the adult stage of the nematode in the intestine, but not in the immature stage. Comparison of treated and untreated pigs showed that the growth rate of the untreated pigs was very low and this nematode infection might be a cause of heavy economic losses for the farmers. Anderson et al.³) reported that the growth rate decreased to 20% after *Ascaris* infection in Denmark. Calculations showed that the economic loss was about 25,000 Don Vietnam (about US\$2.0) per head in an experimental farm¹⁷). Low nutrition level including deficiency in protein and vitamin A may exert more deleterious effects on the infected hosts⁷). If farmers use anthelmintic therapy for their pigs, the growth period of the pigs may be shortened at least by 2 weeks. Total cost for the treatment was about 5,000 Don Vietnam. It may be necessary that the farmers use anthelmintics in order to increase productivity. Bossaler et al.⁴) pointed out that the treatment of parasites contributed to the production of good quality meat.

One untreated pig which was clinically thin and infected with 12 *A. summ* showed moderate pathological changes. The main pathogenetic mechanism of ascariasis may involve physical stimuli²⁰) and the effects of inhibitors of host pepsin, trypsin, chymotrypsin, and carboxypeptidases which are contained in the extract of *A. summ*¹). Intestinal ascariasis directly interferes with the absorption of protein, fat, and carbohydrates¹⁴). Larval migration caused "white spots in the liver" and "thumps in the lungs." In the primary phase of severe infection, the growth rate of the pigs decreased¹⁵).

Further examinations should be carried out to identify the presence of other zoonotic parasitoses and to determine the relation between the presence of parasites and the economic losses in the VAC system.

---Abstract-----

Impact of fruit tree incorporation into farming systems on employment and income in the hill region of Nepal was analyzed, by applying the Gini decomposition analysis as a case study. In the study village, the introduction of orange production reduced employment opportunities in farming by 10% as a whole. The effect was most conspicuous for female labor (both family and hired) which decreased by 20%, while the use of hired male labor increased by 10%. It appears that the farm size was the major factor for the introduction of orange cultivation. Neither human resources (both quantity and quality) nor direct access to cash affected the dissemination of orange cultivation. Income from orange farming accounted for 44% of the total household income and for 56% of the total income inequality. Replacement of traditional upland crops by commercial orange may have worsened the income distribution, though absolute income increase might be significant. No villagers participated in marketing activities of orange, which has a large potential of employment and income generation. To further promote rural development focusing on the poor, use of labor for postharvest activities such as marketing and processing is recommended.

Discipline: Agricultural economics/Crop production/Horticulture

Additional key words: Gini decomposition analysis, mandarin orange, less-favored area

[1...7:References](#)

(Received for publication, January 13, 1999)

---Introduction-----

The hill region of Nepal, which supports nearly half of the nation population, has been facing environmental degradation due to increasing population pressure as well as expanding cultivation and overgrazing. In this context, incorporation of high value fruit trees such as citrus into the farming systems could be an alternative to improve the welfare of small farmers without impairing the resource base. As the access to urban market improved, commercial production of mandarin orange has increased in some of the hill regions since the mid-1970s. This paper aims to clarify the impact of the incorporation of commercial orange production into the existing farming systems.

First, we describe the agrarian conditions of the study village, then compare the labor use between traditional and new cropping systems. In the third section, impact of income distribution of orange is examined. We conclude with policy implications for rural development in less-favored areas.

---Data and methods-----

An in-depth household survey was conducted in 2 villages in Kavre district, central mid-hill region, in 1993. Farmers from randomly sampled 125 farm households were interviewed with a prepared questionnaire assisted by local resource persons. The field visits and group discussions with local key informants and some of the sample farmers were combined to verify the data collected.

The data of 1 village where orange is well disseminated were analyzed in this study. The sample size was reduced to 51 from originally surveyed 60 due to incompleteness and low reliability of some data.

---Agrarian conditions and cropping systems in the study village-----

The study village is located 50 km east of Kathmandu, the nation capital. This site has a moderate slope with a south-facing aspect at 1,300 to 1,600 m above sea level. The climate is warm temperate, ranging from 7°C in December-January to 30°C in April to September. The annual precipitation is about 1,300 mm. Within the village there is a great deal of microclimate variation due to the topography, altitude and the slope orientation.

Rough description of land use is presented in Table 1. The data from group discussions with key informants revealed that one-third of the village land is classified as lowland (*Khet* in Nepalese) for rice cultivation. Upland (*Bari*) accounts for about 40% in which annual crops grow in 16% and orange trees are planted in the remaining 24%. Privately owned forests or bushes account for only 4%, while community forests and grazing lands occupy one-third of the village area.

Table 1. Farmland use in the study village, Nepal, 1994

Land type	%
Lowland (<i>Khet</i>)	26
Upland (<i>Bari</i>)	
Annual crops	16
Orchard (orange)	24
Private forests /bushes	4
Community forests and grazing lands	30
-----	----
Total	100

Source: Informal survey, 1994.

Table 2 shows the size distribution of farmland holdings of the sample households. All of them were owner farmers. Tenant farming is seldom observed in the village, while at the national level 16% of the total farms are under tenancy¹⁾. Average farm size of 1.2 ha is equivalent to 0.96 ha of the national average¹⁾. In terms of number, the middle-sized farms ranging from 0.51 to 2.00 ha accounted for 73% in number and 62% in area. However, only 12% of farms with more than 2 ha accounted for 34% of the total area. This distributional structure resulted in highly skewed land holdings with a Gini coefficient of 0.70 compared with the national figure of 0.52¹⁾.

Table 2. Size distribution of farmland holdings of sample farms in the study village, Nepal, 1993

Area (ha)	Number of farms	Share (%)	
		In number	In area
- 0.50	8	16	4
0.51 - 0.75	10	20	11

Under rainfed conditions, seasonal distribution of rainfall is the major determinant of cropping systems. The wet season in this area extends from May to October with a rainfall peak in July-August as shown in [Fig. 1\(31KB\)](#). In the lowland, rice is transplanted in July and harvested in November. Immediately after rice harvest, wheat is planted then harvested in April-May. In the upland, maize is planted in April and harvested in September. After maize harvest, farmers plant wheat or mustard or both. Orange is planted in July only once in its life cycle and starts bearing fruits after 6-7 years. In August-September, weeding is performed in

the orchard. Harvest season of orange falls in December-January.

Though the initial introduction of a few orange trees in the village dates back to nearly 100 years ago by a government official working at the Royal Palace in Kathmandu, commercial cultivation started only after 1974 when the government organized a mass campaign for the dissemination of new agricultural technologies. The government provided seedlings, input materials with subsidies and credit for fruit production in the hill regions. Some innovative resource-rich farmers quickly adopted orange cultivation at that time. However, the majority of the small farmers could not adopt immediately the cultivation of this crop, due to risks of long-term investment and low technical confidence. After observing the success of orange production by neighbor farmers, the followers gradually introduced this new commercial crop as a substitute for subsistence crops such as maize, wheat, mustard and millet in the upland. Mutual exchange of planting materials and technical know-how among farmers played a crucial role in wider dissemination. Initial capital mainly originated from informal sources such as relatives and middlemen³).

---Impact of orange production on employment-----

To determine how the introduction of orange cultivation affected the employment of the village farmers, we compared the cases of farmers who cultivated or did not cultivate orange. Labor input per ha by cropping system is presented in Table 3. The rice-wheat system was found to be the most labor-absorptive system followed by the maize-wheat/mustard system, while perennial orange required the least labor input. In terms of employment status (family vs. hired), rice-wheat system has a neutral feature in which family and hired labor is almost evenly distributed, while it is slightly male-biased, as male labor accounted for 60% of the total. Comparison between the maize-wheat/mustard system and orange, shows that total labor used in the latter system was only 66% of that in the former, while the latter slightly relied on more hired labor (42 vs. 53%) and consisted mainly of male labor (44 vs. 71%).

Table 3. Labor input of major cropping systems in the study village, Nepal, 1993

	Lowland		Upland	
	Rice-Wheat		Maize-Wheat/Mustard ^{b)}	Orange ^{c)}
	----- man-days/ha (%) -----			
Family labor ^{a)}	173 (53)		141 (58)	76 (47)
Male	9 (28)		63 (26)	51 (32)
Female	83 (25)		78 (32)	25 (16)
Hired labor	153 (47)		103 (42)	85 (53)
Male	68 (21)		44 (18)	62 (39)
Female	85 (26)		59 (24)	23 (14)
Total	326 (100)		244 (100)	161 (100)

a): Including unpaid exchanged labor.

b): Assuming that wheat and mustard are planted in 0.5 ha each.

c): Case of maturing trees 7 years after planting.

Source: Household survey, 1993.

Then to estimate the change in labor use at an absolute level, we calculated the labor input based on actual land use vs. the counterfactual one without orange (Table 4). In 1993, the sample farms actually cultivated a total of 56.2 ha in which 21.9 ha consisted of rice-wheat, 16.9 ha of maize-wheat/mustard and 17.4 ha of orange. Total labor input was estimated at 14,064 man-days for this pattern of land use. We assumed that there was no technical change in farming practices, especially in terms of labor use, during the process of orange dissemination. Assuming that the maize-wheat/mustard system is practiced also in the actual orange area of 17.4 ha, labor input can be estimated at 15,509 man-days. From this simulation, introduction of orange cultivation might reduce employment opportunities in farming by 10% for the sample farms. However, the impact varied with the gender and employment status due to the difference in the labor use pattern among the cropping systems. Orange production might have reduced female labor by 20% (both family and hired), while increased hired male labor by 10% and not changed the family male labor.

Table 4. Comparison of labor use in the study village, Nepal

	Actual in 1993 with orange cultivation ^{a)}	Counterfactual without orange cultivation ^{b)}	With/ without orange cultivation
	----- man-days -----		
Family labor ^{c)}	7,494	8,625	0.9
Male	3,923	4,132	1.0
Female	3,571	4,493	0.8
Hired labor	6,570 ^{d)}	6,884 ^{d)}	1.0
Male	3,312	2,998	1.1
Female	3,259	3,885	0.8
Total	14,064	15,509	0.9

a): Rice-Wheat; 21.9 ha, Maize-Wheat/Mustard; 16.9 ha, Orange; 17.4 ha, Total; 56.2 ha.

b): Rice-Wheat; 21.9 ha, Maize-Wheat/Mustard; 34.3 ha, Total; 56.2 ha.

c): Including unpaid exchanged labor.

d): Round error.

To analyze the economics of orange production, unique features of the tree crop must be considered. A typical economic life of orange tree is as follows³⁾. The gross margin (gross products * cash expenditure) is negative until 6 years after planting of seedlings as the tree does not bear fruit. After 7 years, the gross margin becomes positive with increasing rate until the 14th year, then it starts to decrease gradually. Simple comparison of the gross margin between maturing orange trees (Rs. 71,000/ha) and that of maize-mustard system (Rs. 9,000/ha) is misleading considering the conditions mentioned above. However it may be safe to state that orange production is much more profitable than traditional upland crop production.

[Continue to:-Effect on income distribution-](#)

[Contents](#)

---Effect on income distribution-----

We shall determine how highly profitable commercial orange farming affected the income distribution among the village farmers. Before analyzing the effect on income distribution, the factors that may promote orange adoption will be outlined. Table 5 shows the Pearson's correlation coefficient between the area planted with orange and various characteristics of sample households. Human dimensions of the farm such as age and educational level of household head, endowment of family labor (both farm and non-farm) were not related to the orange area. Neither rice yield, proxy of farming skill level, nor the non-farm income, indicator of cash access, affected the adoption of orange cultivation. It is obvious that the larger the farm size, the larger the orange area. The upland area in which orange can be planted as well as the lowland area, where trees can not grow, may affect the diffusion of orange. This fact suggests that households with secure supply of staple food such as rice could expand commercial production.

Table 5.
Correlation coefficient between orange-planted area and household characteristics in the study village, Nepal, 1993

	<u>Correlation</u>	<u>Probability</u>
Age of household head	0.025	0.859
Schooling years of household head	-0.002	0.990
Family farm-labor	0.255	0.068
Family non-farm labor	0.001	0.995
Upland area	0.395	0.004
Lowland area	0.765	0.000
Rice production	0.612	0.000
Yield of rice	-0.157	0.286
Non-farm income	0.128	0.367

* Significant at 1% level.

The high correlation between the farm size and orange production suggests that the diffusion of orange might have worsened the income distribution among the village farmers. To answer this question, we applied the Gini decomposition analysis (2,6,5) that enables to quantify the contribution of each income component to the overall income inequality. Gini decomposition is formulated as follows:

$$G(y) = S_i R(y, x_i) G(x_i),$$

where

y = Total household income

$G(y)$ = Gini ratio of total income,

x_i = Income from i th source,

S_i = Average income share of i th source,

$R(y, x_i)$ = Rank correlation ratio,

$G(x_i)$ = Gini ratio of i th income.

The rank correlation ratio is defined as:

$$R(y, x_i) = Cov[x_i, r(y)] / Cov[x_i, r(x_i)],$$

where $r(y)$ and $r(x_i)$ denote the ranking of the household in terms of total income and income from i th source, respectively. $R(y, x_i) = 1$ if $r(y) = r(x_i)$. Otherwise $R(y, x_i)$ is less than 1. In general, the larger the rank correlation ratio is, the larger the correlation between the ranking of total income and the ranking of component income.

Thus the formula decomposes the total Gini ratio into 3 factors, namely, income share, correlation effect of total and component income and the Gini ratio of component income. As in the case of the study village, farm households in developing countries generally earn income from various sources. We can not determine to what extent a certain income component contributes to the overall income inequality by simply comparing the Gini ratio of each income. The component with a large Gini ratio may not contribute substantially to the overall income inequality if its share is quite small. Or even it may equalize the overall income distribution if its ranking is negatively correlated with that of total income.

The results of Gini decomposition are presented in Table 6. Total income Gini ratio of 0.43 was significantly smaller than that of land holding (0.70 in Table 2). This finding suggests that various non-farm job opportunities which accounted for 26% of the total household income, including hired farm jobs, contributed to the leveling off of the economic status of the villagers.

Table 6. Decomposition of income Gini ratio in the study village, Nepal, 1993

	Income share	Rank correlation ratio $R(y, x_j)$	Component Gini ratio $G(x_j)$	Component Gini contribution $S_j R(y, x_j) G(x_j)$
Rice	0.24 (0.24) b)	0.76 (0.72)	0.40 (0.38)	0.08 (0.07)
Upland crops a)	0.06 (0.07)	0.50 (0.46)	0.35 (0.37)	0.01 (0.01)
Orange	0.44 (0.44)	0.90 (0.88)	0.61 (0.59)	0.24 (0.23)
Farm Wage	0.02 (0.03)	-0.16 (0.18)	0.89 (0.89)	-0.00 (0.00)
Non-farm wage	0.06 (0.06)	0.25 (0.37)	0.86 (0.87)	0.01 (0.02)
Small business	0.12 (0.10)	0.67 (0.54)	0.85 (0.84)	0.07 (0.04)
Formal job	0.06 (0.06)	0.66 (0.70)	0.88 (0.89)	0.03 (0.04)
Total	1.00 (1.00)	–	–	0.43c) (0.41)

a): Wheat, maize and mustard.

b): Number in parenthesis is based on per capita income.

c): Round error.

The major income source contributing to total income inequality was the income derived from orange cultivation. The highest income share (0.44) and rank correlation ratio (0.90) resulted in the highest component Gini contribution (0.24), which accounted for 56% of the total income inequality (0.24/0.43). This finding is consistent with the fact that the orange-planted area was highly correlated with the farm size (Table 5). The contribution of rice income was the second largest, though its figure (0.08 or 19% of total Gini) was much lower than that of orange income. A previous study also revealed that even in a typical rice-dependent village, rice income does not play a major role in the overall income inequality⁷). Contribution of traditional upland crops (wheat, maize and mustard) was negligible (0.01 or 2%) since its share in the total income (0.06), rank correlation ratio (0.50) and component Gini (0.35) was significantly smaller than that of orange and rice. These facts suggest that replacement of upland crops by orange may have worsened the income distribution.

In contrast to the relatively lower component Gini ratio of farm income (0.35 to 0.61), that of non-farm income was much larger ranging from 0.85 to 0.89. However non-farm income, including farm wage income, as a whole accounted for only 25% of the total income inequality, while the remaining 75% was attributed to farm income. Farm wage income showed a highly skewed distribution with a component Gini ratio of 0.89 and a negative rank correlation ratio (-0.16), indicating that the poorer the households, the more they engaged in hired farm jobs. Though this absolute figure was very small (less than 0.005), farm wage income contributed to equalizing the total household income distribution. The common non-farm wage jobs in the village include employment at local building construction sites, brick factory and portering of milk and daily necessities to and from local markets. Small businesses include miscellaneous self-employed jobs such as carpenter, tailor and small trade. Opportunities to work in the formal sector in the village are limited to the jobs of government officials, teachers, trekking company, police and army both in Nepal and India. Income share of small businesses and formal jobs (0.18) was smaller than that of rice (0.24), though the component Gini contribution (0.10) was larger than that of rice (0.08), due to the larger component Gini ratio than that of rice (0.85, 0.88 vs. 0.41).

---Conclusion-----

Introduction of profitable commercial orange production reduced employment opportunities in farming in the surveyed village by 10% as a whole. The effect was most conspicuous for female labor (both family and hired) which decreased by 20%, while the use of hired male labor increased by 10%. It appears that the area of both lowland and upland was the major factor for orange cultivation, though orange was planted only in the upland. Neither human resources (both quantity and quality) nor direct access to cash affected the dissemination of orange cultivation. Income from orange farming accounted for 44% of the total household income and for 56% of the total income inequality. Replacement of traditional upland crops by commercial orange may have worsened the income distribution, though absolute income increase might be significant. No villagers participated in marketing activities of orange, which has a large potential of employment and income generation. To further promote rural development focusing on the poor, use of labor for postharvest activities such as marketing and processing is recommended⁴).

---Abstract-----

Antimutagenicity of the water extracts prepared from the outer or inner portion of storage roots (hereafter referred to as 'outer and/or inner portion') of 4 varieties of sweetpotato differing in the flesh color was investigated using *Salmonella typhimurium* TA 98 to determine the distribution of the antimutagenic components. Analysis of anthocyanin pigments in both portions revealed a large distribution of anthocyanin pigments in the outer portion and showed that the content of cyanidin in the outer portion was higher than in the inner one. The strong antimutagenicity of Ayamurasaki outer portion was attributed chiefly to the high concentration of cyanidin. The extracts from the outer portions of Koganesengan, Sunny Red, and Joy White varieties showed an antimutagenic activity unlike the inner ones, suggesting that the antimutagenic component in the outer portions of these varieties was mainly associated with phenolics

Discipline: Food

Additional key words: antimutagenicity, anthocyanin, phenolics

---Introduction-----

Recently, new varieties of sweetpotato (*Ipomoea batatas*) differing in the flesh color have been released for new uses by the Kyushu National Agricultural Experiment Station. Several investigators have reported the presence of an antioxidative activity²⁾, reduction of liver injury induced by carbon tetrachloride in rats⁷⁾ and in man⁸⁾ which consumed purple-colored sweetpotato juice. Our recent study indicated that the anthocyanin pigments purified from purple-colored sweetpotato effectively decreased the reverse mutations induced by purified mutagens such as Trp-P-1, Trp-P-2, IQ, B[a]P, and 4-NQO, and also by dimethyl sulfoxide (DMSO) extracts of grilled beef¹³⁾. The anthocyanin pigment from purple-colored sweetpotato is more stable than other anthocyanins from red cabbage, elderberry and purple corn⁶⁾. At present, the flour from Ayamurasaki variety has been developed as a material for noodles, bread, a new type of alcohol drink, and a food colorant. However the distribution of functional components in sweetpotato is not clear. The functional components are not necessarily distributed uniformly in the sweetpotato storage roots. For instance, calcium⁴⁾ and phenolics¹⁰⁾ are abundant in the cortex of sweetpotato. Therefore it is important for effective application of sweetpotato to analyze the distribution of functional components such as nutritional or physiologically functional ones.

In this paper, we describe the distribution of the antimutagenic components of the storage roots of sweetpotato differing in the flesh color.

---Materials and methods-----

1) Sweetpotato materials

Four varieties of sweetpotato differing in the flesh color, Koganesengan, Sunny Red, Joy White, and Ayamurasaki ([Table 1](#)) were cultivated in 1996 under the same conditions in an experimental field at Miyakonojo (Japan). Harvested roots were cut into 2 portions and one half was used as the whole root. In the remaining half, the peeled outer layer (about 0.5 cm thick) as the outer tissue containing the skin and the cortex was separated from the inner portion without outer layer as the inner tissue, respectively. The peeled outer layer comprised all of the cortical region, which included the periderm, laticiferous ducts, and cambium. All the sections in each case were diced, lyophilized, and ground to flour. The flour samples were kept at -20 until use.

Table 1.
Effect of sweetpotato water extracts on the mutagenicity of Trp-P-1 against *Salmonella typhimurium* TA 98^{a)}

Variety	Flesh color	Amount of extract (mg/plate)	Inhibition (%) ^{b)}

Distribution of Antimutagenic Components in Colored Sweetpotatoes

Ayamurasaki	Purple	1.0	41
		5.0	55
		10.0	62
Koganesengan	Yellow	1.0	0
		5.0	0
		10.0	5
Joy White	White	1.0	0
		5.0	0
		10.0	4
Sunny Red	Orange	1.0	5
		5.0	9
		10.0	8

a):Trp-P-1 was added at a dose of 0.075 $\frac{1}{4}$ g/plate. Mutagenicity was tested with S-9 mix.

b):Each value represents mean \pm SD of triplicate plates. In the values shown, the spontaneous mutation frequency was subtracted. The His⁺ revertant value of the control was 625 \pm 12.

2) Chemicals and bacteria

Trp-P-1 was obtained from Wako Pure Chemical Industries Ltd. Chlorogenic acid (ChA) was purchased from Sigma Chemical Co. S-9 Fraction prepared from rat liver treated with phenobarbital and 5,6-benzoflavone and cofactors were purchased from Oriental Yeast Co., Ltd. Folin-Ciocalteu phenol reagent was purchased from Nacalai tesque, Inc. (Kyoto, Japan). Other chemicals used were of special grade. Strain TA 98 of Salmonella typhimurium was supplied by the Institute for Fermentation, Osaka, Japan (IFO). The bacteria were cultured in nutrient broth for 16 h at 37 before the mutagenicity assay was conducted.

3) Preparation of sweetpotato water extract

The extract was made from lyophilized flour (1 g), using 20 mL of ice-cold water for 1 h. The suspension was centrifuged at 18,000 x g for 20 min, and the resultant precipitate was re-extracted under the same conditions. The collected supernatant was lyophilized.

4) Assay of antimutagenicity

The mutagenicity assay was performed by a modification of the method of Yahagi et al.¹¹⁾ The antimutagenic activity was evaluated for TA 98 using the purified mutagen, Trp-P-1. These mutagens require metabolic activation to induce mutation in TA 98. S-9 Mix contained 50 $\frac{1}{4}$ mol of sodium phosphate buffer (pH 7.4), 4 $\frac{1}{4}$ mol of MgCl₂, 16.5 $\frac{1}{4}$ mol of KCl, 2.5 $\frac{1}{4}$ mol of glucose-6-phosphate, 2 $\frac{1}{4}$ mol of NADH, 2 $\frac{1}{4}$ mol of NADPH, and 50 $\frac{1}{4}$ L of S-9 fraction in a total volume of 0.5 mL. For the inhibition test, 0.1 mL of each mutagen, 0.1 mL of sweetpotato water extract or DMSO-dissolved pigment solution, and 0.5 mL of S-9 mix or phosphate buffer were simultaneously incubated with 0.1 mL of bacterial suspension at 37 for 20 min, and then poured on minimal glucose agar plates with 2 mL of soft agar.

5) Measurement of color value and HPLC analysis of anthocyanin pigments from extracts of Ayamurasaki inner or outer portion

The color value was measured by absorbance at 530 nm after the 0.5% sulfuric acid extract from each portion was diluted 4 times with McIlvaine's buffer (pH 3.0).

Individual anthocyanin pigments were analyzed using a HPLC (Model LC-9A, Shimadzu, Kyoto, Japan) equipped with a variable wavelength spectrum flow monitor. The samples for HPLC analysis of the anthocyanin pigments were prepared by extraction with 0.5 % sulfuric acid. Separation of the pigments was carried out on a 4.6 mm x 10 cm Luna C18(2) column (Phenomenex) and detected at 530 nm. The column was conditioned with Solvent A (1.5% phosphoric acid), and the pigments were eluted using a linear solvent gradient of 0-100% Solvent B (1.5% phosphoric acid, 20% acetic acid, 25% acetonitrile) for 40 min at a flow rate of 1 mL/min.

6) Extraction and determination of phenolics

The lyophilized sweetpotato flour was vigorously mixed with 10 times its equivalent volume of 80% ethanol. The mixture was boiled for 5 min under a hood and centrifuged at 5,000 x g for 10 min. The residue was mixed with additional 80% ethanol and boiled for 10 min to re-extract the phenolics and centrifuged under the same conditions. The extracts were combined and made up to 10 mL. These extracts were used for the determination of total phenolics. Total phenolics were determined by the procedure described by Coseteng and Lee¹⁾. The alcohol extract was diluted to obtain an absorbance reading within the range of the standards (800-40 $\frac{1}{4}$ g ChA/mL). The absorbance in the microplate wells was measured at 600 nm with a dual wavelength flying spot scanning densitometer (Shimadzu, Kyoto), with a microplate system. The results were expressed as mg ChA/100 g flour.

[Results and Discussion](#)

[Contents](#)

---Results-----

1) *Effects of water extracts from whole storage roots on the mutagenicity of Trp-P-1*

The antimutagenic effect of the water extracts from whole storage roots of 4 varieties differing in the flesh color was examined using Trp-P-1 at a dose of 0.075 µg/plate (Table 1). The extract was used at doses of 1, 5, and 10 mg/plate. The Ayamurasaki extract inhibited the Trp-P-1-induced mutation by 41 to 62% and showed a dose-dependent antimutagenicity. The extracts from Koganesengan, Joy White, and Sunny Red varieties showed inhibitory activities of 5, 4, and 8% at a dose of 10 mg/plate, respectively. The antimutagenic effect of the extracts from whole storage roots of Koganesengan, Joy White, and Sunny Red on Trp-P-1 was negligible compared with that from Ayamurasaki.

2) *Antimutagenic activity of the extracts from the inner or outer portion of sweetpotatoes*

Table 2 shows the antimutagenic activity of the extracts from the inner or outer portion of Ayamurasaki, Joy White, Koganesengan, and Sunny Red. The extract in the Ayamurasaki variety was used at doses of 1, 5, and 10 mg/plate. The extract of Ayamurasaki inner portion inhibited the Trp-P-1-induced mutation by 14 to 74%, while that of the outer one by 53 to 80%. The extracts from both portions of Ayamurasaki showed a dose-dependent antimutagenicity. The extract of the outer portion showed an antimutagenic activity about 4 times stronger than that of the inner one at a dose of 1 mg/plate. The extracts from the portions in 3 varieties other than Ayamurasaki were used only at a dose of 10 mg/plate since the extracts from the whole root of these varieties did not display the antimutagenic activity at doses of below 5 mg/plate as shown in Table 1. The extracts from the outer portion of Joy White, Sunny Red, and Koganesengan inhibited the mutation by 24, 25, and 18%, unlike those of the inner one.

Table 2. Effect of extracts from sweetpotato inner or outer portion on the mutagenicity for Trp-P-1 against *Salmonella typhimurium* TA 98^{a)}

Variety	Portion	Amount of extract (mg/plate)	Inhibition (%) ^{b)}
Ayamurasaki	Inner	1.0	14
		5.0	69
		10.0	74
	Outer	1.0	53
		5.0	77
		10.0	80
Joy White	Inner	10.0	0
	Outer	10.0	24
Sunny Red	Inner	10.0	0
	Outer	10.0	25
Koganesengan	Inner	10.0	0
	Outer	10.0	18

a): Trp-P-1 was added at a dose of 0.075 µg/plate. Mutagenicity was tested with S-9 mix.

b): Each value represents mean ± SD of triplicate plates. In the value shown, the spontaneous mutation frequency was subtracted. The His⁺ revertant value of the control was 609±16/plate.

3) *Color value and HPLC analysis of anthocyanins of extracts from Ayamurasaki inner or outer portion*

The color value of the extracts from both portions of Ayamurasaki was measured at an absorbance of 530 nm ([Table 3\(28KB\)](#)). The color value of the extract from the outer portion was 15.8 and that from the inner portion 10.9. Anthocyanin content in the outer portion was 1.4 times higher than that in the inner

portion. These results indicate that anthocyanin pigments are abundant in the outer portion.

The difference in both color values was reflected in the HPLC pattern in that the peaks of the extract from the outer portion were generally higher than those of the inner one ([Fig. 1\(19KB\)](#)). Sweetpotatoes with purple-colored flesh contain at least 12 anthocyanins⁶ and their contents vary with the sweetpotato varieties²). The main anthocyanin pigments were respectively designated as YGM1 to YGM6. Ratios of each pigment in the extracts from both portions indicated in Fig. 1 are shown in Table 3. YGM5 in the extract from the outer portion was clearly separated into 2 components, YGM5a and YGM5b unlike the extract from the inner portion. The total content of YGM5 in the extracts from both portions was practically similar but the contents of HMG5a in the extracts from the outer portion were clearly higher than those in the inner portion. YGM1a, YGM1b, YGM2, YGM3, and YGM5a were more abundant in the outer portion, while the pigments with a ratio below that of YGM1 and above that of YGM6 showed a high concentration in the inner portion. Especially the contents of YGM1, YGM3, and YGM5a in the extract from the outer portion were about twice as high as those in the inner portion.

4) Phenolic contents in the extracts from the inner or outer portion of 4 varieties of sweetpotato

Phenolics are known to inhibit the reverse mutation induced by various mutations. We determined the phenolic distribution of sweetpotato roots to analyze the relationship between the phenolic contents and the antimutagenicity. The contents of total phenolics in the extracts from both portions of the varieties tested were expressed as mg/100 g flour ([Fig. 2\(15KB\)](#)). The phenolic contents in the extracts from the outer and inner portions in Ayamurasaki roots were 1,900 mg and 1,650 mg/100 g flour, respectively. In the extract from the inner portion of Koganesengan, Joy White, and Sunny Red the contents were about 100, 110, and 150 mg/100 g flour, while in the outer one 400, 240, and 360 mg/100 g flour. The high phenolic content of Ayamurasaki probably enhanced the reaction of anthocyanin pigments with Folin-Ciocalteu phenol reagent. Odake et al.⁵) and Goda et al.³) reported that anthocyanins of the purple-colored sweetpotato have a caffeoyl or feruloyl group in their structural formula.

---Discussion-----

The antimutagenic activity of the extracts from the inner or outer portion of the storage roots was investigated to analyze the distribution of the antimutagenic components in sweetpotatoes differing in the color of the flesh. In 4 varieties tested, only the extract of the whole root of Ayamurasaki inhibited effectively the Trp-P-1-induced mutation (Table 1). As anticipated, the extracts from both portions also decreased the reverse mutation, and the antimutagenic activity was stronger in the extract from the outer portion than in that from the inner portion (Table 2). The determination of the color value in both portions indicated that the content of anthocyanins in the outer portion was about 1.5 times higher than that in the inner portion (Table 3). These results appear to reflect the strong antimutagenicity detected in the outer portion of Ayamurasaki. However the antimutagenic activity of the extract from the outer portion was about 4 times stronger than that from the inner portion at a dose of 1 mg/plate. These results did not always reflect the difference in the anthocyanin contents in both portions.

HPLC analysis revealed the compositional difference of anthocyanin pigments in both portions. Namely, anthocyanin pigments corresponding to YGM1a, YGM1b, YGM2, YGM3, and YGM5a were more abundant in the outer portion. Anthocyanin pigments corresponding to YGM1 to YGM3 consist of cyanidin and those to YGM4 to YGM6 of peonidin^{3,5,6}). Total percentage of YGM1 to YGM3 in the outer portion was 18.6%, while 12.2% in the inner portion. Furthermore, the total percentage of YGM4 to YGM6 in the outer portion was 66.9%, while 65.7% in the inner portion. The cyanidin content in the outer portion was 1.5 times higher than that in the inner portion. These values were in agreement with the increase of the color value in the outer portion, suggesting that cyanidin was abundant in the outer portion. Our previous data also indicated that cyanidin showed a relatively stronger antimutagenic activity than peonidin¹³). These results suggest that the high concentration of cyanidin in the outer portion partially contributes to the strong antimutagenicity.

The extracts of the outer portion of Joy White, Sunny Red, and Koganesengan without anthocyanin in the flesh also effectively inhibited the reverse mutation (Table 2). The phenolic contents in the extracts of the outer portion were several times higher than those in the inner portion (Fig. 2). Yamada and Tomita¹²) reported that many kinds of extracts containing compounds analogous to caffeic acid or ChA effectively decreased the mutagenic activity of the

mutagens as heterocyclic amines. We also confirmed that chlorogenic acid showed a dose-dependent antimutagenicity against Trp-P-1- or Trp-P-2-induced reverse mutation (data not shown). Walter and Schadel¹⁰) indicated that phenolics including ChA are abundant in the outer tissues of the sweetpotato roots. Their results suggest that phenolics in the outer portion mainly suppress the reverse mutation.

In conclusion, the outer portion of Ayamurasaki contained a large amount of cyanidin reflecting the strong antimutagenicity of the outer portion. These results suggest that this new variety of sweetpotato with higher physiological functions should be selected. Furthermore our data showed that the functional components were more abundant in the outer portion of sweetpotatoes. Suzuki et al.⁹) reported that the calcium content was high in the cortex of sweetpotatoes. These results suggest that the utilization of the whole root including the skin is important for maximizing the beneficial physiological functions of sweetpotato. Such an utilization may contribute to the effective use of biological resources, and result in the reduction of the negative environmental impact of wastes from sweetpotato processing.

Discrimination of Basidiomycete Species and Strains by Random Amplified Polymorphic DNA (RAPD) Analysis

Yasuhiro ITO and Sonoe O. YANAGI

Biological Function Division, National Food Research Institute
(Tsukuba, Ibaraki, 305-8642 Japan)

---Abstract-----

To develop a method for the discrimination of basidiomycete species and strains with vegetative mycelia, DNAs isolated from the mycelia of *Coprinus* and *Tricholoma* strains, were subjected to random amplified polymorphic DNA (RAPD) analysis. Seven *Coprinus* species could be distinguished, clearly showing species-specific DNA patterns in the RAPD analysis. One specimen of unknown *Coprinus* strain was identified as *C.cinereus* by this method. Six strains of *C.cinereus* and 4 of *C.angulatus* could also be distinguished by the presence of strain-specific RAPD fragments. Five members of the *Tricholoma* family, *T.matsutake* and related 4 species, also showed species-specific DNA patterns in the RAPD analysis. The discrimination of *Tricholoma* species was confirmed by cluster analysis based on 192 RAPD fragments. The 5 species could be clearly divided into 5 groups in complete agreement with the taxonomic classification. RAPD analysis of mycelial DNA, as shown in these studies, is a suitable method for distinguishing basidiomycete species and strains.

Discipline: Genetic resources

Additional key words: *Coprinus*, *Tricholoma*

---Introduction-----

Basidiomycetes are mainly classified based on the morphology of fruit bodies. However many strains of basidiomycete species do not form fruit bodies readily, if not at all, under experimental conditions. The development of a simple method for distinguishing species or strains with vegetative mycelia, therefore, is important.

Recently, molecular markers, such as isozymes, restriction fragment length polymorphisms (RFLP) and random amplified polymorphic DNA (RAPD) have been used to detect genetic differences in species and strains of basidiomycetes. Among these molecular markers, RAPD, which was introduced by the use of polymerase chain reaction (PCR) with arbitrary 10-mer primers¹), can express DNA variations for distinguishing basidiomycetes species and strains with less labor and high reliability⁴).

We used RAPD analysis for 2 basidiomycete groups, *Coprinus* species and *Tricholoma* species. *Coprinus* species, mainly *C.cinereus*, have been used as a model material for basic studies on basidiomycetes since they grow rapidly with a short life cycle span. We used *Coprinus* species to develop the RAPD method for the discrimination of basidiomycete species. Although *T.matsutake* (S. Ito and Imai) Singer is the most valuable edible mushroom in Japan, fruit body formation of *T.matsutake* under artificial conditions has not been achieved yet. Discrimination of *T.matsutake* based on the morphology of mycelia is almost impossible too because these are no clamps. This paper describes the successful application of the RAPD method.

---Materials and methods-----

1) Strains and culture conditions

Coprinus and *Tricholoma* strains examined are listed in Table 1. To maintain the strains, MYG medium [1.0% (w/v) of malt extract (Difco, USA), 0.4% (w/v) of yeast extract (Difco, USA) and 0.4% (w/v) of glucose] with 1.5% (w/v) agar was used. For DNA extraction, mycelia of each strain were inoculated into 20 mL of liquid MYG medium each in 100 mL flasks, and cultured statically at 30 for 2-3 days for the *Tricholoma* strains, or at 20 for 1-2 months for the *Tricholoma* strains. Harvested mycelia were stored at -20 for DNA extraction.

2) DNA extraction and PCR reaction

Mycelial DNA of each *Coprinus* strain was extracted by the method of Doyle and Doyle (1987) (1). DNA amplification was performed following a modification of the protocol of Williams et al. (1990) (11). The reaction mixtures contained 10 mM Tris-HCl, pH 8.3, 50 mM KCl, 1.5 mM MgCl₂, 0.2 mM of dATP, dCTP, dTTP, and dGTP, 1 μM of primer, 0.4 U of recombinant *Taq* DNA polymerase (Takara, Japan), and 10 ng of genomic DNA in a total volume of 10 μL. Ten decamer oligonucleotides were used as RAPD primers (Table 2). Amplification was carried out in a Program Temp Control System PC-800 (ASTECC, Japan) by the following procedure: initial denaturation at 94 °C for 2 min; 45 cycles of 94 °C for 30 s, 36 °C for 1 min and 72 °C for 2 min; and final extension at 72 °C for 2 min.

Table 2. RAPD primers used for discrimination of *Coprinus* strains and *Tricholoma* strains

(Summary)

For the *Tricholoma* strains, total DNA was extracted from mycelia as described by Draper et al. (1988)²). RAPD analysis was performed following a modification of the protocol of Williams et al. (1990)¹¹). The reaction mixtures contained 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 2 mM MgCl₂, 0.1 mM each of dATP, dCTP, dTTP and dGTP, 0.2 μM of RAPD primer (Table 2), 0.2 U of recombinant *Taq* DNA polymerase (Takara, Japan) and 1.0 ng of genomic DNA in a total volume of 10 μL. Amplification reactions were performed as follows: initial denaturation at 94 for 2 min; 30 cycles of 94 for 1 min, 36 for 1 min and 72 for 2 min; and final extension at 72 for 2 min.

Amplified DNA was electrophoresed in 1.6%(w/v) agarose gels, stained with 0.5 μg/L ethidium bromide, and photographed under UV light.

3) *RAPD data analysis for Tricholoma species*

Each polymorphic fragment was treated as a unit character, and compared between each pair of strains. The percentage of different fragments in each pair of strains was obtained by the following calculation: 100×number of different fragments/number of total detected fragments between the 2 strains. Cluster analysis was performed, based on the percentage of similarity of RAPD fragments, using the unweighted-pair-group method¹⁰).

[Results and discussion](#)

[Contents](#)

---Results and discussion-----

1) *Discrimination of Coprinus species*

Several DNA fragments from the genomic DNA of each *Coprinus* strain were successfully amplified with 12 primers. Two typical results of RAPD analysis are shown in [Fig. 1-A and B. \(13KB\)](#)

Strains of the same species gave similar RAPD patterns which included several DNA fragments of equivalent length (sample lanes 3-7, 8-11, and 12-13, respectively), making it possible to distinguish the species. Strains of different species, however, did not yield common fragments. RAPD patterns with other 10 primers gave similar results.

We attempted to identify the species to which a *Coprinus* strain stored as No. 425079 in the gene bank of MAFF belonged (Table 1). The RAPD patterns are presented in lanes No. 2 in [Fig. 1-A and B](#). With all the primers used, the RAPD patterns of strain 425079 clearly showed fragments common to *C.cinereus* strains, and the absence of homology with strains of other species. Therefore, this strain was identified as *C.cinereus*. Compatibility tests of mating between strain 425079 and monokaryotic strains of *C.cinereus* also gave the same results in RAPD analysis.

Hopple Jr. and Vilgalys (1994)³⁾ detected differences in the restriction sites of rDNA between *Coprinus* and related species, and estimated their phylogenetic relationship. However in the RAPD patterns in this study, since different *Coprinus* species showed few similarities to each other, the RAPD patterns were not suitable for use for phylogenetic analyses. On the other hand, the low similarity of the patterns between species makes this technique suitable for the discrimination of *Coprinus* species, as demonstrated by the identification of the species to which an unknown *Coprinus* strain belonged.

2) *Discrimination of strains of C.cinereus and C. angulatus*

RAPD patterns of the *Coprinus* strains showed the presence of polymorphic DNA fragments among the strains in the same species. As shown in [Fig. 2-A\(15KB\)](#), 5 of such polymorphic fragments (indicated by arrows) were found simultaneously with 4 common fragments in the RAPD patterns of 7 *C.cinereus* strains using the primer TTCGAGCCAG. These polymorphic fragments were strain-specific, and the 7 strains could be distinguished by the presence or absence of these 5 polymorphic fragments which were generated with one primer only.

The RAPD patterns for 4 strains of *C. angulatus* are depicted in [Fig. 2-B\(15KB\)](#). One primer, TGCGTGCTTG, gave 2 polymorphic fragments shown in lanes 1-4. These 2 markers allowed the discrimination of strains 225 and 711, while strains 516 and 624 could not be distinguished. Another primer, GACTAGCCTC, amplified another polymorphic fragment, as shown in lanes 5-8. By the presence or absence of this fragment, strain 516 was clearly distinguished from strain 624. Thus, the combination of 2 primers, in this case, allowed a clear discrimination of the strains.

The clarity and simplicity of these examples in the discrimination of the strains of *C.cinereus* and *C. angulatus* indicated that the RAPD method is very efficient for strain discrimination. RAPD markers specific for strains could be obtained easily, and seemed to be useful as genetic markers.

Several papers on the identification of strains of *Coprinus* by DNA analysis have been published. Wu et al. (1983)¹² reported the presence of DNA polymorphisms caused by the insertion/deletion of DNA fragments or base pair substitutions by RFLP analysis of *C.cinereus*, and Laroche et al. (1995)⁷ attempted to group and identify *C. psychromorbidus* by RAPD and RFLP analyses.

The method used to identify a strain is important for the protection of commercial mushroom species, like *Agaricus bisporus*, *LenTinus edodes*, *PleuroTus osTreaTus*, and so on. It is easy to isolate the mycelia of commercially superior cultivars and to culture them without permission. To identify the cultivar, morphological characters of the fruit body can not be used, because they display wide variations with the environmental conditions. DNA fingerprinting techniques, such as RAPD, RFLP and AFLP, can describe specific DNA variations of the cultivar, and are useful to identify the cultivar.

3) RAPD analysis for discriminaTion of Tricholoma species

Several amplified DNA fragments were obtained from each of the 15 MAFF strains of the 5 *Tricholoma* species examined using 10 RAPD primers. Most of the RAPD primers gave several common fragments among the strains in the same species, while RAPD patterns of 5 *Tricholoma* species were species-specific ([Fig. 3-A\(11KB\)](#)). However, *T. maTsuTake* showed similar RAPD patterns to those of *T. caligaTum* or *T. magnivelare* in some cases ([Fig. 3-B\(11KB\)](#)). To determine whether the RAPD analysis is suitable for the discrimination of *T. maTsuTake* from other *Tricholoma* species, 192 distinct RAPD fragments obtained by 10 primers were classified. Ten fragments were found only in *T. maTsuTake* strains to be species-specific, 4 were found in all the 7 *T. maTsuTake* strains and all the 2 *T. caligaTum* strains, 7 in all the strains of *T. maTsuTake*, *T. caligaTum*, and *T. magnivelare*, and 1 in all the strains of *T. maTsuTake* and *T. magnivelare*.

Based on the 192 RAPD fragments, cluster analysis was performed to determine the relationship between the five *Tricholoma* species. The 5 species were clearly divided into 5 groups in complete agreement with the taxonomic classification ([Fig. 4\(26KB\)](#)). Intraspecific similarity between each strain was obviously higher than interspecific similarities among all the 5 species in *Tricholoma*. The highest similarity of 52.0% to *T. maTsuTake* was given by *T. caligaTum*. *T. magnivelare*, *T. fluvocasTaneum* and *T. bakamaTsuTake* gave 41.8, 38.7 and 24.6% similarities to *T. maTsuTake*, respectively. Since the intraspecific similarities among *T. maTsuTake* strains exceeded 85.0%, it appears that the RAPD patterns of the *T. maTsuTake* strains can be distinguished from those of the related species. Thus, RAPD analysis is a suitable method for distinguishing the 5 *Tricholoma* species as well as *T. maTsuTake* from the related species.

Six closely related species of *T. maTsuTake* have been reported, that is, the 4 species mentioned above and *T. robustum* and *T. zelleri*⁸). Among the 6 species, *T. maTsuTake*, *T. caligaTum* and *T. magnivelare* have been considered to be closely related in terms of the morphology and fragrant aroma of the fruit body, the characters of cultured mycelia, the morphology of fungal colonies in soil called *shiro*, and mycotrophy with coniferous trees^{8,9,13}). As described above, our RAPD data corresponded to the morphological classification, confirming the close relationship of these 3 species at the genetic level.

The classification of *Tricholoma* species has not yet been completed, although *T. maTsuTake* and related species are widely distributed in the Northern hemisphere. Several species were included in *T. caligaTum* which is distributed in North and Central America, Europe and North Africa^{5,6}). Some

researchers consider that *T. maTsuTake* is an indigenous species in East Asia, but Kytövuori (1988)⁶ stated that it was the synonym of *T. nauseosum* which is one of the species in the *T. caligaTum* group distributed in Europe and North Africa. To define the species and elucidate the phylogenetic relationships of closely related *Tricholoma* species in more detail, it is suggested that DNA analyses, especially RAPD method as indicated in this study, may provide accurate genetic information.

Determination of Optimum Spraying Time for Chemical Control of Mulberry Scale, *Pseudaulacapis pentagona* (Targioni) (Hemiptera: Diaspididae) in Tea Fields

Akio TATARA

Shizuoka Agricultural Experiment Station
(Toyoda, Shizuoka, 438-0803 Japan)

---Abstract-----

Monitoring methods of mulberry scale larvae, *Pseudaulacapis pentagona*, were evaluated for determining the spraying time for effective chemical control. Among them, the ratio of "more than half hatched egg batches" which was found to be suitable due to its accuracy, is, however, time-consuming. Optimum spraying time is defined as the duration of the period required to achieve a ratio of more than half hatched eggs in egg batches (60 to 90%), which is referred to as "more than half hatched egg batches." The use of sticky traps set inside a tea bush to capture crawlers of the mulberry scale is a simple and accurate monitoring method. The optimum spraying time occurs 2 to 5 days after the peak capture of the crawlers by the traps. The traps should be set up from the beginning of the egg hatching period, and should be examined daily or every other day to determine the peak capture of the crawlers. The use of sticky traps for monitoring is suitable for only the first generation of mulberry scale. Thus observations of "more than half hatched egg batches" are needed to determine the optimum spraying time for the second and third generations of the mulberry scale.

Discipline: Insect pest / Tea industry

Additional key words: sticky trap, crawler, egg batch

(Received for publication, December 4, 1998)

---Introduction-----

The mulberry scale, *Pseudaulacapis pentagona* (Targioni), has been a serious pest of tea in Japan. Outbreaks have been reported sporadically since 1955 in Shizuoka Prefecture³). Recently an outbreak was reported in 1994-1996 and the scales occurred in 40% of the tea-cultivated area in Japan²). The scale population frequently breaks out and occasionally even kills tea hosts. Three generations can occur per year in central Japan. The female lays eggs under her shell. The crawlers, i.e. walking first instar larvae, just after hatching walk out from under the shell. After 30 m to 11 h, the crawlers settle on tea branches and molt to the succeeding developmental stage within 15 days³).

It is difficult to find the crawler scale in the tea fields because the mulberry scale lives only on branches inside the tea bushes and the body size of the crawler is very small (0.2 mm). However, in the case of the mulberry scale, the effective period for pesticide application is very short⁹). Even if farmers detect the occurrence of this scale, it is difficult to determine the time of optimum control. Three monitoring methods were suggested to determine the spraying time for mulberry scale. These methods were evaluated in terms of accuracy and simplicity.

---Effect of insecticide application to mulberry scale-----

Generally, chemical control for scale insects is applied to larvae and adults. In the case of the larvae, it is effective only for young ones. Therefore chemical control methods for adult scales which do not involve a selection of the spraying time were examined. Spraying of petroleum oil during winter enabled to control effectively the arrow-head scale, *Unapsis yanonensis* (Kuwana), which is a kind of armored scale, that injures citrus⁷). However, the control by the use

of some pesticides including petroleum oil in the case of the adult female of mulberry scale in winter is less effective than in the case of the larvae¹²). Though fumigation with hydrocyanic acid gas applied to the adult of the mulberry scale and the arrow-head scale is effective^{4,6}), this method is very dangerous to man and its application is not realistic presently.

Some of the insect growth regulators and organophosphates are known to be effective insecticides against the larval stage of armored scales. The optimum period of pesticide application lasts for more than 4 weeks for the California red scale, *Aonidiella aurantii* (Maskell)¹⁴). Organophosphates are effective for the control of the first and the second instar larvae and also for that of the immature adults of the arrow-head scale¹¹). Many insecticides have been tested for the control of the mulberry scale. Some insecticides (e.g. buprofezin and methidathion) are effective against the larvae of the mulberry scale. However, the optimum period of application of these insecticides is very short and the effectiveness markedly decreases when spraying is performed 6 days after the optimum time⁹). Therefore, since pesticide control of the mulberry scale is more difficult than that of the California red scale or arrow-head scale, it is important to determine the spraying time for the control. Consequently, accurate and efficient monitoring methods are required for determining the optimum spraying time.

---Monitoring methods for insecticide application-----

1) *Observation of the number of crawlers*

Pesticides should be applied during the period of egg hatching³). A farmer goes to his tea fields and observes the walking crawlers on the tea branches. Pesticides should be applied when the farmer finds many crawlers on the branches. This is the easiest method. Alternatively, a farmer brings the branches with mulberry scale females to his house from his tea fields. Spraying of pesticides should be performed when the farmer observes the crawlers on the branches in water¹).

2) *"More than half hatched egg batch ratio"*

It is time-consuming to count the number of hatched eggs that would be statistically significant for calculating the hatchability. This is a simple method in which the ratio of "more than half hatched egg batch" is measured⁸). The female scales are observed under a microscope after their shells are peeled off using pointed tweezers. A group of eggs laid by one female is defined as one egg batch. If one or more eggs in one egg batch have hatched, the term "hatched egg batch" is used. If more than 50% of the eggs in one egg batch have hatched, the term "more than half hatched egg batch" is used. More than 100 live females in a tea field are required for this survey¹³).

Table 1 shows the effect of applications of two kinds of pesticides (buprofezin 25W and methidathion 40E) on different days at short intervals and the ratio of "more than half hatched egg batches" on the day of pesticide application. The most effective date for pesticide application was May 26 for both insecticides based on the colony number of male cocoons. The numbers in the plots sprayed with Buprofezin were small on May 23 and June 1. The colony numbers in the methidathion plots were small when spraying took place on May 26 and 30. Many colonies were observed in both sprayed plots on June 1. Therefore, the effective duration of safe application of these insecticides for the control corresponded to the period around May 26 to 30 in this test. The ratio of "hatched egg batches" reached a value of 100% before the optimum spraying time, while the ratio of "more than half hatched egg batches" increased slightly from May 23 to 26. Therefore it is assumed that the ratio of "more than half hatched batches" is a useful index for determining the duration of the optimum control time. And the effective period of pesticide application coincides with a ratio of "more than half hatched batches" ranging between 60 to 90%.

Table 1. Optimum spraying time for *P. pentagona* control¹³)

Pesticide ^{a)}	Spraying date	Ratio of "more than half date hatched egg batches" on spraying day(%)	Mean number of colonies of male cocoons on June 20 ^{b)}

Buprofezin 2.5 ppm	May 23	25.0	2.75
Buprofezin	May 26	59.0	0.25
Buprofezin	May 30	94.9	2.40
Buprofezin	June 1	95.2	0.95
Buprofezin	June 5	100.0	14.35
-----	-----	-----	-----
Methidathion 4 ppm	May 23	25.0	10.6
Methidathion	May 26	59.0	6.65
Methidathion	May 30	94.9	6.80
Methidathion	June 1	95.2	22.95
Methidathion	June 5	100.0	30.30
-----	-----	-----	-----
Unsprayed	-		30.90

a): 1,000 L per 10 a were sprayed to each plot.

b): When male cocoons covered a large part of the tea branch, male cocoons 2 cm long were counted and defined as one colony.

3) Capture of crawlers by sticky traps

The crawlers of scale insects have been shown previously to disperse passively by the wind^{5,10,15}. They can be caught by sticky traps. Ozawa (1994a)⁸ who used a small sticky card trap (10×10 cm) placed inside the tea bush to monitor the crawlers and the male adults, tried to predict the optimum spraying time for chemical control by trap catches and the ratio of hatched eggs ([Fig. 1\(33KB\)](#)). Since both the number of captured crawlers by the traps and the hatchability increased rapidly during a period of about 10 days, more detailed data are necessary to determine the optimum spraying time.

[Fig. 2\(44KB\)](#) shows the changes in the numbers of captured crawlers using the Ozawa trap and hatching ratio of egg batches for the first generation at short intervals¹³. The results of the survey conducted in 1995 are shown in Table 1. The optimum spraying duration in 1995 during the period between May 26 and 30 corresponded to the period of 1 to 5 days after the peak of crawler captures. In 1996, the duration of period when the ratio of "more than half hatched egg batches" reached values of 60 and 90% corresponded to the period of June 5 to 10. This period corresponded to 2 to 7 days after the peak of the trap catches. Though the dates of the optimum spraying period and the peak of trap catches were different in 1995 and 1996, the optimum spraying time can be estimated from the peak of trap catches of the crawlers.

[Fig. 3\(50KB\)](#) shows the changes in the numbers of catches and hatching ratio of the egg batches for the second generation. The optimum spraying time was estimated to occur around August 1 based on the ratio of "more than half hatched egg batches." While the traps captured the crawlers on July 24 initially, the peak occurred on July 28. Since the difference in the number of catches between July 24 and 28 was not appreciable, it is difficult to detect the peak of trap catches in this case. In 1996, the optimum spraying time was estimated to occur from August 5 to 8 based on the 60 to 90% ratio of "more than half hatched egg batches." It is difficult to detect the peak because the number of trap catches markedly fluctuated from the trap setting. Based on the results obtained in both years for the second generation, it is difficult to detect the peak date from the changes in trap catches. The peak date of trap catches could be detected in the third generation in 1995, while crawlers were not caught in the traps in 1996. Therefore it is difficult to determine whether the sticky traps are useful to estimate the optimum spraying time for the third generation based on the results of both years ([Fig. 4\(26KB\)](#)).

The hatching duration of crawlers is longer in the second and third generations than in the first generation. It is very difficult to control the mulberry scale in the second and third generations with insecticides because the hatching of eggs continues for a long period. Even though monitoring by using sticky traps is possible only for the first generation, this method is suitable because the control of the first generation of the mulberry scale is very important to achieve further control.

Ozawa⁸) indicated that the optimum spraying time of the mulberry scale by sticky traps under the plucking surface of the tea tree corresponded to 5 days after the first catch by the trap. However, it is preferable to determine the pesticide application date based on the peak number of crawlers caught in the sticky traps. The optimum spraying time was 1 to 5 days after the peak of the trap captures in 1995 and 2 to 7 days in 1996 (Fig. 2). Considering the safety of the effect of chemical control, the period of optimum spraying time should corresponded to 2 to 5 days after the peak.

[Fig. 5\(27KB\)](#) shows simulations of different intervals of trap changes using an actual data set¹³). The actual peak of the number of captured crawlers occurred on May 25. In the case of two-day intervals, if the traps are set on May 19 or 20, the peak occurred on May 25 or 26 and the optimum duration of spraying corresponded to May 27 to 30 or May 28 to 31, respectively. In the latter case, since the peak was detected on May 28, preparations for the control can be made. In case of three-day intervals, if the traps are set on May 19, 20 or 21, the peak may occur on May 25, 26 or 27, respectively. When the peak occurred on May 27, the optimum spraying time should take place during the period from May 29 to June 1. But, in this case, the peak day can not be determined until May 30 when the next traps are set up. Since the actual period for optimum spraying to control the mulberry scale corresponded to May 27 to 30, preparations for the control cannot be made at that time. Therefore, traps should be changed daily or every other day.

---Evaluation of monitoring methods for optimum spraying time-----

The method involving only observations is the easiest and required little time. However, this method is not accurate since the results depend on the farmers' individual perception. For example, when a few percents of crawlers come out from the female shell under a high density of females, a farmer may make a mistake in deciding to spray due to the observation of a large number of crawlers. Though the observations of "more than half hatched egg batches" are accurate to determine the optimum spraying time for the control of the mulberry scale, this procedure is time-consuming.

Monitoring using sticky traps placed under the plucking surface of the tea tree requires less time than monitoring of the egg hatching ratio. The adhesive sheet (8 x 10 cm) is stuck on both sides of an acrylic card (10 x 10 cm) which is used as a sticky trap. The traps are placed vertically at 10 cm under the plucking surface of the tea canopy ([Fig. 6\(31KB\)](#)). The traps face the same direction as the tea hedge. The new traps were set in the same position after trap change. Captured crawlers are counted under a microscope. The sticky traps may enable to capture the crawlers over a wide area of tea fields. Since this monitoring method is not suitable for the second and the third generations, it is useful for the purpose of decision making for pesticide application only for the first generation of the mulberry scale. It is considered that the observation of egg hatching is necessary for the second and the third generations to identify the optimum spraying time.

目的 Objetivo

El proyecto de "Estudios Comprensivos sobre el Mejoramiento, Producción y Utilización de la soja en América del Sur" tiene designado expertos de diferentes especialidades en la Argentina, Brasil y Paraguay, siendo asignado al Paraguay los estudios referentes a medidas de control de nematodos.

El nematodo del quiste, es una plaga muy severa para la soja, está apareciendo en los países vecinos, Argentina y Brasil, no registrándose aún en el Paraguay; en el Ministerio de Agricultura y Ganadería(M.A.G.) se esta llevando a cabo actividades para informar y advertir, de modo a prevenir cualquier ingreso casual.

Además de nematodo del quiste, se están realizando estudios de otras especies de nematodos de la soja, observándose sus distribuciones, hábitos y respectivos medios de control.

線虫 Nematodo

Que es un nemátodo?

El nemátodo pertenece a la clase de los gusanos no metaméricos, con cuerpo redondo y alargado correspondiendo al grupo menor de las lombrices, cuyas estructuras se encuentran en una bolsa tubular donde se incluyen los órganos de reproducción y digestión.

Desde el punto de vista agronómico, los que causan daños son aquellas especies que parasitan las plantas, siendo estas imperceptibles; en todo el mundo son conocidas mas de 2000 especies de estos parásitos, siendo 15 géneros, 45 especies las que perjudican a la soja. Según estudios realizados en el año 1998, se han encontrado 8 generos, 9 especies en 7 departamentos del Paraguay.

Con el microscopio se observan los nemátodos, como en la imagen de arriba.

Como es el nemátodo del quiste?

La hembra en estado joven, su piel se vuelve liso y fuerte, formando una bolsa dentro de la cual oviposita para posteriormente perecer; esta situación se lo conoce como quiste.

El nemátodo del quiste, igual que el de las agallas queda dentro de la planta; con el avance del estado larval, su cuerpo sale mas de la mitad quedando la cabeza dentro de la raíz, en estos instantes si se extrae la raíz, se puede observar el cuerpo en forma de granos blancos. Estas adultas a medida que maduran, el color de la piel se convierte del blanco al color crema, luego al marrón, momento en el cual el, quiste se desprende separándose de la raíz de la soja.

Al quiste parásito de la soja se lo denomina nemátodo del quiste de la soja (*Heterodera glycines*) conociéndose en total 16 razas.

La soja una vez germinada, exuda una substancia denominada Glycinoeclepin A, el cual estimula la rápida eclosión del huevo del nemátodo. La larva recién eclodida, penetra en la raíz de la soja repitiendo su ciclo igual que el nemátodo de las agallas (*Meloidogyne spp.*), a diferencia que no forman agallas.

El área de ataque del nemátodo del quiste de la soja es estrecho, atacando solamente cuatro especies de leguminosas. Cuando no existen estas 4 especies, entran en estado de dormencia por tiempo prolongado, en cuyas situaciones llegan a sobrevivir por más de diez años, la soja que fue atacada con esta especie, no consigue desarrollar nódulos del rhyzobium impidiendo el suministro de Nitrógeno, cuya consecuencia se observa en el bajo rendimiento.

Los daños son relacionados con la densidad del nemátodo en el momento de la siembra; si existe mas o menos 7 huevos en un gramo de suelo, disminuye el rendimiento en 5%.

Preguntas o comentarios con respecto a este sitio esperamos su E-Mail : jircas@foznet.com.br

試験内容 Estudio

En el año 1998, se hizo un estudio de suelo en los departamentos más cercanos a Brasil y Argentina que son: Amambay, San Pedro, Canindeyu, Alto Paraná e Itapúa, el nemátodo del quiste no se a detectado en ninguno de las muestras. Pero si aparecieron otras especies, que actualmente estamos realizando el estudio de control.

De esta forma se realizan los estudios de control, con los suelos extraídos de diferentes departamentos.

En esta sala se realiza la separación del nematodo del suelo, por método de berman, para luego examinar con el microscopio.

試験結果 Resultado

Según estudios realizados en el año 1998, se han encontrado 8 géneros, 9 especies en 7 departamentos del Paraguay. De estos 7 departamentos les vamos a presentar el resultado de 4 géneros en 5 departamentos.

Los lugares que están en color rojo, son los 5 departamentos que recorrimos.

a=Amambay, b=Canindeyú, c= San Pedro, d=Alto Parana, e=Itapua

Meloid.: *Meloidogyne*,
 Pratyf.: *Pratylenchus*,
 Rotyle.: *Rotylenchulus*,
 Helico.: *Helicotilenchus*

Como se ve en el resultado no se a detectado el nemátodo del quiste en Paraguay. Pero, en el transcurso del tiempo existen posibilidades de que ingresen por medio de máquinas contaminadas.

Para el control del cultivo cuando se observen la aparición de este nemátodo, se debe evitar el monocultivo, introduciendo aquellas que no sean hospederos (como maíz) y la introducción de plantas trampas tales como abonos verdes (tagetes o botón de oro, crotalaria, sorgo, avena, etc.) y mínimo dejar dos zafras para nuevamente cultivar la soja.

Si se dispone de variedades resistentes al quiste, se recomienda averiguar primeramente las razas de nemátodos existentes para proceder a la elección de los cultivares resistentes.

a=Amambay, b=Canindeyu, d=Alto Parana, e=Itapua, f=Misiones

El resultado de arriba es del año 1999, no se a encontrado el nemátodo del quiste.

En comparación al grafico de anterior aparece nuevo departamento que es Misiones.

Research Highlights No.8•@(2000)

Contents

[1. China's WTO accession and its impact on domestic agriculture](#)

Research Information Division

[2. Genetic difference of resistance to Fusarium head blight in Japanese and Chinese wheat cultivars, Nobeokabouzu-komugi and Sumai 3](#)

Biological Resources Division

[3. Antisense suppression of proline degradation improves environmental stress tolerance in *Arabidopsis*](#)

Biological Resources Division

[4. The Nitrogen cycle for agricultural production in Khon Kaen province in Northeast Thailand](#)

Environmental Resources Division

[5. N balance in the grassland and in the soybean field, Brazil](#)

Environmental Resources Division

[6. Stimulated methane emission from a rice paddy under elevated atmospheric CO₂](#)

Environmental Resources Division

7. A method to retrieve snow depth and its melting condition

Environmental Resources Division

8. Varietal resistance to the whitebacked planthopper in Chinese japonica rice

Crop Production and Postharvest Technology Division

9. Evaluation of Indonesian soybean varieties for tofu and Tempe processing

Crop Production and Postharvest Technology Division

10. Isolation of white-spored mutants from the koji molds for the production of Kecap, an Indonesian soy sauce

Crop Production and Postharvest Technology Division

11. Alley cropping on the sloping upland field in Northeast Thailand

Crop Production and Postharvest Technology Division

12. Subsoiling treatment on the sloping upland field

Crop Production and Postharvest Technology Division

13. No-tillage cultivation of crops on the sandy upland field in Northeast Thailand

Crop Production and Postharvest Technology Division

14. Effects of mechanical weeding on the dominant upland weeds in Northeast Thailand

Crop Production and Postharvest Technology Division

15. Optimum seed rates in wet seeded rice culture in the Mekong Delta of Vietnam

Crop production and Postharvest Technology Division

16. Selection of soybean varieties, non-host crop and antagonistic plant for nematode control in Paraguay

Crops Production and Postharvest Technology Division

17. Inhibition of the adipocyte differentiation of 3T3-L1 by an amino acid derivative in fermented foods

Crop production and postharvest technology division

18. The roles of tumor necrosis factor alpha (TNF α) in genetic resistance of mice to *Trypanosoma congolense* infection

Animal Production and Grassland Division

19. Seeds of forage legume esparcet of Kazakhstan have a local seed size and high allelopathic activity

Animal Production and Grassland Division

20. Dry matter productivity and forage quality of *Panicum maximum* pastures established in agropastoral systems

Animal Production and Grassland Division

21. Nutritional diagnosis of sulfur in soybean plants

Research Information Division

22. Low impact harvesting method for tropical natural forests

Forestry Division

23. Decrease of organic waste by the polyculture of giant tiger prawn and green mussel

Fisheries Division

24. Purification of the wastewater from aquaculture ponds using the mangrove ecosystem

Fisheries Division

25. Alleviation of the incidence of internal tipburn in Chinese cabbage by subsurface drip fertigation

Okinawa Subtropical Station

26. Complete nucleotide sequence and genetic organization of papaya leaf distortion mosaic virus RNA

Okinawa Subtropical Station

27. Molecular cloning of Na⁺-ATPase cDNA from a marine alga, *Heterosigma akashiwo* (Sodium-pump in plant cell)

Okinawa Subtropical Station

28. Simple crossing method of snap bean using physiological pollen sterility caused by high temperature treatment

Okinawa Subtropical Station

29. Occurrence of male sterile cytoplasm in 'Kurodane Kinugasa' snap bean

Okinawa Subtropical Station

30. Distinction of sucrose phosphate synthase loci in sugarcane

Okinawa Subtropical Station

Title : China's WTO accession and its impact on domestic agriculture

Division : Research Information Division

Author : Akihide IKEGAMI

Key Words : China, WTO, Agriculture

Synopsis : The day is not far distant when China joins WTO. So we need to evaluate the impact of WTO accession to Chinese agriculture. In this research, we try to investigate the impact of assumption that (1) Chinese government observes "Agreement on Agriculture" of WTO, (2) adoption of tariff-rate quotas in major crops and tariff reductions of other agricultural products depend on U.S.-China WTO Accession Agreement.

7. 結論と今後の課題

本研究では、SSM/I の 19GHz 垂直偏波と 37GHz 垂直偏波の輝度温度差を用いて、積雪深を推定した。本研究で得られた結果は、観測された積雪深とよく一致していることが確認された。また、積雪の融解過程においても、この手法が適用できることが示された。今後の課題として、観測データの品質向上と、積雪深推定の精度向上が挙げられる。

1. Title : China's WTO accession and its impact on domestic agriculture

Division : Research Information Division

Author : Akihide IKEGAMI

Key Words : China, WTO, Agriculture

Synopsis : The day is not far distant when China joins WTO. So we need to evaluate the impact of WTO accession to Chinese agriculture. In this research, we try to investigate the impact of assumption that (1) Chinese government observes "Agreement on Agriculture" of WTO, (2) adoption of tariff-rate quotas in major crops and tariff reductions of other agricultural products depend on U.S.-China WTO Accession Agreement.

2. Title : Genetic difference of resistance to Fusarium head blight in Japanese and Chinese wheat cultivars, Nobeokabouzu-komugi and Sumai 3

Division : Biological Resources Division

Author : Tomohiro BAN

Key Words : disease resistance, doubled haploid, Fusarium head blight (Scab), integration of resistance genes

Synopsis : Fusarium head blight (FHB, scab) caused by *Fusarium graminearum* is one of the most destructive diseases of wheat in areas where the weather is warm and humid after the heading of wheat. It reduces grain yield and quality due to grain shriveling. FHB also produces mycotoxins harmful to animals and human health, such as deoxynivalenol (DON), nivalenol (NIV), T-2 toxin, zearalenone (ZEA) and their derivatives. For controlling this disease, host resistance should be considered. Repeated screening of the genetic resources led to the identification of several resistant cultivars of spring wheat, such as Shinchunaga, Nobeokabouzu-komugi and Nyubai from the Japanese gene pool. Sumai 3, Ning 7840 and CIt 11028 were also identified as resistant cultivars to FHB from the Chinese gene pool. The genetic constitutions of sources of resistance to FHB originating from different gene pools, however, have not yet been elucidated. It is essential to study the genetics of the resistance to FHB, including the identification of the genes responsible for resistance to FHB in several gene pools, so that different genes can be combined to improve the overall resistance of wheat. The objectives of the present study were to examine the difference in genetic constitution of resistance to FHB between Nobeokabouzu-komugi and Sumai 3 using doubled haploid lines (DHLs) derived from F1 cross.

From the cross combination of both highly resistant cultivars, transgressive segregants with the reaction of moderately resistant to FHB were found. Both parents seem to have at least one common gene for the resistance, because no DHL with the susceptible class was segregated. Chi-square test indicated that the segregation for the reaction to FHB fitted a three-gene model (7 R : 1 MR) in the population (Table 1 and Fig. 1). It is suggested that Nobeokabouzu-komugi have three dominant genes for the resistance, of

which two are unique and the another gene is identical to that of Sumai 3. This finding presents an important promise for pyramiding resistance genes from different genetic background. Furthermore, many lines with very high level of resistance combining genes from the both parents have been selected for possible use as parental lines.

3. Title : Antisense suppression of proline degradation improves environmental stress tolerance in *Arabidopsis*

Division : Biological Resources Division

Author : Kazuko YAMAGUCHI-SHINOZAKI

Key Words : Proline, Transgenic plant, Antisense, Freezing tolerance, Salinity tolerance

Synopsis : Many plants accumulate free proline (Pro) in response to environmental stresses such as drought, high salinity, and low temperature. P5CS is a rate-limiting enzyme in Pro biosynthesis and ProDH is an enzyme responsible for the first step of Pro degradation. To elucidate essential roles of Pro, we generated antisense transgenic *Arabidopsis* plants with P5CS or ProDH cDNAs. The P5CS antisense transgenic plants accumulated Pro at a significantly lower level than wild-type plants, and were susceptible to osmotic stress. In contrast, the ProDH antisense transgenic plants showed enhanced accumulation of Pro and tolerance to freezing and high salinity. These results will help us to improve crop tolerance to abiotic stresses. The constitutive accumulation of Pro due to inhibition of its degradation may be a promising approach to creating environmental stress tolerant crops.

4. Title : The Nitrogen cycle for agricultural production in Khon Kaen province in Northeast Thailand

Division : Environmental Resources Division

Author : Naruo MATSUMOTO

Key Words : Nitrogen Cycle, Nitrogen Flow, Nitrogen Balance, Crop Residues, Animal Feces

Synopsis : Soils in Northeast Thailand are characterized by a sandy texture and being low in capacity for nutrient supplying. These inherited characteristics typical of a poor fertile soil are the major limiting factors for crop productivity. One possible way to improve soil fertility may be to use locally available nutrient resources such as crop residues and animal feces more efficiently. In order to identify the available resources, it is necessary to quantify nutrient cycle through agricultural activities such as crop and livestock production in the region, and clarify limiting factor for effective utilization of the nutrient resources. In this report emphasis is placed on nitrogen as it is a major nutrient element.

A complete picture of the nitrogen cycle for agricultural production in Khon Kaen province was developed based on data from crop yields, chemical fertilizer application rate, animal feed supply, human food supply, production and usage of crop residues, animal and human feces and garbage, etc. These data were collected from agricultural statistics (1990-92), research reports, study reports, field observation, interview with farmers, and information from Thai researchers.

The nitrogen left as crop residues amounted to 52 kg ha⁻¹ yr⁻¹, out of which 12 kg was fed to animals, 29 kg emitted to the environment by burning, and 11 kg returned to farmland. It is speculated that although crop residues were the main nitrogen resource in the area, the rate of recycling back to the farmland was limited. Animals received 23 kg ha⁻¹ yr⁻¹ of nitrogen from the weeds as feeds besides the crop residues and provided 22 kg ha⁻¹ yr⁻¹ of nitrogen to the farmland as feces, which was 80 % of nitrogen produced as animal feces. The nitrogen withdrawal as crop harvests (30 kg ha⁻¹ yr⁻¹) was more than the nitrogen amendment as animal feces, suggesting that it was not feasible to fulfill the crop N demand only through application of the animal feces because of limited animal husbandry activities in the area. Chemical fertilizer application was limited only to 18 kg ha⁻¹ yr⁻¹ of nitrogen, clearly indicating that local farmers have applied no or low rate of chemical fertilizer to most of the crops even in the recent years. The nitrogen losses through denitrification, leaching, erosion and emission, and nitrogen gains through atmospheric N₂ fixation, irrigation and rainfall were also roughly estimated to draw a nitrogen balance sheet that consequently showed a negative value of 40 kg ha⁻¹ yr⁻¹. Considering that there is still 58 kg ha⁻¹ yr⁻¹ of nitrogen deficit to the farmland, more efficient utilization of available organic resources should be necessary in order to reduce negative value in the nitrogen balance.

5. Title : N balance in the grassland and in the soybean field, Brazil

Division : Environmental Resources Division

Authors : Kenichi KANDA

Key Words : Brazil, Cerrado, N balance

Synopsis : N balance was measured in a continuous grassland and a continuous soybean field, Cerrado in Brazil. Large amount of nitrate was observed to be accumulated in the subsoil of the continuous soybean field. Although N fertilizer was not applied, N balance showed negative values for the continuous grassland as well as the continuous soybean field. The negative values were greater in the continuous soybean field than those in the continuous grassland.

6. Title : Stimulated methane emission from a rice paddy under elevated atmospheric CO₂

Division : Environmental Resources Division

Author : Kazuyuki YAGI

Key Words :

Synopsis : Flooded rice cultivation is considered to be one of the major sources of atmospheric methane. It is pointed out that recent increase in the rice production has contributed to the global warming by increasing methane emissions. Elevated CO₂ in the atmosphere may have a positive effect on the emission increase through accelerating the rate of carbon turnover in rice-soil system. We examined the effect of elevated CO₂ on methane emission from a rice paddy using six

computer-controlled growth chambers. The experiments were conducted for two entire growing seasons of rice in 1998 and 1999. The CO₂ concentration was kept at 350 ppm (ambient) in three of the chambers, and at 650 ppm (elevated) in the other three chambers. Methane emission rates in the chambers were determined by an automated monitoring system.

Seasonal methane emission rates in ambient and elevated conditions were 18.4 and 21.8 g/m², respectively, in 1998. The rates in 1999 were 5.6 and 13.7 g/m², respectively, which were significantly lower than those in 1998, possibly caused by lower application rate of rice straw prior to transplanting rice plants. The results showed that elevated CO₂ increased seasonal methane emission significantly ($P < 0.05$). The increase in the emission rates was mainly observed after the middle growth stage. Elevated CO₂ also increased aboveground biomass of the rice plant.

7. Title : A method to retrieve snow depth and its melting condition

Division : Environmental Resources Division

Authors : Hiroyuki OHNO

Key Words : microwave, SSM/I, snow depth, snow melt

Synopsis : Synopsis: In this study, authors improved the accuracy of snow depth estimation and established an index which represented melting situation of deposited snow from microwave brightness temperature, observed by a space born passive microwave radiometer (SSM/I). A daily dataset consisting of ground measured snow depth and microwave brightness temperature for 339 points over North East Asia, from October 1993 to April 1998 was produced. Data archives produced by NCDC, NSIDC and IMH in Mongolia were used as the data sources.

At most of the points, the difference of brightness temperatures between 19GHz and 37GHz (T) indicated almost linear relationship with snow depth. Its slope and offset did not change much on a year to year basis although they changed markedly from place to place. Based on this fact, a multi-linear formula that determined the parameters from five geographic information (climatic maximum snow depth, vegetation index, polarization index of 37GHz in February, brightness temperature of 19GHz in February, and altitude) was established. Using the pair of raster map of the slope and offset generated with the equation, one can estimate snow depth from satellite image more accurately.

It was found that difference of T in the morning and that in the preceding evening, was able to detect the melting snow pack.

8. Title : Varietal resistance to the whitebacked planthopper in Chinese *japonica* rice

Division : Crop Production and Postharvest Technology Division

Authors : Kazushige SOGAWA

Key Words : Varietal resistance, Whitebacked planthopper, Chinese *japonica* rice

Synopsis : Despite its significant contribution to the rice production increase in 1980's in China, Chinese hybrid rice has caused great changes in insect pest status in the paddy fields, because of its high vulnerability to insect infestations. Among the insect pests, the whitebacked planthopper, *Sogatella furcifera*, has dramatically emerged as a key pest of the hybrid rice. *S. furcifera* infests not only the hybrid rice, but also the japonica rice in Middle China by massive immigrations from the hybrid rice-prone area in South China. There is a growing fear of deterioration of sustainable rice production ecosystem under the increasing insecticide treatments. Insect resistance in rice varieties is an alternative tool to cope with the pest threats, which is compatible with biological and ecological approaches of pest management.

A Chinese japonica rice, Chenjiang 06 (CJ-06), expressed a strong field resistance to *S. furcifera* infestations. The immigrants of *S. furcifera* did not prefer to settle on CJ-06, and failed to establish populations on the variety. Significantly less honeydew excretion by female adults of *S. furcifera* indicated their reluctant sucking on CJ-06 sap. Adult fecundity was reduced to about one third on CJ-06 as compared with susceptible varieties, because of suppressed sap ingestion on CJ-06. Besides, *S. furcifera* eggs suffered from a high mortality in the watery lesions induced at oviposition sites of CJ-06. From these results, field resistance in CJ-06 to *S. furcifera* was explained by two distinct mechanisms, namely the sucking suppression and the ovicidal function. The sucking suppression was the primary cause of the antixenosis of CJ-06 against *S. furcifera* immigrants as well as the antibiosis to reduce fecundity of the inhabitants. The ovicidal function is another antibiotic resistance induced by a specific interaction between CJ-06 and *S. furcifera* eggs.

The sucking suppression and ovicidal function were inherited independently. The F₂ populations from the crosses between CJ-06 and the susceptible TN1 variety were segregated into 4 phenotypes with different combinations of sucking suppression and ovicidal function. The segregation ratios fitted statistically to the theoretically expected ratio of 45:15:3:1, where 2 dominant and 1 recessive genes presumably controlled sucking suppression and ovicidal function, respectively.

Preliminary genealogical analysis indicated that the both resistance traits to *S. furcifera* in CJ-06 were derived conjointly from a single parental line, Xiushui 620. The other parental line, C81-40, had only the ovicidal activity. Sucking suppression and ovicidal resistance in Xiushui 620 were independently inherited from Xiushui 04 and Xianghu 24, respectively.

9. Title : Evaluation of Indonesian soybean varieties for tofu and Tempe processing

Division : Crop Production and Postharvest Technology Division

Author : Sayuki NIKKUNI

Key Words : characteristics of soybean, Indonesian soybean, tofu, Tempe

Synopsis : In the collaborative research project with Research Institute for Legume and Tuber Crops (RILET) of Indonesia, physical, chemical and processing characteristics of 14 Indonesian soybean varieties were investigated. Indonesian soybeans contained much more proteins and less lipids than the soybean samples imported from USA did. One hundred grain-weights of Indonesian soybeans except Argomulyo, Bromo, and Burangrang varieties were lower than those of imported ones. Tofu was

prepared using either glucono- δ -lactone (GDL) or acetic acid as a coagulant. Acetic acid is commonly used as a coagulant in Indonesia. The results obtained in this work showed that protein content of soybean is the most important factor for the hardness and yield of tofu prepared using either GDL or acetic acid. It is clarified that Indonesian soybeans are superior for preparing tofu using either GDL or acetic acid as a coagulant compared to the soybean imported from USA due to their protein contents and whitish color of tofu product. In Tempe making, the 100-grain weight of raw soybeans was found to be the most important factor for both yield and sensory evaluation of Tempe. An Indonesian soybean variety that has a 100-grain weight of around 15 grams as imported soybeans do was found to be suitable for Tempe processing.

10. Title : Isolation of white-spored mutants from the koji molds for the production of Kecap, an Indonesian soy sauce

Division : Crop Production and Postharvest Technology Division

Authors : Sayuki NIKKUNI

Key Words : Kecap, Tauco, koji, aflatoxin, *Aspergillus* , white-spored mutant, inoculum

Synopsis : A collaborative joint research work between JIRCAS and Research Institute for Legume and Tuber Crops (RILET) on improvement of fermented soybean food, Kecap, was conducted at RILET in Indonesia. Koji samples were collected from Kecap and Tauco factories in Java Island. Aspergillus was the dominant mold genus in five out of six koji samples, while one sample contained Mucorales as dominant fungi. Aspergillus contributed to hydrolysis of soybean proteins much more than the Mucoraceous fungus isolated from Tempe starter did. Although no aflatoxin was detected in these koji samples, two isolates out of 24 isolates from the Kecap and Tauco koji samples produced aflatoxins. In order to develop a pure culture starter for Kecap koji making, white-spored mutants were isolated by UV-irradiation from the selected Aspergillus strains. All white-spored mutants were proved to be aflatoxin-negative. The Kecap koji prepared by inoculating the mutant could be distinguished from that prepared by inoculating the original koji mold strain or the aflatoxin producer by developing a typical white color spores during koji making. The formol nitrogen contents of the Kecap mashes prepared by using white-spored mutants were almost same as those of prepared using original strains. Therefore, it is expected that a white-spored mutant can be applied as a starter for Kecap koji making from the standpoint of food safety.

11. Title : Alley cropping on the sloping upland field in Northeast Thailand

Division : Crop Production and Postharvest Technology Division

Authors : Nobuyuki KABAKI

Key Words : Alley cropping, *Leucaena leucocephala*, Pruning

Synopsis : A model field for alley cropping (0.5ha:50x100m) was set up with a leguminous tree species, *Leucaena leucocephala*, on the contour lines in the 5% sloping field in Northeast Thailand to prevent erosion and to supply organic materials into upland fields. Growth of crops (sweet corn, mungbean etc.) was evaluated at various distances from trees. Shading by tree canopy in rainy season and depletion of water by roots of trees in dry season were the main obstacles to crop growth when the trees and crops were planted closely. Width of tree rows was recommended to be 20m in view of crop production, mechanized crop management and prevention of soil erosion. Pruning of alley trees and subsequent supply of organic materials were effective to improve soil properties. Regeneration of twigs after pruning followed a similar pattern as that of the annual rainfall, and the appropriate frequency of pruning was three times in a year to save the labor under the sequential crop cultivation through rainy and dry season.

12. Title : Subsoiling treatment on the sloping upland field

Division : Crop Production and Postharvest Technology Division

Authors : Nobuyuki KABAKI

Key Words : Subsoiling, Soil moisture, Soil hardness

Synopsis : Subsoiling treatment was conducted at the beginning of rainy season by cracking soil layer (50~60cm depth) in the direction of contour lines in the sloping upland field. It was effective to accumulate running rain water leading to a higher moisture content in the deep layer of soil in dry season. Soil hardness was also reduced by subsoiling treatment reflecting higher soil moisture. Growth of crops was accelerated owing to the availability of water, which was more distinctive in dry season cultivation. In addition, enhanced physiological activities in the leaves as indicated by leaf color index and transpiration were also noticed. Combination with no-tillage cultivation was recommended in order to withdraw maximum advantage from the treatment.

13. Title : No-tillage cultivation of crops on the sandy upland field in Northeast Thailand

Division : Crop Production and Postharvest Technology Division

Authors : Nobuyuki KABAKI

Key Words : No-tillage, Erosion, Soil moisture

Synopsis : No-tillage cultivation of seed crops (maize, legumes, etc.) is a promising technique to develop a large scale production on the sandy soil in Northeast Thailand. No-tillage seeding alleviated busy and laborious odd jobs for land preparation at the beginning of rainy season, and prevented soil erosion which was commonly observed after the tillage of fields. It was also effective to preserve soil moisture in dry season due to the undisturbed soil condition. The growth of crops in no-tillage was generally superior to that in tillage seeding. In rainy season, crust formation on the soil surface inhibited the growth in tillage seeding. The higher soil moisture in no-tillage contributed to a vigorous growth in dry season. A no-tillage seeder with rotary disk and drill seeder was manufactured and tested for applicability, which

worked Satisfactorily on the sandy soil performing accurate grooving and seeding.

14. Title : Effects of mechanical weeding on the dominant upland weeds in Northeast Thailand

Division : Crop Production and Postharvest Technology Division

Author : Nobuyuki KABAKI

Key Words : Mechanical weeding, *Richardia scabra*

Synopsis : Mechanical weeding with the use of small rotary tiller attached to soil manipulator was effective to control a dominant upland weed, *Richardia scabra* L in Northeast Thailand. Inter-tillage between the row of crops could be conducted at a walking speed (1.6 m/min) alleviating the hard labor for hand weeding. Weeds lost the water content after uprooting and eventually withered to death. In the field condition, 2~3 hours was enough to reach this critical water deficit, which could be used as a criterion of operation under variable weather conditions. We also observed the difference in the effects of mechanical weeding on the growth of crops and weeds. The fast growing crops such as sorghum and pearl millet were more tolerant to weeds, and the frequency of weeding could be reduced compared to that for relatively slow growing crops such as sweet corn and mungbean. Proliferation of weeds was also suppressed by the former crops.

15. Title : Optimum seed rates in wet seeded rice culture in the Mekong Delta of Vietnam

Division : Crop production and Postharvest Technology Division

Author : Hiroyuki HIRAOKA

Key Words : Wet seeded rice culture, Double cropping, Triple cropping, Seed rate, , Mekong Delta, Vietnam

Synopsis : Double and triple cropping in wet seeded rice culture(WSC), which is broadcasting the pre-germinated seeds on the wet soil after the land preparation and draining out the standing water on the paddy fields, is predominant in the Mekong Delta area. The rice yields per hectare in the WSC have been stagnated since 1995. A feature in the WSC is to use seed rates as high as 200 to 300kg ha⁻¹ . So, we tried to identify the optimum seed rates in order to increase the yields per hectare and decrease the seed rates. The field trials on the seed rates were carried out in the fields at Cuu Long Delta Rice Research Institute and two other sites in Can Tho Province. Number of panicles per m² significantly decreased as the seed rates decreased from the conventional one (200kg ha⁻¹) in both dry and wet seasons. In contrast, the filled grains per panicle significantly increased as seed rates decreased from the conventional one in both seasons. As the 1000 filled grains weight at different seed rates were almost same, the grain yields at different seed rates were decided by the number of filled grains per m² . The

highest yields were obtained at the seed rates from 50 to 100 kg ha⁻¹ in both seasons. However, taking the establishment of sufficient number of seedlings into consideration, 80 to 100 kg ha⁻¹ were recommended as the practical seed rates. The recommended seed rates also have another advantage of saving 1/2 to 1/3 of the conventional seed rates. It is important that the seed rates should be applied to the paddy fields with smooth land level, and good irrigation and drainage facilities, and to the renovated farmers.

16. Title : Selection of soybean varieties, non-host crop and antagonistic plant for nematode control in Paraguay.

Division : Crops Production and Postharvest Technology Division.

Author : Kei SHIMIZU

Key Words : *Meloidogyne javanica*, *Pratylenchus coffeae*, *Rotylenchulus reniformis*, soybean, control, Paraguay.

Synopsis : Five soybean varieties for *Meloidogyne javanica* control, one soybean variety, one non-host crop and one antagonistic plant for *Pratylenchus coffeae* control, three soybean varieties and one non-host crop for *Rotylenchulus reniformis* control were selected.

17. Title : Inhibition of the adipocyte differentiation of 3T3-L1 by an amino acid derivative in fermented foods

Division : Crop production and Postharvest Technology Division

Author : Kazuhiko NAKAHARA

Key Words : 3T3-L1, adipocyte, differentiation, fermented food, soybean, MTCA

Synopsis : The inhibitory activity toward the adipose differentiation of 3T3-L1 preadipocyte was determined for ten kinds of fermented foods. A promising activity was detected in the methanolic extracts of miso (fermented soybean paste), soy sauce, tau-jaw (fermented soybean in Thailand, semi-liquid) and su-fu (fermented tofu). Two compounds were isolated from miso as the active principle. They were identified as (-)-(1*S*, 3*S*)- and (-)-(1*R*, 3*S*)-1-methyl-1, 2, 3, 4-tetrahydro- β -carboline-3-carboxylic acid. The morphological change in 3T3-L1 adipose differentiation was suppressed in the presence of these compounds. The induction of glycerol-3-phosphate dehydrogenase was suppressed to 55.9 \pm 3.1% and 44.9 \pm 2.7% by (1*S*, 3*S*)-MTCA and (1*R*, 3*S*)-MTCA, respectively, at a concentration of 20 μ g/ml.

18. Title : The roles of tumor necrosis factor alpha (TNF α) in genetic resistance of mice to *Trypanosoma congolense* infection

Division : Animal Production and Grassland Division

Author : Hiroshi KITANI

Key Words : trypanosomiasis, genetic resistance, tumor necrosis factor alpha, mice

Synopsis : To extend observations on the roles of tumor necrosis factor alpha (TNF α) in murine genetic resistance to trypanosomiasis, TNF α -gene knockout mice (on a C57BL/6 background) and C57BL/6 wild-type mice were infected with *Trypanosoma congolense* IL 1180. As reported previously, TNF α -deficient mice are highly susceptible to *T. congolense* infection with a mean survival time of 35 days in this study, while the wild-type mice had a mean survival time of 91 days. TNF α -deficient mice showed significantly higher parasitaemia levels than the wild-type mice and they also failed to develop germinal centers in the peripheral lymphoid organs. However, production of *T. congolense*-specific immunoglobulin M (IgM) and IgG was similar in the two mouse strains. Hepatic acute phase proteins, including ceruloplasmin, α 1-acid glycoprotein and serum amyloid P were induced similarly in knockout and wild-type mice. These findings indicate that TNF α contributes to control of parasitaemia during experimental *T. congolense* infection in mice. Further studies will be needed to determine whether TNF α controls *T. congolense* parasitaemia in mice directly or indirectly.

19. Title : Seeds of forage legume esparcet of Kazakhstan have a local seed size and high allelopathic activity

Division : Animal Production and Grassland Division

Author : Kenzi SATO

Key Words : Allelopathy, Esparcet, Germination, Kazakhstan, Legume, Locality, Seed size

Synopsis : Esparcet (*Onobrychis* spp.) is cultivated in Central Asia and is an important legume for soil fertilization and for feeding. We evaluated the germination and allelopathic activity of the esparcet seed produced in Kazakhstan. An individual plant of esparcet has many seeds, but one seed is in one pod. These seeds have a local morphology including seed size. The germination of esparcet seed without pod was faster than that of seed within the pod. In checking allelopathic effect using the sandwich method (Fujii and Shibuya, 1991), allelopathic activity of seed without pod was much higher than those of seed with pod and only pod. These results will help us in establishing a technology of esparcet in connection with weed control using the allelopathy.

20. Title : Dry matter productivity and forage quality of *Panicum maximum* pastures established in agropastoral systems

Division : Animal Production and Grassland Division

Author : Tsutomu KANNO

Key Words : Crude protein, Digestibility, Dry matter productivity, *Panicum maximum*

Synopsis : Dry matter productivity and forage quality were evaluated for *Panicum maximum* pastures established after 4 years of consecutive soybean cultivation in the summer (PM-SO), and 4 years of rotation of soybeans in the summer and millet for winter grazing (PM-MI). In the PM-SO pasture, dry matter production was much higher than that in the PM-MI pasture, and the content of crude protein and digestibility of the aboveground plant parts of PM-SO were also higher than those of PM-MI counterparts. It was considered that the cropping sequence before the pasture establishment affected the soil nitrogen fertility, which resulted the differences in the forage productivity and quality of the two *P. maximum* pastures.

21. Title : Nutritional diagnosis of sulfur in soybean plants

Division : Research Information Division

Author : Kiyoko HITSUDA

Key Words : Soybean, Criterion of sulfur concentration, Protein composition, Sulfur concentration in soybean plants

Synopsis : Soybean cultivation is expanding rapidly into the northeastern areas of Brazil and a study on soil fertilization in the region is necessary to serve as a basis for soil management. The criteria to maintain appropriate contents of nutrient elements in the plants should be studied. The supply of sulfur (S), manganese (Mn), zinc (Zn), boron (B) and copper (Cu) in two cerrado soils of the region was studied. The first limiting factor for soybean growth was S-deficiency in both the soils. The S concentration in the 3rd leaf at the flowering and in the grains at harvesting varied in a 1:1 ratio. Both concentrations were categorized from a point of grain production and of its protein composition. The classification was as follows: Severly lacking in case less than 1.0 g/kg; lacking at the range from 1.0 g/kg to 2.0 g/kg; low from 2.0 g/kg to 2.3 g/kg; and the normal at more than 2.3 g/kg. To obtain a satisfactory yield, the sulfuric material should be applied until the S concentration in 3rd leaf and/or grains becomes as high as 2.3 g/kg.

22. Title : Low impact harvesting method for tropical natural forests

Division : Forestry Division

Author : Shozo SASAKI

Key Words : Reduce impact logging, harvesting method, tropical forests

Synopsis : To reduce harvesting impacts of selective cutting operations in tropical natural forests, we are conducting the following studies; 1. Examination of soil compaction caused by bulldozer logging operations, and the effect of controlled felling direction, 2. Development of new cable yarding system using mobile tower yarder, which has an advantage in harvesting impacts over conventional system.

23. Title : Decrease of organic waste by the polyculture of giant tiger prawn and green mussel

Division : Fisheries Division

Author : Junya HIGANO

Key Words : Giant tiger prawn, green mussel, organic matter polyculture

Synopsis : Intensive prawn culture discharges a large amount of organic waste to the environment. We carried out studies on the monoculture of giant tiger prawn and the polyculture of giant tiger prawn and green mussel in concrete tanks and the earthen ponds in Thailand in relation to nutrient budget and water quality. In concrete tanks, the survival rates of shrimp at densities of 20, 30, 50 ind/m² were 75, 70, 62% in monoculture and 68, 65, 59% in polyculture, and the survival rates of green mussel were 43, 24 and 0.3%, respectively. Conversion ratio of feed's nitrogen to prawn was 21% in polyculture and 16% in monoculture, and ratios for the discharge were 56 and 71%, respectively. In earthen ponds, the production of prawn in polyculture and monoculture was 1.5 and 2.05 tons/ha, respectively. Green mussel only assimilated 2.7% and 4.4% of feed's nitrogen and carbon, respectively. However, the amount of the organic sediment was 368 and 793 m³/ha, in polyculture and monoculture, respectively. Consequently the polyculture contributed to reduction of the organic sediment, presumably due to the assimilation by green mussel and the other effects.

24. Title : Purification of the wastewater from aquaculture ponds using the mangrove ecosystem

Division : Fisheries Division

Author : Toru SHIMODA

Key Words : mangrove, nutrients, chlorophyll, nitrogen removal rate

Synopsis : An experiment was carried out using a semi-closed system, in which the wastewater from the prawn aquaculture ponds was passed through a mangrove afforested area with the aim of improving its quality before its return to the aquaculture ponds. The effect on the decrease in environmental load was examined. Watercourse 1, leading from the aquaculture ponds to the mangrove ponds, appeared to be the main site of decomposition for uneaten feed and generation of nutrients. Furthermore, a balance between decomposition and generation was observed in the mangrove pond; and nutrients were taken up by the phytoplankton in the prawn aquaculture ponds. During the experimental period, 22.37 kg of nitrogen was removed by the mangrove ecosystem. The nitrogen removal rate was calculated to be 62 - 232 mgN/m³/day.

25. Title : Alleviation of the incidence of internal tipburn in Chinese cabbage by subsurface drip fertigation

Division : Okinawa Subtropical Station

Author : Kazuo SUGAHARA

Key Words : Chinese cabbage (*Brassica pekinensis* Rupr), fertigation, internal tipburn, subsurface drip system

Synopsis : The potential of subsurface drip fertigation in reducing the incidence of internal tipburn in Chinese cabbage (*Brassica pekinensis* Rupr) was evaluated against conventional fertilization. In fertigation plots, nutrient solutions were applied weekly at a rate of 5 g N m⁻² through subsurface drip system for eight consecutive weeks. In the control plots, a compound fertilizer containing crotonylidene diurea was applied at a rate of 25 g N m⁻² before transplanting. Fertigation significantly reduced the tipburn incidence in all the five cultivars tested without any adverse effect on the yield. Among the five cultivars, Yuki in the fertigation plots expressed almost the complete tolerance to the tipburn incidence. Alleviation of the tipburn incidence was closely related to the level of total N and Ca/TN ratio in the inner leaves.

26. Title : Complete nucleotide sequence and genetic organization of papaya leaf distortion mosaic virus RNA

Division : Okinawa Subtropical Station

Author : Tetsuo MAOKA

Key Words : Papaya, Plant virus, Papaya leaf distortion mosaic virus, Complete nucleotide sequence

Synopsis : Papaya leaf distortion mosaic virus (PLDMV) and *Papaya ringspot virus* P type (PRSV-P) have been reported as the causal viruses of papaya disease in Japan. Both of them belong to the genus *Potyvirus*. The complete nucleotide sequence of the RNA genome of PLDMV was determined by overlapping cDNA clones and primer extension. The genomic RNA is 10,153 nucleotides in length,

excluding the poly(A) tract, and contains one large open reading frame encoding a polyprotein of 3,269 amino acids. Cleavage sites were predicted by analogy with the other potyviruses. The genetic organization of PLDMV RNA is proposed to be P1, the first proteinase; Hc-Pro, helper component proteinase; P3, the third protein; 6K1 and 6K2, 6kDa protein 1 and 2; CI, cytoplasmic inclusion protein; NIa, nuclear inclusion protein "a" including the VPg (NIa-Vpg) and NIa proteinase (NIa-Pro); NIB, nuclear inclusion protein "b"; CP, coat protein. The genetic organization of PLDMV is similar to that of the other potyviruses. The P1 protein of potyviruses is the most variable and may be considered important for identification of individual potyviruses. It might be useful for distinguishing between PLDMV and PRSV-P by RT-PCR. The sequence will be used for achieving transformation into papaya to make a PLDMV resistant papaya.

27. Title : Molecular cloning of Na⁺-ATPase cDNA from a marine alga, *Heterosigma akashiwo* (Sodium-pump in plant cell)

Division : Okinawa Subtropical Station

Author : Mariko SHONO

Key Words : Salt tolerance, Na⁺-pump, Na⁺-ATPase, Alga

Synopsis : Soil salinity is a major abiotic stress in agricultural production worldwide. Breeding of salt tolerant crops through genetic engineering is considered as one of the effective methods to solve that problem. Novel Na⁺-ATPase (HANA) cDNA from *H. akashiwo* was cloned as a target gene for the transformation. The full-length HANA cDNA was 4467-bp long and coded for a 1330-amino acid protein with a molecular weight of 146 and 306. HANA showed around 40% homology with animal Na⁺/K⁺-ATPase α -subunits in regards to identity of amino acids. A hydrophilic sequence of 285 amino acid residues that showed no homology with any sequence listed in databases existed in the M7-M8 junction of HANA. A phylogenetic tree of a P-type ATPase family comprised of three major clusters, mainly correlating with cation specificity, as follows: Ca²⁺-ATPases, H⁺-ATPases, and Na⁺/K⁺-ATPases. HANA is included in the cluster of Na⁺/K⁺-ATPases, being especially close to the Na⁺/K⁺-ATPases in invertebrates such as *Artemia*, *Drosophila*, or *Hydra*. However, yeast Na⁺-ATPases are classified into the cluster of Ca²⁺-ATPases. This is the first report on the primary structure of putative Na⁺ transporting ATPase from the plant cells.

28. Title : Simple crossing method of snap bean using physiological pollen sterility caused by high temperature treatment

Division : Okinawa Subtropical Station

Author : Yoshinobu EGAWA

Key Words : Crossing method, Snap bean, *Phaseolus vulgaris* , Heat treatment, Pollen sterility, Pod setting

Synopsis : High temperature causes pollen sterility in snap bean (*Phaseolus vulgaris* L.) rather easily. When 'Light Green' snap bean was exposed to a high temperature (35 °C) for 72 hours, the flowers that opened 8 to 12 days after the onset of heat treatment did not set pods by selfing. However, pod setting was 75% and 100 % 10 days and 11 days after the treatment, respectively, when the heat-treated 'Light Green' was crossed with fertile pollen of 'Haibushi' snap bean following the procedures described below. Crossing was carried out on the day of flowering without castration. Stigma easily protruded from the open mouth of keel petal by pressing down wing petals with fingers, which was pollinated with fertile pollen of 'Haibushi'. Hybridity of the plants obtained from the crossing were examined after 8 to 12 days of the heat treatment based on the coloration of hypocotyl. It was concluded that crossing method proposed by us did not require skilful castration technique and enabled us to produce F₁ hybrids for practical and experimental uses efficiently and highly successfully.

29. Title : Occurrence of male sterile cytoplasm in 'Kurodane Kinugasa' snap bean

Division : Okinawa Subtropical Station

Author : Yoshinobu EGAWA

Key Words : Cytoplasmic male sterility, Snap bean, *Phaseolus vulgaris* , 'Kurodane Kinugasa'

Synopsis : 'Kurodane Kinugasa' Snap bean produced semi-sterile hybrids when crossed as a seed parent with 'Haibushi'. Pollen stainability of the hybrid plants by aceto-carmin staining was 36.8 %. Since the reciprocal cross, 'Haibushi' × 'Kurodane Kinugasa' exhibited a high pollen stainability (83.8 %), the occurrence of male sterility in this cross combination is concluded to be cytoplasmic. B₁F₁ progeny derived from ('Kurodane Kinugasa' × 'Haibushi') × 'Kurodane Kinugasa' segregated into semi-sterile (12.8 to 26.5 % pollen stainability) and fertile (87.0 to 95.4 % pollen stainability) plants in a 1:1 ratio. 'Kurodane Kinugasa' is considered to have a single major restorer gene whose action is gametophytic. We have developed a cytoplasmic male sterile line of 'Haibushi' by recurrent backcrossing. 'Haibushi' is a heat-tolerant variety and exhibits high yielding ability in summer cultivation. To establish F₁ varieties of snap bean using male-sterile 'Haibushi' line as one parent, we are now exploring snap bean lines with sporophytic restorer gene(s) against this cytoplasmic male sterility.

30. Title : Distinction of sucrose phosphate synthase loci in sugarcane

Division : Okinawa Subtropical Station

Author : Takayoshi TERAUCHI

Key Words : Locus, Sucrose phosphate synthase, Sugarcane, Southern blot

Synopsis : Sucrose phosphate synthase (SPS) is considered to be an important enzyme in sucrose accumulation in sugarcane stems, as well as in sucrose transportation in photosynthesis of higher plants. Sugarcane genomic DNA was analyzed by southern blot analysis using combination of three restriction enzymes and four DNA fragments constructed from maize SPS cDNA as probes. Two recognition sites of each *Hin* d III and *Sac* I enzyme commonly existed in detected sugarcane SPS gene. Southern blot analysis using combination of *Sac* I enzyme and the 3'-end-side fragment of maize SPS cDNA as probe is considered to indicate SPS loci variation in sugarcane. Polymorphic band patterns were observed in sugarcane genetic resources by this method. The method enables SPS loci screening on genetic resources.

1.

Title	Simulation analysis of food security using a food supply-demand model
Division	Research Information Division
Author	Osamu Koyama
Key words	Food supply-demand model, trade liberalization, food security
Synopsis	A simulation analysis was conducted using an econometric model, which was partially modified from a food supply-demand model built in OECD. The results shows that introduction of trade liberalization policy in the low-income food deficit countries in Asia would undermine the food security situation in the region, if external shocks such as crop failure in food exporting countries or currency depreciation in food importing countries occurred.

2.

Title	Local rice varieties indigenous to the Mekong Delta, Vietnam, for screening of salinity tolerance.
Division	Biological Resources Division
Author	Tomohiro Ban, Vuong Dinh Tuan
Key words	DNA marker, Genetic diversity, Local rice, Microsatellite, Salinity tolerance
Synopsis	<p>JIRCAS' Comprehensive Project on the "Development of new technologies and their practice for sustainable farming systems in the Mekong Delta" has an important component addressing the genetic diversity angle in Mekong Delta agriculture. Due to the introduction of high-yielding rice varieties, traditional varieties with stress tolerance might disappear rapidly. Dr. V. D. Tuan, JIRCAS Research Fellow, worked with JIRCAS staff in the analysis of genetic diversity of traditional varieties in the region.</p> <p>A total of 43 microsatellite primers were used for the genetic diversity analysis of 60 traditional rice varieties, five upland rice varieties from the region and 10 other lines as reference. Those 75 lines were grouped into four major groups (Figure 1). All japonica type varieties were clustered into Group I and indica type into Groups II to IV. Traditional varieties are grouped into Group II and IV, expressing a great deal of genetic diversity. Moreover, salinity tolerance was assessed. A total of 14 traditional varieties had shown levels of tolerance similar to or more than that of the standard tolerant varieties such as Pokkali and NipponBare.</p> <p>A high level of genetic diversity among traditional rice varieties in the Mekong Delta was confirmed. This indicated that conservation of those traditional varieties is important and further progress in breeding using those rice cultivars are feasible due to high level of variation observed. The discovery of salinity-tolerant rice varieties is highly encouraging. Tolerance was observed in all groups, indicating a wide spread of salinity tolerance and, consequently, a wide genetic base for the trait. Pyramiding genes of salinity tolerance with different genetic background seems possible based on the results.</p>

3.

Title	Improving drought, salt, and freezing stress tolerance in transgenic plants
Division	Biological Resources Division
Author	Kazuko Yamaguchi-Shinozaki, Mie Kasuga, Qiang Liu, Kazuo Nakashima, Zabta K. Shinwari and Kazuo Shinozaki
Key words	drought tolerance, freezing tolerance, transgenic plants, multigene expression, stress-inducible promoter
Synopsis	<p>Plant productivity is greatly affected by environmental stresses such as drought, salt loading, and freezing. We reported that a <i>cis</i>-acting promoter element, the dehydration response element (DRE), plays an important role in regulating gene expression in response to these stresses in <i>Arabidopsis</i>. The transcription factor DREB1A specifically interacts with the DRE and induces expression of stress tolerance genes. We show here that overexpression of the cDNA encoding DREB1A in transgenic <i>Arabidopsis</i> plants activated the expression of many of these stress tolerance genes under normal growing conditions and resulted in improved tolerance to drought, salt loading, and freezing. However, use of the strong constitutive 35S cauliflower mosaic virus (CaMV) promoter to drive expression of DREB1A also resulted in severe growth retardation under normal growing conditions. In contrast, expression of DREB1A from the stress inducible rd29A promoter gave rise to minimal effects on plant growth while providing an even greater tolerance to stress conditions than did expression of the gene from the CaMV promoter. As the DRE-related regulatory element is not limited to <i>Arabidopsis</i> the DREB1A cDNA and the rd29A promoter may be useful to improve the stress tolerance of agriculturally important crops by gene transfer.</p>

4.

Title	Groundwater quality and nitrogen cycling in agro-ecosystems of Lingxian county, Shandong province, China
Division	Environmental Resources Division
Author	Kazuyuki Yagi and Yasukazu Hosen
Key words	Environment, Fertilizer, Nitrate, Nitrogen flows, Nitrogen pollution
Synopsis	<p>A regional analysis of nitrogen cycling in the agro-ecosystems of Lingxian County, Shandong Province, China was carried out. Total input of nitrogen to arable land, derived from chemical and organic fertilizer, sewage, precipitation, irrigation, and nitrogen fixation, was estimated to be, on the average, 584 kgN ha⁻¹ year⁻¹. The nitrogen output, including plant uptake and denitrification, was 296 kgN ha⁻¹ year⁻¹. These results indicate that arable land in this area should receive a balance of 288 kgN ha⁻¹, annually. A survey of the ground water quality in the area shows that nitrate pollution of ground water has not been widely noticeable at present. However, the analysis of nitrogen cycling in agro-ecosystems predicts the large potential risk of nitrogen pollution in the environment in the near future.</p>

5.

Title	Root distribution in soil and sensitivity to water stress of upland rice in the tropics.
Division	Environmental Resources Division
Author	Motohiko KONDO
Key words	Phosphorus, Roots, Upland rice, Water uptake
Synopsis	<p>Response of upland rice to water stress in terms of root growth and water uptake from soil layers was characterized. Water uptake is more sensitive to soil drying as compared with nitrogen uptake, which signifies that water uptake is a major limiting factor for the plant growth under stressed conditions. Low water uptake under severe stress in rice can be attributed to shallower root distribution and poorer water capture from deep soil layer, deeper than 40 cm depth as compared with maize. Maize increased root growth in deep soil layers in responding to severe stress. In contrast, rice showed few stimulated root growth and limited water extraction rate per unit length of root under severe stress. Field investigation in acidic soils indicated that phosphorus application led to the formation of deeper root system. Amendment of phosphorus is considered to improve water capture from deep layers to sustain plant growth under stress in acidic soils with low available phosphorus.</p>

6.

Title	Quantitative analysis of 2-acetyl-1-pyrroline in aromatic rice.
Division	Crop production and postharvest technology division
Author	Tadashi YOSHIHASHI
Key words	Aromatic rice, Flavor components, 2-acetyl-1-pyrroline, Isotope dilution method
Synopsis	<p>A “popcorn*-like flavor compound, 2-acetyl-1-pyrroline, has been reported as an important flavor component of aromatic rice because of its lower odor threshold, i.e. 0.1 ppb (in H₂O), than the other volatile compounds in rice. In conventional method, 2-acetyl-1-pyrroline and other volatile components were extracted from 500g of rice sample by using simultaneous steam distillation / solvent extraction apparatus.</p> <p>In conventional method, the extracts were analyzed by gas chromatography / mass spectrometry in full scan mode or gas chromatography / flame ionization detection with internal standard method using 2,4,6-trimethyl pyridine as standard.</p> <p>Isotope dilution method, isotope labeled compounds is used as internal standard, is an ideal method for quantification using gas chromatography / mass spectrometry /selective ion monitoring which has higher sensitivity than full scan mode.</p> <p>An improved method, Gas chromatography / mass spectrometry / selected ion monitoring with isotope dilution method, can enhance the sensitivity for quantification of 2-acetyl-1-pyrroline in aromatic rice samples using small quantities (0.5g) with high specificity.</p>

7.

Title	Cultivar identification of milled rice.
Division	Crop production and postharvest technology division
Author	Tadashi YOSHIHASHI
Key words	Milled rice, DNA extraction, Microsatellite analysis, cultivar identification
Synopsis	<p>In our laboratory, we developed DNA extraction method based on a freeze-and-thaw cycle for extracting purified, high molecular weight DNA from grains. The developed technique does not require expensive equipment and materials, and is not a time-consuming procedure. By applying this method, we were able to obtain DNA for microsatellite analysis within 2h and the whole process of identification required 6h. Time saving and unemployment of expensive instruments or toxic chemicals of the present method is an attractive alternative to existing methods of identification. Obtained results showed that DNA extracted from tested samples was of high quality and hence could be used in PCR-based techniques for cultivar identification even in laboratories with a moderate level of technology. Another feature of this developed technique was saving in time and cost as well as the safety of this procedure.</p>

8.

Title	Digestion characteristic and energy requirement of native ruminants in Northeast Thailand
Division	Department of Research Planning and Coordination, National Institute of Animal Industry
Author	Tomoyuki Kawashima, W. Sumamal, P. Pholsen and R. Narmsrilee
Key words	Native cattle, Swamp buffalo, Energy requirement, Digestibility
Synopsis	Native ruminants, such as Thai native cattle and swamp buffalo, are able to efficiently digest low quality roughage without protein supplement. And these animals require less energy to maintain basal metabolism. Therefore, these animals can be effectively raised with low quality feed.

Title	Tropical grasses available for agropastoral systems, with high function in supplying organic matter into soil
Division	Animal Production and Grassland Division
Author	Tsutomu KANNO, Manuel C. MACEDO, and Valeria P.B. EUCLIDES
Key words	root biomass, soil organic matter, tropical grass
Synopsis	<p>Root biomass of five tropical grasses was compared as the function in supplying organic matter into soil of Brazilian savanna (Oxisol). Pastures of the five grasses, <i>Brachiaria decumbens</i> (BD), <i>B. brizantha</i> (BB), <i>Panicum maximum</i> cv. Tanzania (TA), <i>P. maximum</i> cv. Tobiata (TO), and <i>Andropogon gayanus</i> (AN), were established, and grazed for three years. Then the root biomass was measured in 0-10, 10-20, and 20-40cm of soil layers. Measured root biomass represented 53-76% of total biomass of the five grasses. Among the five grasses, root biomass level per square meter was in the order of BB>BD>TA>TO>AN, with the root biomass of BB significantly higher than those of the other grasses. Root biomass decreased quickly with the increase of soil depth, whereas the percentage of root biomass to dry soil of BB was highest among the five grasses in all of the soil layers. It is concluded that BB is the best option to introduce in crop-pasture rotation for soil quality improvement.</p>

10.

Title	Regeneration technique of Seraya on the logging roads in Peninsular Malaysias.
Division	Forestry Division
Author	OCHIAI(JIRCAS) and AZMAN Hassan(FRIM)
Key words	Hill forest, Seraya, Dipterocarp, Logging road, Regeneration
Synopsis	<p>The regeneration of Seraya, one of the most valuable tree species in hill forests where most logging operations are being carried out in Peninsular Malaysia, is investigated on a logging road with 500 m length in compartment 28, Semangkok forest reserve. About 400 seedlings of Seraya are found on the road. Their distribution is not uniform yet. All the seedlings are found on ridges while no seedlings are found on the lower slopes. This result is caused by the fact that most mother trees are distributed on the ridges and only a small number are on the lower slopes. On the ridges, the level ridges have more developed Seraya seedlings while the sloping ridges have less developed Seraya. This results from the seeds from mother trees being easily washed out by rainfall immediately after logging on the sloping ridges. Thus, germination there can only take place after sufficient litter has accumulated again. It is clear from the results that it is necessary to prevent the rainfall from washing away the seeds on the road in order to recover the logged-over forest quickly. Seraya's regeneration after logging is not difficult if microtopography is considered.</p>

11.

Title	Simplified pre-germination treatments for indigenous legume trees in the Philippines
Division	Forestry Division
Author	Kazunori TAKAHASHI, Wilfredo M., CARANDANG and Antonio F. GASCON
Key words	Germination, Hot Water Treatment, <i>Laucaena leucocephala</i> , Philippines
Synopsis	Simplified pretreatment to improve seed germination was investigated for reforestation tree species of Leguminosae and Mimosaceae which were indigenous to the Philippines. Seeds of these species are treated with hot water time-courses on several temperatures for 0.5-5 min, seed scarification and fire-heating by burning grass, and then sowed to nursery. Three varieties of <i>Laucaena leucocephala</i> , which were the most common reforestation planting species there, were all highly improved the germination rates in their most appropriate time-courses of hot water treatment. The fire-heating, which was usual pretreatment for the legume direct sowing, was also effective, but less than hot water treatment. Thus, the appropriate hot water treatment for seeds found should be given before the direct seed sowing to ensure the establishment of rehabilitated legume forest on the degraded grassland.

12.

Title	Determination of amino acid sequence and site of mRNA expression of four vitellins in the giant freshwater prawn, <i>Macrobrachium rosenbergii</i>
Division	Fisheries Division
Author	Marcy N. Wilder and Wei-Jun Yang
Key words	amino acid sequence, cloning, mRNA expression, vitellin
Synopsis	Four major yolk proteins, designated as vitellins (Vns) Macr-VnA, B, C and D, were extracted from mature ovary of <i>Macrobrachium rosenbergii</i> . These were purified to homogeneity by reversed-phase HPLC employing a unique separation system based on the hydrophobic properties of the Vn molecule. More than 33 N-terminal and 57 internal amino acid residues were determined for each of the four Vns. The cDNA fragments encoding the four Vns were amplified by PCR using degenerate oligonucleotide primers derived from the N-terminal and internal amino acid sequences. These cDNA fragments were cloned, sequenced and used as probes to examine the transcription of mRNAs encoding the four Vns. Significant accumulation of these mRNAs was observed in female hepatopancreas only, while mRNA expression was not detected in male hepatopancreas or any other female tissue including ovary, subepidermal adipose tissue, gill and muscle.

13.

Title	Productivity and diversity of fish in brackish water mangrove ecosystems
Division	Fisheries Division
Author	Masachika MAEDA
Key words	mangrove, fish, diversity, diatoms, nutrients
Synopsis	<p>Japan International Research Center for Agricultural Sciences (JIRCAS) and Malaysia (Fisheries Department, Forestry Department and Malaya University) organized the new project on "Brackish Water Mangrove Ecosystems* from April, 1995 * March, 2000. In three research areas of the mangrove estuary in Malaysia adopted as a project site, the characteristic differences between these are the ratios of the mangrove forests area/river area, in which the values for Matan (4.7), Merbok (2.1) and Lumut (1.1) are calculated, respectively. In the Matang mangrove estuary area (ratio: 4.7), the quantity of fish catch is larger than that in Merbok (ratio: 2.1) and Lumut (ratio: 1.1). In case of the diversity index of fish, however, shows a higher value in Merbok than in the other two mangrove areas. In Lumut, the volume of fish catch and diversity index are the lowest of the three areas. Based on these results, we conclude that the value of the ratio of mangrove forest area/river area is a useful index, with a value of between 4.7 and 2.1 being a precondition for sustainable fish production in mangrove estuary areas.</p> <p>The dominant macrobenthic animal group in Matang was the bivalves, accounting for 46 % of the total abundance, but in Lumut, polychaetes were the clearly dominant group, making up about 46 % of the total benthos population. In addition it was found in this project that wet land retains silicates where phytoalgal diatoms are present at high concentrations, which provide not only oxygen to benthic animals inside the wet land but also flow into the sea, resulting in high concentrations of biomass in seawater. These diatoms repress the growth of dinoflagellates due to the competition among the phytoalgae communities.</p>

14.

Title	Evaluation of heat tolerance in snap bean based on pollen stainability.
Division	Okinawa Subtropical Station
Author	Katsumi SUZUKI, Hiroyuki TAKEDA, Yoshinobu EGAWA and Tadashi TSUKAGUCHI
Key words	Heat stress, High temperature, Snap bean(<i>Phaseolus vulgaris</i>), Pollen stainability
Synopsis	Pollen stainability of snap bean decreases by being subjected to heat stress 8 to 11 days before flowering in a greenhouse. When mean air temperature about 10 days before flowering is over 28 , pollen stainability of snap bean decreases in the field at Okinawa Subtropical Station. Heat tolerant varieties show higher pollen stainability than heat sensitive varieties under high temperatures. Based on pollen stainability, tolerance to high temperature about 10 days before flowering can be evaluated.

Title	Characteristics of rainfall kinetic energy and raindrop size distribution in subtropical zone area
Division	Okinawa Sub-tropical Station
Author	Kenji BANZAI, Tamon FUMOTO, Yoshinari OHWAKI, Kazuo SUGAHARA
Key words	Rainfall intensity, Rainfall energy, Soil erosion, Raindrop size
Synopsis	<p>Characteristics of rainfall energy and raindrop size distribution were examined in a subtropical zone area using a disdrometer. Rainfall energy values were calculated from the observations obtained from the device which measures raindrop size distributions continuously and automatically. The device however can not measure raindrops below 0.3 mm, hence rainfall energy values may give an error of about 2.48 %. Measured kinetic energy vs. rainfall intensity data showed wide distribution between the upper limit equation by Wischmeier and the lower equation by Mihara. Kinetic energy over and above the Wischmeier equation was also observed below 30 mm/h rainfall. In Ishigaki, there were large size raindrops at rainfall intensities below 30 mm/h. The distribution of raindrop size was wide from 1 mm to 5 mm in diameter compared with those measured in Tsukuba where raindrop size was concentrated between 1-2 mm.</p>

Title	Long-range migration of rice planthoppers in monsoonal East Asia
Division	Crop Production and Postharvest Technology Division
Authors	Kazushige SOGAWA and Akihiko TAKAHASHI
Key Words	Brown planthopper, Whitebacked planthopper, Southwest monsoon, East Asia, Winter-spring rice, Early rice , Two-staged migration, Immigration
Synopsis	<p>The brown planthopper, <i>Nilaparvata lugens</i>, and whitebacked planthopper, <i>Sogatella frucifera</i>, are international insect pests of rice, which undertake long-range migrations from tropical to temperate rice areas in East Asia every year. The rice planthoppers are transported downwind by a synoptic scale of wind systems associated with the southwest monsoon and Baiu climate. We demonstrated that the migratory planthoppers emigrating from North Indochina migrate to Japan <i>via</i> South China by means of trajectory analyses of airflow at 850hPa.</p> <p>The migration process involved two major stages of habitat displacements; from winter-spring rice in North Vietnam to early rice in South China in April to May, and from early rice to single rice in Japan in June to July. These two stages of migrations were achieved by seasonal advance of monsoon climate and geographical shifting of the rice cropping period in the migration zone in East Asia.</p>

Title	Serological diagnosis of citrus greening disease
Division	Crop Production and Postharvest Technology Division
Authors	Yoshihiro OHTSU, Maitree PROMMINTARA, Koji KAWASHIMA, Seiichi OKUDA, Kazuo NAKASHIMA and Takeshi KANNO
Key Words	Citrus greening, Midrib, Phloem tissue, Microprecipitin test.
Synopsis	Accurate serological diagnosis with microprecipitin test was developed for greening disease. Phloem tissues were separated after digestion of diseased midribs in enzyme solution. Partially purified greening organisms GO concentrated up to 40 times of the midrib weight were obtained from final pellets after one cycle of centrifugation of homogenate of phloem tissue. Microprecipitin test was conducted by adding one drop 5% of the partially purified GO to one drop of the GO antiserum.

Title	Comparative studies of fish production in brackish waters between intact (Matang) and exploited (Merbok) mangrove areas
Division	Fisheries Division
Authors	Shigeo HAYASE, Ahmad HUSIN (FRI), Yoh YAMASHITA (TNFRI), Katsuhisa TANAKA (NRIFS), A. SASEKUMAR and Chong Ving CHING (UM)
Key Words	Brackish water, Mangrove ecosystems, Matang mangrove area, Merbok mangrove area, Fish juvenile, Density, Biomass, Growth rate, Production, Food-chain
Synopsis	<p>The brackish waters in which sea water and fresh water are mixed occur mainly in tropical and subtropical coastlines, and many mangrove trees spread out along the brackish water coastlines. Mangrove trees are not only utilized for charcoal production but also serve as nursery grounds for fish and prawns. In the comprehensive studies conducted to evaluate the productivity of brackish water mangrove ecosystems and identify criteria for sustainable utilization of the areas, comparative studies have been carried out on fish biomass between intact (Matang) and exploited (Merbok) brackish water mangrove ecosystems in Peninsular Malaysia. The distinct C-N isotopic ratio gradient in the Matang brackish water mangrove ecosystems suggests that the food pathway start from the mangrove leaf-based detritus to carnivorous fish and squids through herbivorous shrimps and crabs. The Matang Mangrove Forest Reserve in Perak consisting of 40,711 hectares and situated on the northwestern coast of Peninsular Malaysia has been under sustainable yield management since the early part of the century. On the other hand, in the case of the Merbok Mangrove area in Kedah, situated in a further northwestern direction from Matang and covering 8,000 ha which has been exploited, the mangrove area during the past ten years has been reduced by about 11% from 9,037ha in 1980 to 8,034ha in 1990 and the loss of mangroves is still continuing. Biomass of juvenile anchovy, <i>Stolephorus</i> spp., in Matang was 4.3 times higher than in Merbok. The information obtained here will be useful to scientists in many fields to improve the technology for sustainable utilization of brackish water mangrove ecosystems, which will bring about benefits especially to dwellers in the areas and also to policy-makers.</p>

Title	Improvement of rice cropping for farming systems in the Mekong Delta, Vietnam
Division	Crop Production and Postharvest Technology Division
Authors	Tadao KON, Pham Sy TAN, Tran Ngoc HUAN, Trinh Quang KHUONG and Hoang Dinh DINH.
Key Words	Diagnosis, Fertilizer application, Leaf color, Water management, Yield component
Synopsis	<p>Under <i>Doi Moi</i> policy which started in 1986, farming systems combining agriculture, animal husbandry and fisheries developed widely in the Mekong Delta, Vietnam. Rice production, an important component of farming systems in the Delta, rapidly increased owing to field reclamation, canal excavation and dike construction, and introduction of double or triple cropping of rice together with newly bred high-yielding varieties.</p> <p>In the collaborative research project with Cuu Long Delta Rice Research Institute, we carried out studies for the improvement of rice cropping. Some useful results were obtained to achieve higher yields of rice. Firstly, leaf color was found to be a good indicator of the leaf nitrogen content which markedly affects the growth, yield components and lodging of rice plants. Fertilizer application can be improved by the diagnosis of nutrient conditions through leaf color measurement. Secondly, top dressing of nitrogen at an early stage of rice development was found to be rather hazardous because of easier and earlier lodging especially in the wet season. Thirdly, drainage of flooding water in rice fields during growth period of rice was effective for the prevention of lodging and for achieving higher yields, as observed in farmers' fields where a rice-fish farming system was adopted.</p> <p>The results will contribute to the development of low input sustainable rice production in farming systems in the Mekong Delta.</p>

Title	Changes in the agricultural structure under the <i>Doi Moi</i> policy in the Mekong Delta, Vietnam
Division	Crop Production and Postharvest Technology Division
Authors	Ryoichi Yamazaki
Key Words	Market-oriented economy, Differentiation of farmers, Diversified farming
Synopsis	After 1988, in the Mekong Delta of Vietnam, the differentiation of farmers made rapid progress under the market-oriented economy, introduced by the <i>Doi Moi</i> policy. Some farmers have expanded their farm size rapidly. Others have reduced their farm size and finally became landless. However, medium or small-scale landowner's have attempted to stabilize their household economy by introducing diversified farming. In future diversified farming will be reorganized on a community basis.

Title	Isolation of genes essential for molecular breeding of drought tolerant plants
Division	Biological Resources Division
Authors	Kazuko Yamaguchi-Shinozaki <i>et al.</i>
Key Words	Transcription factors, Drought-inducible genes, Promoters, Drought-tolerant plants
Synopsis	Plant genes for transcription factors were isolated that control expression of genes involved in drought tolerance. Regulatory elements in promoters were also identified that control drought-responsive gene expression. These transcription factors and promoters are expected to be useful for molecular breeding of drought-tolerant plants by regulating the number of genes involved in drought tolerance.

Title	Development of assessment method for vegetation stability using Neural Network
Division	Environmental Resources Division
Author	Yukiyo YAMAMOTO
Key Words	Australia, Neural Network, Vegetation stability
Synopsis	In the test site located in central Australia, two Neural Network models to estimate vegetation abundance and changes were developed based on 7 factors including slope, geomorphic systems, hydrological units, soil units, vegetation units, distance from water points and distance from ridges. Furthermore, an assessment map for vegetation stability was constructed by the integration of two results of estimation using the Neural Network models mentioned above.

Title	Development of a method to estimate the distribution of agricultural land use based on satellite data in the central part of the Deccan plateau in India
Division	Environmental Resources Division
Author	Satoshi UCHIDA
Key Words	Satellite data, Vegetation index, Semi-arid area of India, Rabi season, Agricultural land use, Spatial distribution
Synopsis	Vegetation index calculated from satellite remote sensing data reveals specific patterns of seasonal changes depending on land use types. In the semi-arid area of India, the value of the vegetation index of agricultural land use could be differentiated from that of other land uses during the latter half of the post-rainy cropping season called Rabi. In this study a method to estimate the spatial distribution of agricultural land use by adapting the temporally variable threshold value of vegetation index was developed. This method has enabled to collect quantitative information on Rabi cropped area for several years with available satellite data. Investigations of temporal changes showed that the location of the cropped area was correlated with the amount of rainfall during the sowing period and with the suitability of land conditions.

Title	Measurement of nitrous oxide emissions from upland fields in Thailand
Division	Environmental Resources Division
Authors	Takeshi WATANABE, Katsuyuki MINAMI and Prapai Chairroj (DOA)
Key Words	Nitrous Oxide, Nitrogen fertilizer, Upland soils, Tropics
Synopsis	Nitrous oxide emissions from upland soils were measured during a period of one year by the closed chamber method at four experimental sites in Thailand. Two treatments consisting of the application and absence of application of nitrogen fertilizer were set in triplicate at each experimental site. The total amount of nitrous oxide emitted throughout the maize cultivation period ranged from 0.08 to 0.48% of applied nitrogen fertilizer and these rates not significantly different from those recorded in the temperate zone.

Title	Edible insects in Kenya
Division	Crop Production and Postharvest Technology Division
Authors	Shigemi Yagi, E. Kokwaro, Kesa Kishida and Mitsuo Yazawa
Key Words	Edible Insects, Western Kenya, Termites
Synopsis	New uses of edible insects such as locusts, grasshoppers, termites, flies and wild silkmths were investigated in rural areas of Kenya. Field surveys conducted in the Maragoli area in western Kenya showed that villagers easily distinguish species and the emergence patterns of termites which are the most common edible insects in Kenya. Cooked termites are sold not only in the local markets but also in some open markets in Kisumu or Nairobi because they can be stored up to at least several days without spoilage. These results suggest that termites play an important role in the daily food consumption in this area in the rainy season, during periods of maize shortage, and that they may be especially valuable for children and pregnant women who require a high calorie and nutritious diet.

Title	Analysis of mechanical properties of collapsible soils and development of a quantitative method
Division	Crop Production and Postharvest Technology Division
Authors	Yuji Kohgo, S. B. Tamrakar and H. B. Tang
Key Words	Collapsible soil, Unsaturated soil, Suction, Elastoplastic model
Synopsis	The mechanical properties of the collapsible soils distributed in Northeast Thailand were investigated by using a triaxial compression test apparatus, oedometer and pressure plate test apparatus. A method for estimating the amount of collapse by using the elastoplastic model for unsaturated soils was also developed. Comparison of the experimental and estimated data of volume change due to the collapse showed that both agreed well. This method is suitable for the estimation of volume change due to collapse.

Title	Immunohistological analysis of the tick attachment site of <i>Rhipicephalus appendiculatus</i> infected with <i>Theileria parva</i>
Division	Animal Production and Grassland Division
Author	Yutaka MATSUBARA
Key Words	East Coast fever, <i>Theileria parva</i> , Tick, Skin, Immunohistochemistry
Synopsis	The brown ear tick, <i>Rhipicephalus appendiculatus</i> , transmits <i>Theileria parva</i> protozoan which causes theileriosis, commonly known as East Coast fever (ECF) in Africa. To enhance our understanding of the early events of <i>T. parva</i> infection <i>in vivo</i> for vaccine development against ECF, we have identified cell populations present at the site of tick attachment in cattle. Skin biopsies were immunohistochemically investigated by the biotin-streptavidin method using monoclonal antibodies against bovine leukocyte surface antigens.

Title	<i>In situ</i> hybridization to detect bovine cytokine mRNAs in protozoan disease
Division	Animal Production and Grassland Division
Author	Yutaka MATSUBARA
Key Words	Cytokines, <i>In situ</i> hybridization, Bovine cytokine mRNAs
Synopsis	Cytokines are a family of low molecular weight protein regulatory molecules involved in inflammation and immunity. They play an important role in the immune system to control cell growth and differentiation of immunocompetent cells. An <i>in situ</i> hybridization protocol using nonradioactively labeled RNA probes was established to detect bovine cytokine mRNAs TNF- α , IFN- γ , IL-2IL-4IL-6IL-10and IL-12p35 on cytospin preparations.

Title	Age determination of tropical fishes and squids in Indonesia
Division	Fisheries Division
Authors	Satoshi SUYAMA, Syarifuddin Tonnek and Shinji UEHARA
Key Words	Age, growth, daily growth increments, otolith
Synopsis	Age and growth of fishes and squids distributed in Indonesia were estimated by analyzing daily growth increments in otolith. Ground otoliths were observed by light and scanning electron microscopy. Three of eight species, <i>Atherinomorus lacunosus</i> , <i>Sphaeramia orbicularis</i> and <i>Sepioteuthis lessoniana</i> , had clear increments which enabled the estimation of age in days. We additionally verified the daily periodicity of increment formation of <i>Sphaeramia orbicularis</i> under rearing experiments.

Title	Enzyme activity of early maturing sugarcane stalks with high sugar content
Division	Okinawa Subtropical Station
Authors	Takatyoshi TERAUCHI, Makoto MATSUOKA, Makoto KOBAYASHI, Hiroshi NAKANO, Shunsuke ODA and Masahiro OKAMOTO
Key Words	Sugarcane, Early maturing, Acid invertase, Sucrose phosphate synthase
Synopsis	NiF4, an early maturing variety with a high sugar content, shows a high Brix-value even in the growing season compared to F172. Acid invertase activity, a negative factor for sugar accumulation, of NiF4 is relatively higher than in F172. Sucrose phosphate synthase activity, a positive factor for sugar accumulation, of NiF4 is higher than in F172. This enzyme activity increases in both the maturing season and under low temperature conditions with Brix increment.

Title	Evaluation of mungbean cultivars for resistance to iron deficiency
Division	Okinawa Subtropical Station
Authors	Yoshinari OHWAKI, Yoshinobu EGAWA, Kazuo SUGAHARA, Sanayh KROKAW (DOA) and Somsong CHOTECHUEN (DOA)
Key Words	Acidification, Chlorosis resistance, Iron deficiency, Mungbean (<i>Vigna radiata</i> (L.) Wilczek).
Synopsis	Ten mungbean cultivars were evaluated for their resistance to iron deficiency based on the developed of chlorosis symptoms, plant growth and seed yield under field conditions on a calcareous soil in Thailand. KPS2 cultivar was highly susceptible ; KPS1, PSU1 and Pag-asa1 cultivars were somewhat susceptible ; VC1163B cultivar was moderately tolerant ; CN36, CN60, UT1 and CNM-I cultivars were tolerant and ; CNM8509B cultivar was highly tolerant to iron deficiency. Compared with the susceptible cultivar KPS2, the tolerant cultivar UT1 had a greater ability to lower the pH of the nutrient solution in response to iron deficiency. Acidification of the medium in response to iron deficiency may contribute to the efficient solubilization of iron from calcareous soils, and it is closely related to the tolerance of iron deficiency in mungbean cultivars.

Title	Stimulation of ethylene synthesis from husks of rice seeds by ferrous iron
Division	Laboratory of Soil Management, Department of Agro-environmental Management, Chugoku National Agricultural Experiment Station
Author	Minoru YAMAUCHI
Key Words	Coleoptile, Ethylene, Ferrous iron, Husk, Oxygen concentration, Rice.
Synopsis	<p>Rice farmers in Asia are adopting direct seeding because this practice requires less labor than transplanting. The main constraint of the adoption is the inconsistent seedling establishment, because O_2 is deficient in flooded soil. It has been found recently that ferrous iron (Fe), which is commonly present in flooded soil, stimulates coleoptile elongation. This study was conducted to analyse the mechanism of Fe - stimulation of coleoptile elongation. Germinated rice seeds were placed and sealed in Erlenmeyer flasks or vials and then 2 mM Fe or water (as a control) was administered. We found that Fe application increased ethylene production as well as the elongation of coleoptile. When ethylene was applied exogenously to the germinating seeds, the effect of Fe on coleoptile elongation was eliminated. When Fe was applied to the germinated intact seeds, germinated caryopsis, or husks, ethylene production was stimulated by Fe in intact seeds and husks and not in caryopsis, suggesting that ethylene was produced in the reaction between husks and Fe. Trichloroacetic acid did not inhibit the reaction. Ethylene production was as low as at 0.02 mM Fe and maximum at between 2 and 200 mM. Ethylene production increased linearly up to 3hr after the application of Fe, even in the absence of O_2. The results suggest that Fe in flooded soil reacts with husks of germinating seeds, produces ethylene, and elongates the coleoptile to the soil surface where O_2 is present.</p>

Title	Contribution of caoutchouc to durability of teak (<i>Tectona grandis</i> L. f.) wood
Division	Forestry Division
Authors	Koichi Yamamoto, Maruli Simatupang (USM) and Rokiah Hashim (USM)
Key Words	Teak, Caoutchouc, Durability, Decay resistance, XPS, Water repellency,
Synopsis	Caoutchouc is present in very small amounts in sapwood, starting from it the central part. It occurs in heartwood parenchyma, especially in ray parenchyma, and in small amounts in fibers and vessel elements. Untreated teak heartwood cuttings showed a high contact angle with water, indicating hydrophobic properties. Extraction with acetone increased the contact angle slightly, due to the removal of polar compounds and redistribution and enrichment of apolar caoutchouc on the surface. X-ray photoelectron spectroscopy confirmed these findings. Reconstituted panels made from ethanol extracted teak heartwood meal were prone to decay. Specimens made from wood meal successively extracted with ethanol and chloroform showed a slightly lower resistance than specimens made from ethanol-extracted one. It is suggested that the high resistance to decay of untreated teak heartwood is due to the synergetic effect of decay active ethanol extracts and non-active caoutchouc.

Title	Development and utilization of hybrid rice in Malaysia
Division	Biological Resources Division
Author	Hiroshi Kato
Key Words	Malaysia, Hybrid rice, High yielding variety
Synopsis	<p>The instability of CMS in rice can only be attributed to a mixture of volunteer or contaminated plants mistakenly classified as revertants. We can use CMS lines for practical hybrid rice breeding without encountering instability problems. IRRI hybrids IR69690H and IR69694H always showed heterosis levels as high as 120 on the average, which were associated with 20 % higher yield over MR 84. IR69692H and IR67693H also occasionally showed a high heterosis level. In addition, these four hybrids headed about two to three weeks earlier compared with MR 84. In Malaysia, direct seeding is very popular. Based on the results of direct seeding yield trials of hybrids, it is not recommended to cultivate hybrid rice by reducing the seeding rate of hybrids in direct seeding. For the practical utilization of hybrids, the use of machine transplanters for reducing the amount of hybrid rice seed per unit area is recommended.</p>

Title	Performance assessment for water resources management at watershed level using existing management data
Division	Okinawa Subtropical Station
Author	Shigeo Yashima
Key Words	Water resources management, Performance assessment, Management data
Synopsis	Competition for water is increasing even in developing countries. In order to conserve irrigation water resources, the author developed a new method to assess water resources management at watershed level using management data left in stores after the use of data for regulating irrigation systems. The method will lead to the improvement of water resources utilization with minimum financial and personnel investment through detailed identification of constraints on proper performance.

Title	Rice market situation in Vietnam
Division	Research Information Division
Authors	Mitsuhiro NAKAGAWA, Dang K. SON and Naguyen X.LAI
Key Words	Export quota system, Over-supply, Rice price
Synopsis	The Vietnamese government has imposed on export quota system on its rice exports to maintain the domestic rice at the targeted level. However, this export quota system exerts a negative impact on the income of the rice producers, because the expanding rice production causes a market situation characterized by over-supply. Based on an econometric model, a simulation study projected a further decline in the rice price when the export quota system is fixed at the current level. The relaxation of export control was found to be effective in raising the rice farmers' income in Vietnam.

Title	New rice cultivars 'Hexi 34' and 'Hexi 35' in Yunnan Province of china
Division	Biological Resources Division
Authors	Kazuo ISE <i>et al.</i>
Key Words	China, Yunnan, Rice, New cultivar, High yield, Good quality
Synopsis	We developed new rice cultivar, 'Hexi 34' and 'Hexi 35' in Yunnan Province of China; they will be officially registered by the Yunnan Provincial Government. The pedigree of these new cultivars can be traced to some Japanese rice genetic resources: a high-yielding cultivar 'Todorokiwase', a cool weather-tolerant cultivar 'Narukaze', blast-resistant germplasm accessions 'BL 1' and 'BL6', and others. 'Hexi 34' and 'Hexi35' performed very well in the uniform trails conducted at twelve sites representative of the japonica rice-growing areas in 1993 and 1994. They showed a higher yielding ability and better grain quality than the standard cultivar 'Yunkeng 9'. They were also tolerant to cool weather conditions during the growing season. They could become adapted to cool areas with an elevation of 1800-2000m in Yunnan and neighboring provinces.

Title	Influence of physical properties of rocks on rockdissolution process
Division	Environmental Resources Division
Author	Tamao H _{ATTA}
Key words	Chemical weathering, Dissolution, Porosity
Synopsis	To elucidate the characteristics of dissolution of rocks and to examine the effect of physical properties on their dissolution characteristics, closed-system experiments were carried out thirteen rock types. The experiments using small block samples showed that the rocks with a higher porosity display higher rates of dissolution, particularly in the initial stage of the water-rock interaction. This evidence indicates that the concentration of dissolved materials is controlled by the porosity of the rocks.

Title	Response of 2,4-D resistant biotype of <i>Fimbristylis miliacea</i> (L.) Vahl. to several herbicides and its distribution in the Muda area , Malaysia
Division	Crop Production and Postharvest Technology Division
Authors	Hiroaki WATANABE, Md. Zuki ISMAIL (MADA) and Nai-Kin Ho (MADA)
Key Words	Malaysia, 2,4-D resistance, <i>Fimbristylis miliacea</i> (L.) Vahl.
Synopsis	Biotype of <i>Fimbristylis miliacea</i> (L.) Vahl. resistant to 2,4-D was found in the Muda area, Malaysia, which was 29 times more resistant to 2,4-D dimethylamine than the susceptible biotype. The 2,4-D resistant biotype was also resistant to other phenoxy compounds including MCPA, but no difference was observed in the reaction toward propanil, paraquat and glufosinate ammonium between the biotypes. Other types of herbicides with different modes of action could be useful to control the 2,4-D resistant biotype.

Title	Increase in agricultural damage associated with the invasion of leaf-cutting ants in southern Brazil and Paraguay
Division	Crop Production and Postharvest Technology Division
Authors	Lui Carlos FORTI and Katsuya ICHNOSE
Key words	Leaf-cutting ant, Distribution, Damage, Brazil, Paraguay
Synopsis	Surveys on the geographical distribution and density of leaf-cutting ants were performed in southern Brazil and Paraguay from 1992 to 1996. The results showed that they were most abundantly distributed in the northern and southern regions of the area surveyed while much less or practically not in central Parana to Santa Catarina. Compared with the data obtained until 10 years ago, it appears that the ants have been expanding into and increasing their distribution in the surveyed areas, and that the ants can be distributed in all the regions. Studies should be carried out in order to control the expansion of the ants.

Title	Nutritive value of sugarcane stalks as a roughage for dairy cows
Division	Animal Production and Grassland Division
Authors	Tomoyuki KAWASHIMA, W.SUMAMAL and P.PHOLSEN
Key words	Sugarcane stalk, Nutritive value,Cattle
Synopsis	<p>The use of sugarcane as a roughage for cattle was examined in Northeast Thailand. Metabolizable energy (ME) content in sugarcane stalk amounted to 9.05 MJ/kg based on a metabolic trial. It was estimated that sugarcane can produce nearly 3times more ME per area than ruzi grass which is the major grass grown in the region. Sugarcane can remain until the end of the dry season without withering, which allows farmers to cut it when they need it without having to preserve it. The use of sugarcane stalks can be a key feeding strategy in the dry season, especially in dairy production.</p>

Title	Wetwood and its formation in <i>Acacia mangium</i>
Division	Forestry Division
Authors	Koichi YAMAMOTO, SULAIMAN and O. R. HASHIM
Key Words	<i>Acacia mangium</i> , Wetwood, Tropical plantation species
Synopsis	<p>The report on the existence of wetwood, in <i>Acacia mangium</i> Willd. is the first one among tropical plantation species. Trees at two of the three different sites examined showed higher moisture contents in the inner heartwood than in the adjacent outer heartwood or sapwood. An increase in the moisture content in the heartwood region is normally referred to as wetwood which has been defined as an abnormal type of heartwood caused by decay or wound. As close relationship between inorganic element concentrations and moisture contents in wetwood have been described in the literature, the distribution of inorganic elements in this species was investigated. Radial distribution of 4 major elements from alkali metals and alkaline earth metals from sapwood to heartwood in the stem was analyzed in view of their relationship with wetwood using inductively coupled plasma spectroscopy. Wood from three plantation sites showed a similar pattern of K and Mg distribution. The concentration of K and Mg decreased gradually from the sapwood toward the outer heartwood, and did not show any significant variations within the heartwood. Radial distribution of Na and Ca failed to display any obvious trend. In all the analyzed samples that displayed wetwood or even without wetwood, generally the content of inorganic elements in heartwood was lower than in sapwood. Close relationship between the concentration of inorganic elements and moisture content which is found in the wetwood of temperate species, was not recognized in <i>A. mangium</i>. The characteristic and origin of wetwood may be different between temperate species and tropical ones. The origin of water in wetwood of <i>A. mangium</i> is an important problem to be clarified.</p>

Title	Elucidation of molting and reproductive mechanisms in the giant freshwater prawn, <i>Macrobrachium rosenbergii</i>
Division	Fisheries Division
Authors	Marcy N. WILDER, Nguyen Anh TUAN, Thanh PHUONG, Tran Thi Thanh Hien, Dang Thi Hoang OANH and Truong Quoc PHU
Key Words	Southeast Asia, Giant freshwater prawn, Reproduction, Molting, Endocrinological factors, Ecdysteroids, Juvenile hormone
Synopsis	<p>The giant freshwater prawn, <i>Macrobrachium rosenbergii</i>, is a commercially important crustacean species cultured extensively throughout Southeast Asia. In order to promote a more stable, efficient form of aquaculture, the development of improved technology for the production of seed (larvae) is highly necessitated. Artificial production techniques are based on the ability to induce reproduction and spawning in captivity, but knowledge concerning the basic mechanisms of these physiological processes is insufficient. In this research, the involvement of various endocrinological factors in the control of molting and reproduction were investigated in <i>M. rosenbergii</i>. Ecdysteroids which control molting, were additionally found to accumulate in maturing ovaries and to be present in newly-laid eggs, indicating a potential role in ovarian development and embryogenesis in this species. In addition, juvenile hormone (JH)-related substances were investigated, revealing the presence of the JH precursor, methyl farnesoate (MF) in the hemolymph. (MF) was seen to fluctuate during the molting cycle, suggesting that this hormone has a role in molting in addition to reproduction. This research also examined the synthesis of yolk protein, vitellogenin and its hormonal control. These results will form a basis for the promotion of cooperative research between JIRCAS and Cantho University, College of Agriculture, Vietnam within the framework of a cooperative project on combined farming systems in the Mekong Delta.</p>

Title	Manual for analyzing the genetic variability of fishes of economic importance in Southeast Asia
Division	Fisheries Division
Authors	Motoyuki HARA and Uthairat NA-NAKORN
Key words	Genetic variability, Isozyme, Breeding, Southeast Asia, Fisheries
Synopsis	A manual on isozymic, analysis was prepared in order to analyze the genetic variability of important fishes in Southeast Asia. By using this manual, the genetic differentiation among local populations of catfish was analyzed. The results showed that the local populations of catfish display genetic differences and are important genetic resources. It was also observed that the analysis of genetic variability enables the efficient selection of breeding methods.

Title	Large-scale production of lateral shoot seedlings of sugarcane using hydroponics systems
Division	Okinawa Subtropical Station
Authors	Yoshimitsu KATUTA, Shigenari SAKUMA and Eiichi KUROSHIMA
Key words	Low-input hydroponics, Sugarcane, Mother palnt cultivation, Lateral shoot seedlings, Large-scale production
Synopsis	The JIRCAS Okinawa Subtropical Station developed a low input hydroponics system allowing the cultivation of sugarcane by large-scale production of lateral shoot seedlings.

Title	Cryopreservation of shoot tips of taro (<i>Colocasia esculenta</i> (L.) shott) by vitrification
Division	Okinawa Subtropical Station
Authors	Hiroko TAKAGI, Nguyen Tien THNH, Toshihiro SENEBOKU and Shigeo YASHIMA
Key words	Cryopreservation, shoot tips, Vitrification Taro (<i>Colocasia esculenta</i> (L.) shott) , Long-term preservation
Synopsis	<i>In vitro</i> -grown shoot tips of taro (<i>Colocasia esculenta</i> (L.) shott) were successfully cryopreserved by vitrification. By the protocol developed in this study, the average rate of shoot recovery amounted to 100% for the triploid taro cultivars and 80% for the diploid taro cultivars. The protocol appeared to be very promising for the long term preservation of taro germplasm.

17.

Title	Detection of capsid proteins of viruses in papaya plant using protease inhibitor : antipain
Division	Okinawa Subtropical Station
Authors	Tetsuo MAOKA and Chiyoichi NODA
Key words	Plant viruses, Detecting method, Protease inhibitor, Papaya
Synopsis	Modified western blotting for detecting capsid proteins of papaya's viruses directly from papaya plants was developed. This method is expected to accelerate the production of transgenic papaya plants.

1.

Title	Development of a statistical information system relating to world agriculture, forestry and fisheries
Division	Research Information Division
Authors	Osame KOYAMA
Key Words	Food demand and supply analyses, Software, Socio-economic statistics
Synopsis	In order to promote studies on food demand and supply world wide and to enhance the strategic planning of international joint research projects, a software for integrated accumulation and handling of socio-economic statistics relating to world agriculture forestry and fisheries was designed and developed.

2.

Title	Haploid production in wheat crossed with stored pearl millet pollen
Division	Biological Resources Division
Authors	Masanori INAGAKI, Abdul MUJEEB-KAZI(CIMMYT)
Key Words	Wheat, Pearl millet, Haploid, Wide cross, Pollen storage
Synopsis	Pearl millet pollen germinated at frequencies in the range of 40-50% when pollen water contents were reduced from 50-60%(fresh)to 5-7%.Dried pollen showed similar germination frequencies after the freezing process. In crosses of wheat with pearl millet pollen stored for 3months, haploid wheat embryos were obtained at frequencies of 14-29% which were comparable to those in case of crosses with fresh pollen. These results suggest that stored pearl millet pollen can be used for wheat haploid production when and where fresh pollen is not available.

3.

Title	Screening cowpea for drought tolerance
Division	Biological Resources Division
Authors	Tomio TERA0, Iwao WATANABE, B.B. SINGH (IITA)
Key Words	Africa, Cowpea, Adaptation to drought conditions
Synopsis	Drought-tolerant lines of cowpea were screened for adaptation to the semiarid tropics of West Africa. These lines were able to grow vigorously in the dry season using residual soil moisture and they yielded an adequate amount of fodder and grains (about 1 ton per ha) without any precipitation and irrigation.

4.

Title	Distribution patterns and characteristics of the lowland soils in the Philippines
Division	Environmental Resources Division
Authors	Kenzo MIURA
Key Words	Philippines, Luzon Island, Lowland, Soils, Characteristics, Parent materials, Climate, Topography, Distribution patterns
Synopsis	Distribution patterns and characteristics of the soils in the major lowland rice areas in Luzon Island, the Philippines were analyzed in relation to factors such as parent material s, climate, and topography. The characteristics of the Philippine lowland soils were essentially controlled by the basic nature of the parent materials. However, differences in the soil characters among regions and within a region were induce d by factors such as rainfall and topography, which may control the local soil moisture conditions.

5.

Title	Physiological mechanisms for acid-soil tolerance of upland rice in the savanna of South America
Division	Environmental Resources Division
Authors	Kensuke OKADA, Albert FISCHER (CIAT), Elcio GUMARAES
Key Words	Acid-soil tolerance, Upland rice, Al, Savanna, South America, Rhizosphere, Soil solution, Physiological mechanism, pH
Synopsis	The Physiological mechanisms controlling genotypic differences of upland rice in tolerance to acid-soils were investigated in the savanna of South America. It was found that the soil pH decreased to 4.3 during crop growth, and the Al concentration in the soil solution increased to the level which brought about direct toxic effect on root growth. The tolerant genotypes the rhizosphere showed a slightly higher pH were able to avoid Al toxicity.

Title	Mechanism on desertification relating to micrometeorology caused by over grazing
Division	Environmental Resources Division in collaboration with National Institute of Agro-Environmental Sciences
Authors	Yoshinobu HARAZONO
Key Words	Grazing intensity, Grassland, Penetration of rain Evaporation
Synopsis	Experiments involving different grazing intensities (change in sheep numbers grazing in the plots) were carried out in the semi-arid grassland in eastern part of Inner Mongolia, China. Changes in biomass and micrometeorology in each plot were examined. Biomass in the grassland decreased and the number of sheep footprints increased with the increase of the grazing intensity, leading to soil hardening. Penetration of rain water into the ground was prevented in plots with higher grazing in intensity resulting in increased evaporation just after rainfall and suppression of grass development.

8.

Title	Ecological traits of weedy rice (padi angin) in direct seeded rice fields in Malaysia and control strategy.
Division	Crop Production and Postharvest Technology Division
Authors	Hiroaki WATANABE, Azmi MAN (MARDI), Md. ZUKI Ismail (MADA), Duncan A. VAUGHAN (NIAR)
Key words	Malaysia, Direct-seeded rice, Weedy rice, Weedy control
Synopsis	In Malaysia, weedy rice (<i>Oryza sativa</i> L., locally designate d as •padi angin•h) induces crop losses by reducing the yield and quality of commercial rice. Weedy rice plants showed a wide variation in their morphology and in some ecological weedy traits such as easy grain shattering and seed dormancy, indicating that integrated control measures based on ecological methods should be applied to overcome the problems.

9.

Title	Reproductive strategy of the parasitoid fly, <i>Exorista japonica</i> (Diptera: Tachinidae) -clutch size regulation in response to host density-
Division	Crop Production and Postharvest Technology Division
Authors	Satoshi NAKAMURA
Key words	<i>Exorista japonica</i> , Tachinidae, Oviposition behaviour, Noctuidae, Biological control
Synopsis	Effect of host encounter rate and host density per patch on the oviposition decision of <i>Exorista japonica</i> females, natural enemies of many noctuid larvae, was studied in the laboratory. The number of eggs laid per bout increased as the rate of host encounter decreased and as the host density per patch increased. The results indicated that <i>E. japonica</i> females were able to regulate the clutch size with the host density (the rate of host encounter).

10.

Title	Formulae and processing methodology of urea molasses•@blocks for ruminant animals in Malaysia
Division	Animal Production and Grassland Division
Authors	A. OSHIBE, M. WAN ZAHARI(MARDI)
Key Words	Supplement, Molasses, Ruminant, Malaysia
Synopsis	Urea molasses block (UMB) is a promising feed supplement for ruminant animals in Malaysia. We developed formulae and a processing methodology that can be utilized on a semi-commercial scale through the collaborative research program with the Malaysian Agricultural Research and Development Institute (MARDI)

11.

Title	Utilization of oil palm frond silage in the tropics
Division	Animal Production and Grassland Division
Authors	Motohiko ISHIDA and Abu Hassan OSMAN (MARDI)
Key Words	Oil palm frond, Feed, Tropical cattle
Synopsis	Digestion and feeding trials were conducted to determine the feeding value of oil palm frond (OPF) silage in the tropics. It was found that beef and milk could be produced by utilizing OPF silage as one of the feed ingredients in the diet of fattening bulls and lactating dairy cows.

12.

Title	Statistical procedure for the assessment of the association between multiple DNA markers and phenotypic records
Division	Animal Production and Grassland Division
Authors	Kenji TOGASHI and J.E.O. REGE(ILRI)
Key Words	Breeding value, Genetic markers, Accuracy of selection
Synopsis	A procedure for the assessment of the associations between DNA markers and phenotypic records was developed. Remarkable increase of selection accuracy was found by restricting the number of DNA markers to the top 30 in the order of magnitude. These findings that DNA markers for small effects tend to add noise to the estimation and that the procedure using selected DNA markers for large effects enhances the accuracy of selection.

13.

Title	LA-PCR method for mitochondrial DNA RFLP analysis in pigs and wild pigs
Division	Animal Production and Grassland Division in collaboration with National Institute of Animal Industry
Authors	Masanori KOMATSU, Job. M. MATIAS, Kumiko TAKEDA and Akira ONISHI
Key Words	Mitochondrial DNA, RFLP analysis, Pig, Wild pig, LA-PCR, Philippines
Synopsis	We developed a simple method for amplification of pig and wild pig mitochondrial DNA (mtDNA), 2kb, and for mtDNA RFLP analysis using the long-Accurate (LA) PCR method. The usefulness of the present method for mtDNA amplification and mtDNA RFLP analysis was confirmed in Luzon native pigs and Luzon wild pigs.

14.

Title	Evaluation of land degradation for resource management
Division	Animal Production and Grassland Division
Authors	Yukiyo YAMAMOTO, Haruhiro FUJITA, Gustav GINTZBURGER (ICARDA)
Key Words	Evaluation of land degradation, Neural network Resource map database, GIS, Marginal system
Synopsis	Neural network modelling was applied to evaluate land degradation hazard of a marginal agricultural system using a resource map database. Degradation degree and extent as supervisors, elevation, slope, direction, soil and vegetation as explanatory factors, were selected for the neural network modelling. Precisions of the modelling for the evaluation of the degree and extent of degradation were 86% and 79%, respectively. The evaluation of the degradation hazard was found valid in the northern foothills and plain during the field verification, where hazardously evaluated areas corresponded to sites with frequent gully erosion.

15.

Title	Studies on low regeneration capacity after selective logging in tropical rain forests
Division	Forestry Division in collaboration with Forestry and Forest Products Research Institute (FFPRI)
Authors	Hiroyuki TANOUCHI, Azman HASSAN(FRIM), Nazarudin RAMLI (FRIM), Yosuke KOMINAMI•@•@•@•@•@•@ (FRPRI), Toshio KATSUKI (FFPRI), Keizo HIRAI, Shozo SASAKI (FFPRI), Md. Farid Abd. Rashid (FRIM)
Key Words	Selective logging, Natural regeneration, Logging methods, Soil disturbance
Synopsis	It was suggested that hill forests after selective logging should be maintained for the regeneration of Dipterocarp species. Although there were many saplings after selective logging, they could not become established around logging roads and grow under shaded canopy. Removal of stemless palms was effective in improving the light condition for shaded saplings.

16.

Title	Ecophysiological performance of dipterocarps in response to environmental stress•@-special emphasis on water relations-
Division	Forestry Division
Authors	Yutaka MARUYAMA, S.K.YAP (FRIM)
Key Words	Water relation, Stomatal response, Dipterocarp
Synopsis	Slow growth of dipterocarps appeared to be caused by stomatal closure during daytime, which strongly reduced photosynthetic CO ₂ uptake. Low soil-to-leaf hydraulic conductance in dipterocarps limited water availability and thus caused a decrease in the leaf water potential especially in mature tall trees. Seedlings of dipterocarps grown in the nursery were susceptible to water stress due to the low ability of maintaining turgor. On the other hand, leaves of exposed trees had adapted to water deficiency stress morphologically and turgor was maintained, through osmotic adjustment.

17.

Title	Soil erosion in pineapple fields and its control
Division	Okinawa Subtropical Station
Authors	KAZUO SUGAHARA
Key Words	Pineapple field, Erosion, Weeping lovegrass, Pigeonpea, Non tillage planting
Synopsis	Results indicate that soil erosion occurred downward along roads in a pineapple field. For the alleviation of erosion hazards, we grew pigeonpea in a field and weeping lovegrass on the lower edge before the initiation of nontillage planting of pineapple with residues of pigeonpea.

18.

Title	Low-input hydroponics systems under field conditions
Division	Okinawa Subtropical Station
Authors	Harushige SAKUMA, Katsmi SUZUKI
Key Words	Field conditions, Hydroponics, Low-input, Lack of electricity, Nutrient control, Problem soils
Synopsis	It is difficult to cultivate crops in areas with problem soils such as saline, acid sulphate soils, etc.. For crop Production in such regions we developed new hydroponics systems that could be used field conditions without requiring electricity and control of nutrients.

Title	Agricultural Characteristics and Recent Research Activities in Central Asia
Division	Research Information Division
Authors	Mitsunori Oka, Masaaki Suzuki
Key Words	Agriculture, Livestock, Fisheries, Environment, Soil Conservation, Water Resources, Genetic Research Activities, Central Asia
Synopsis	JIRCAS expanded its research activities to the Central Asia region. To identify the major research topics to be implemented jointly with research institutes in the region, we investigated the characteristics of agriculture and current research topics.

Title	Phylogenetic differentiation of tetraploid <i>Vigna</i> species, <i>V.glabrescens</i> detected by isozyme analysis
Division	Biologica Resources Division
Authors	Yosinobu Egawa, Ithnin Bujang, Somsong Chotechuem, Charaspon Thavarasook, Kitbamroong Charas
Key Words	Phylogenetic differentiation, isozyme, <i>Vigna</i> , <i>Ceratatropis</i> , <i>V. glabrescens</i> , <i>V. reflexo-pilosa</i> , <i>V. minima</i> , <i>V. trinervia</i>
Synopsis	Based on Isozyme analysis, it is suggested that wild tetraploid <i>Vigna</i> species, <i>V. reflexo-pilosa</i> originated from interspecific hybridization between <i>V. minima</i> and <i>V. trinevia</i> followed by netural chromosome doubling <i>V. glabrescens</i> is considered to be derived from <i>V. reflexo-pilosa</i> as cultivated type with erect growth habit.

Title	Molecular Cloning and Characterization of cDNAs for Genes That Are Responsive to Dehydration Stress in Higher Plants
Division	Biological Resources Division
Authors	Kazuo Yamaguti-Sinozaki, Tomio Terao
Key Words	cDNA, dehydration stress, differential hybridization, <i>Arabidopsis thaliana</i> , <i>Vigna unguiculata</i>
Synopsis	We isolated 16 independent cDNAs (ERDs) for genes that are early-responsive to dehydration in <i>Arabidopsis thaliana</i> by using the technique of differential hybridization. We also isolated 10 independent cDNAs (CPRDs) for genes that are responsive to dehydration stress in <i>Vigna unguiculata</i> . Sequence analyses of these genes indicate that their products may play a role in the protection of cells from dehydration

Title	Land degradation analysis of rainfed agricultural area in Pakistan using remote sensing data
Division	Environmental Resources Division
Authors	Satoshi Uchida
Key words	Remote sensing, Land degradation, Vegetation conditions, Soil erosion
Synopsis	To extract a markedly eroded area, spot Panchromatic data were used. Multi-spectral information supplied by landsat tm data was used to calculate several kinds of indices related to vegetation, coverage and soil conditions. The characteristics of the distribution of these indices inside and out side of a markedly eroded area could not be clearly separated from each other, although from the statistical point of view some differences which are reflected in the regional characteristics could be recognized. The results obtained may contributed to a more precise analysis of land degradation and associated environmental deterioration in the study area.

Title	Effect of windbreak rows made of a combination of several tree species on crop growth and improvement of micro-climatic conditions
Division	Environmental Resources Division
Authors	Taichi Maki *, Borong Pan **, Ryoji Sameshima***, Mingyuan Du***
Key words	Climatic improvement , Multiple windbreaks , Arid land, Desert
Synopsis	It is important to improve the climatic conditions in the marginal area extending from barren land (•gdesert•h) to farm land (•goasis•h) to prevent desertification in arid lands. It was shown that the micro-climatic conditions of farm land were improved and alleviated by the construction of windbreak rows made of a combination of several tree species and also that the growth and development of crops were promoted and crop yields increased by windbreaks under the adverse climatic conditions including high temperature ,low humidity and strong wind that prevail at Turpan in Northwest China.

Title	Effects of timing of N fertilizer application on grain production and N use efficiency in pigeonpea/sorghum intercropping (Timing of N fertilizer application in intercropping systems of the semi-arid tropics)
Division	Environmental Resources Division
Authors	Osamu Ito*, Katsuyuki Katayama**, C. Johannsen***, J.J.Adu-Gyamfi***
Key Words	Intercropping, Pigeonpea, Sorghum, Nitrogen fertilizer, Nitrogen use efficiency
Synopsis	Nitrogen fertilizer application at about a month after sowing brought about a higher grain yield, area-time equivalent ratio and nitrogen use efficiency compared with the application before sowing. It is speculated that inorganic nitrogen which accumulated in the soil solution during dry the season contributed significantly to the initial growth of fast-growing component crops (sorghum) in the intercropping system.

Title	Rice direct Seeding-Development of anaerobic Seeding technique in the tropics-
Division	Environmental Resources Division (Department of Agro-Environmental Management, Chugoku National Agricultural Experiment Station)
Authors	Minoru Yamauchi, K. Moody, T. P. Tuong
Key Words	Soil, Crop establishment, Direct seeding, Grain yield, Rice, Weed competition
Synopsis	Anaerobic seeding technique in which pregerminated seeds are sown under the puddled soil surface has been developed to alleviate the constraints direct (erratic crop establishment, increased weed infestation, and lodging) in direct seeding culture of rice in the tropics. Germplasm accessions tolerant to flooded anaerobic soil were identified. The seeds were sown anaerobically by broadcasting or drilling. The technique was tested successfully in fields located in the Philipplines, Vietnam, and Myanmar and was production was as high as in the case of transplanted rice.

Title	In vitro rearing of the tachinid parasitoid, <i>Exorista japonica</i>
Division	Crop Production and Postharvest Technology Division
Authors	Shigemi Yagi, Satoshi Nakamura
Key Words	in vitro rearing, Tachinidae, parasitoid, biological control
Synopsis	<p>A tachinid parasitoid fly, <i>Exorista japonica</i>, a natural enemy of many lepidopterous larvae, was aseptically reared throughout the larval stages from the egg stage in vitro by using various artificial diets based on insect tissue culture media and heat-treated silkworm haemolymph (BMH). When diets containing BMH were used, most of the larvae formed respiratory funnels at the 1st instar stage and developed to the 3rd instar. When BMH was used as a diet, 13% of the larvae developed into adult flies. On the other hand the addition of 20-hydroxy ecdysone in the diets did not affect the larval development of the fly in vitro.</p>

11

Title	Procedure for the construction of a model for simultaneous analysis of a combination of productivity and adaptability traits in African cattle
Division	Animal Production and Grassland Division
Authors	Kenji Togashi
Key Words	Genetic covariance, Simultaneous analysis, Productivity, Adaptability, African cattle
Synopsis	A model the for simultaneous analysis of genetic (co) variances for productivity and adaptability was developed by based in a Bayesian procedure. Herd life and milk yield were selected as adaptability and productivity traits, respectively. This procedure was applied to the data set of Friesian cattle in Kenya. Heritability values for milk yield and herd life were 0.172 and 0.4, 24, respectively. Genetic correlation was -0.452. These data indicate that simultaneous analysis must be carried out to a void losing genetic diversity in each trait.

12

Title	Map database construction for regional resources management and its applicability
Division	Animal Production and Grassland Division
Authors	Haruhiro Fujita, Gustav Gintzburger
Key Words	Map database, Resources management, Land degradation, Thematic maps, GIS, Human influences
Synopsis	Map database of land resources (topgraphy, soil, landform, landunit, vegetation, land degradation) and their utilization (grazing and shrub cutting areas and their intensities) in a local barley/rangeland/livestock agricultural system was constructed within GIS. The map database was found to be useful for the evaluation and integration of human influences on natural resources in such marginal agricultural systems where land degradation prevails.

Title	Registration of a Heat Tolerant Snap Bean Variety in Japan
Division	Okinawa Subtropical Station
Authors	Hiroshi Nakano, Tokuhiro Momonoki et al.
Key Words	Breeding, Heat tolerance, High temperature, Phaseolus vulgaris, Pod setting,
Synopsis	Ishigaki 1 was bred and registered as a new variety by the Ministry of Agriculture, Forestry and Fisheries. It is a heat tolerant variety during pod setting. Critical temperature for pod setting of Isihigaki 1 ranges from 28.0 to 29.5•Z(mean day air temperature). The variety is adapted to the climatic conditions prevailing in the subtropical island of Japan called Nansei-shoto.

もどる

1 趣 旨

我が国の農林水産業に関する試験研究の動きや成果等を、主に開発途上地域を中心に海外に紹介することを目的とする。我が国の研究者が海外で行った研究も含むこととし、内容は必要に応じ要約する。

2 記事の区分

次の区分により、原稿を編集掲載する。

1) 原著論文 (original articles)

著者が行った研究に基づく成果をとりまとめたもので、内容などで他に前例のない論文

2) 個人研究レビュー (personal research reviews)

著者が行った一連の研究について、既発表報文も含め、研究のねらい、成果及び意義等についてレビューし、あわせて今後の展望をとりまとめたもの

3) 一般研究レビュー (general research reviews)

近年関心の高い事項について、関連をもって実施されているいくつかの研究全体について、研究のねらいや成果、意義等についてレビューし、あわせて今後の展望をとりまとめたもの

3 投稿及び査読

1) 編集幹事は、我が国の農林水産業に関わる試験研究の成果等(我が国の研究者が海外において行ったものも含む。)の投稿を受付ける。受付は、国内の研究者が関与した研究成果などに限る。

2) 編集幹事は、投稿論文の分野に応じて編集委員に査読を依頼する。

3) 編集委員は査読の責任を負い、その結果を編集委員長(担当:編集幹事長)に報告する。また、必要に応じ別途査読者を依頼し意見提出を求めることができる。その場合は、当該査読者名もあわせ編集委員長に報告する。

4) 編集委員長は、上記 3) の報告に基づき、投稿論文の再考または不採用を決定することができる。

4 記事の取り扱い

JARQ に掲載された論文に関する著作権は、国際農林水産業研究センターに帰属する。JARQ の全文は JIRCAS ホームページを通じ、インターネット上で公表する。

5 刊 行

JARQ は、原則として年に 4 号発行する。

以 上

(注) 編集委員及び編集幹事は、編集委員長(国際農林水産業研究センター理事長)が、国内の研究機関、大学などの関係者の中から別途任命します。

JARQ 執筆要領

1 原稿の作成

1) 原稿は英文で作成する。

(1)初回は、原稿、フロッピー、JARQ 原稿送り状を JIRCAS 編集室 JARQ 係に送付する。

原稿：本文、表、図（含む写真）を各 2 部（図、写真はコピー可）。

フロッピー：本文は Windows 版 Word、Mac の場合は Windows で読める Word、
又は一太郎で、Table は、Excel 又は花子で作成することが望ましい。

(2)査読、英文校閲を経た後、最終原稿、フロッピーディスク、原図を同上宛送付する。

2) 学術用語は、文部省編学術用語集による。

それに無い学術用語は各学会の慣例に従う。

3) 原稿は、A 4 判用紙を用い、マージンを上下左右各 3 cm とし、

文字フォント：Times New Roman

文字サイズ：11 又は 12 ポイント、25 行で作成する。

4) 原稿の枚数は原則として次のとおりとする。

原稿 8 頁（表、図（含む写真）は別）

刷上り（A 4 判） 6 頁（表、図（含む写真）を含む）

表及び図は別紙に作成し、本文原稿用紙の右欄外に Table 1, Fig. 1 のように
挿入位置を示す。

5) 執筆者は、原則として日本人 1 名以上を含むものとする。

論文が共著の場合には、内外を問わず、執筆者が共著者及び相手機関等に
JARQ 掲載についての了解を得ることとする。

6) タイトルページについて（見本参照）

(1) タイトル：内容を的確かつ簡潔に表わすものとする。

(2) 著者名：フルネーム、名は小文字で前、姓は大文字で後に記す。

(3) 部名、所属機関、所在地：研究が実施された時のものを記す。

(4) Abstract：約 200 words

(5) Discipline：執筆要領 3 に指定する当該論文の関連専門分野名から選ぶ。

(6) Additional key words：タイトルに含まれていないもの、5 words 以内

(7) 研究が海外における共同研究などによって実施された場合、

その背景（プロジェクト名、相手機関名、実施場所、実施期間）を記す。

(8) Present address：研究実施後著者が他に異動した場合には記す。

(9) *Corresponding author：連絡先著者として Fax No. e-mail アドレスを記す。

(10) Received, accepted(受理日) : 最終原稿を作成する時に JARQ 係から指示する。

(11) Running title : 10 語以内で記す。タイトルが 10 語以下の場合そのまま使用する。

7) 見出しの順位は、以下のようにする。

第 1 順位 : 番号なしで 11Point 太字	Introduction
第 2 順位 : 番号なしで 10Point 太字	Analysis
第 3 順位 : 番号.	1. Effect
第 4 順位 : 番号で両括弧	(1)Yield

8) 本文は、ピリオドの後は半角 2 文字空け、コンマの後は半角一文字空けとする。
段落の書き出しは、Space key で空けずに、Tab key で空ける。

9) 学名はイタリックで書く。

10) 単位表示は原則として SI 単位を用いる。

[例] 長さ :	km, m, cm, mm, μm , nm
面積 :	km^2 , m^2 , cm^2 , mm^2 , ha, a
容積 :	kL, L, mL,
体積 :	km^3 , m^3 , cm^3 , mm^3
質量・重量 :	t, kg, g, mg,
時間 :	y, day, h, min, s (hours, hr, hrs など使わない)
質量濃度 :	kg/m^3 , g/L (又は $\text{kg}\cdot\text{m}^{-3}$, $\text{kg}\cdot\text{m}^{-3}$, $\text{g}\cdot\text{L}^{-1}$, $\text{g}\cdot\text{L}^{-1}$)
モル濃度 :	mol/m^3 , mol/L (又は $\text{mol}\cdot\text{m}^{-3}$, $\text{mol}\cdot\text{m}^{-3}$, $\text{mol}\cdot\text{L}^{-1}$, $\text{mol}\cdot\text{L}^{-1}$)
その他 :	, 同位元素 ^{32}P , 酸化還元電位 Eh, 水素イオン濃度 pH

省略のピリオドはつけない(例えば、mg L など)。

複数形を使用しない。

%, の単位は space を空けずに書くこと。(25%, 25)

11) 謝辞は原則として省く。

12) 引用文献はそれを引用してある箇所(本文中、あるいは図表)の右肩上に
文献番号で表示する。

13) 引用文献について

(1) 引用文献は本文のあとに References と表示し、著者名(機関名の場合も含む)のアルファベット順に記載する(通し番号をつける)。

同一著者のものが二つ以上ある場合は発表年次順とする。

著者名が不明の場合は Anonymous とする。

(2) 記載の方法

文献番号： 通し番号

著者名： 姓前、名後（イニシャルのみ）とする。

複数の場合も同様とし、&(and にしない)を使用する。

4人以上の場合は、第1著者名のみ記載し、et al. を付ける。

年号： 西暦で示し、括弧書きとする。

タイトル名：

誌名： 雑誌名の略称は、原則として公表された基準によることとし、イタリックとする。

巻(号)： 巻は太字とする。

発行所： 論文集・単行本の場合には、記載する。

発行地： 論文集・単行本の場合には、都市名・国名を記載する。

頁数： 引用論文の始めと終わりのページをハイフンで分けて記す。
単行本など全体を引用した場合は、pp. で示す。(pp. 251)

注意事項： 日本語の文献の場合は文献の末尾には [In Japanese] とし、
英文サマリーのある場合は [In Japanese with English summary] と記載する。

(3) 記載例

雑誌記事の場合：

文献番号. 著者名(年号): タイトル. 誌名, 巻号, 頁数.

[例] 8. Kondo, T. et al. (1997): Structural changes of forage grass lignin by rumen digestion. *JARQ*, **31**, 49-54.

論文集の場合：

文献番号. 著者名(年号): タイトル. In 書名. ed. 編者名, 発行者(所), 発行地, 頁数.

[例] 8. Chern, S. & Pallardy, S. (1998): Food security in Asia. In Sustainable agricultural development. JIRCAS Int. Symp. Ser. No. 6. eds. Horiuchi, H. & Tsubota, K., JIRCAS, Tsukuba, Japan, 1-11.

単行本の場合：

文献番号. 著者名(年号): 書名. 発行所, 発行地, 頁数.

[例] 8. Atherton, J. G. (1987): Manipulation of flowering. Butterworths, Kent, UK, pp.425.

2 別刷

著者には別刷50部を贈呈する。50部以上の別刷を必要とする場合は実費を著者の負担とする。その場合、実費印刷希望部数のみを「JARQ原稿送り状」に明記する。

Grassland Division, Kyushu National Agricultural Experiment Station

(Nishigoshi, Kumamoto 861-1192, Japan)

Abstract

Experiments were conducted to control spiny amaranth (*Amaranthus spinosus* L.) and velvetleaf (*Abutilon theophrasti* Medic.) in a field of forage corn sown in early, mid- and late

Discipline: Weed control

Additional key words: dense sowing, living mulch, spiny amaranth, swinecress

共同研究の場合

No.6	(1998.11)
No.5	(1997.11)
No.4	(1997.3)
No.3	(1996.3)
No.2	(1995.9)
No.1	(1994.11)

HOME

JIRCAS Journal was established to provide a medium, not only for JIRCAS staff but also for other researchers working on JIRCAS research projects, to publish and share their research findings with the rest of the research community in Japan as well as in other countries. Its first issue was released in November, 1994. Since then, it has been published almost annually, with its 10th issue coming up this year.

On the other hand, the Japan Agricultural Research Quarterly (JARQ) started being published in 1966 with the aim of disseminating overseas, up-to-date information on achievements and trends of research activities pertaining to agriculture, forestry and fisheries that are carried out in Japan that may also be relevant to the needs of other countries, particularly in the developing regions.

As both publications have been pursuing similar objectives, it has been decided to integrate the two journals. Issue No.10 marks the end of JIRCAS Journal. From now on, papers which deserve publication in this journal will be published in JARQ .

We would like to extend our deep appreciation and gratitude for all the support and contribution you have given to JIRCAS Journal. We hope you will find great pleasure in reading JARQ as well.

No. 3 March (1996)

	Title	Authors	Additional key words	page
1.	Detection of 16S rDNA of Thai Isolates of Bacterium-Like Organisms Associated with Greening Disease of Citrus	Kazuo NAKASHIMA, Maitree PROMMINTARA, Yoshihiro OHOTSU, Takeshi KANO, Jun IMADA and Meisaku KOIZUMI	citrus greening, liberobacter, 16SrDNA, PCR, repid diagnosis	1-8
2.	Pathogenic Races of <i>Xanthomonas oryzae</i> pv. <i>oryzae</i> in South and East Asia	Takahito NODA, Tsuyoshi YAMAMOTO, Tsugufumi OGAWA and Hisatoshi KAKU	<i>Xanthomonas oryzae</i> pv. <i>oryzae</i> , race, bacterial leaf blight, rice	9-15
3.	Monitoring Field Populations with Pheromone Trap and Seasonal Trend of Adult Body Size of the Diamondback Moth, <i>Plutella xylostella</i> (L.) (Lepidoptera: Yponomeutidae), in Central Thailand	Masahiko KUWAHARA, Piyaratt KEINMEESUKE and Yoichi SHIRAI	population fluctuation, immigration, forewing length, tropics, biological characteristics	17-22
4.	Effects of Bruchid-Resistant Mungbean Meal on Growth and Blood-Biochemical Values in Mice	Katsuhiko MIURA, Masao ISHIMOTO, Noriko YAMANAKA, Shigeru MIYAZAKI, Miyako HIRAMATSU, Yasuyuki NAKAJIMA, Koichi HIRANO, Keisuke KITAMURA and Shoji MIYAZAKI	<i>Vigna radiata</i> , <i>Callosobruchus chinensis</i> , insect-resistance gene, histopathological changes, feed safety test	23-31
5.	Dynamics of Roots and Nitrogen in Cropping Systems of the Semi-Arid Tropics	Osamu ITO, Ryoichi MATSUNAGA, Katsuyuki KATAYAMA, Satoshi TOBITA, Joseph J. Adu-G YAMFI, Junichi KASHIWAGI, Theertham P. RAO and Gayatri DEVI	semi-arid tropics, intercropping, pigeonpea, root system, nitrogen balance	33-48
6.	Phylogenetic Differentiation of Tetraploid Vigna Species, <i>V. glabrescens</i> and <i>V. reflexo-pilosa</i>	Yoshinobu EGAWA, Ithnin Bin BUJANG, Somsong CHOTECHUEN, Norihiko TOMOOKA and Yoichi TATEISHI	<i>Ceratotoropsis</i> species. <i>V. trinervia</i> , <i>V. minima</i> var. <i>minima</i> , isozyme analysis, interspecific hybridization	49-58
7.	Nematode Species Attacking Crops in Thailand with Measurements of Second-Stage Juveniles of <i>Meloidogyne</i> spp	Yukio TOIDA, Nuchanart TANGCHITSOMKID, Somkuan KEEREewan and Takayuki MIZUKUBO	plant parasitic nematodes, field crops, fruit trees	59-68

8.	Effect of Intensity of Weed Infestation on the Occurrence of <i>Leptocorisa oratorius</i> Fabricius (Heteroptera: Alydidae) in Paddy Fields of Sri Lanka	Atsushi SUGIMOTO and Lionel NUGALIYADDE	Rice bug, alternate host plants, ovarian development	69-74
9.	Salt Tolerance of Cultivated Rice Varieties from Vietnam	Bui Ba BONG, Satoshi TOBITA, Nurliani BERMAWIE and Toshihiro SENBOKU	<i>Oryza sativa</i> L., seed germination, seedling growth, varietal screening	75 -83
10.	Heading Performance of Rice Varieties under Double Cropping on Ishigaki Island	Tsukasa NAGAMINE, Makoto YAMAMORI, Masumi KATSUTA and Makoto KAWASE	rapid generation advancement, Indica, Japonica	85-95

Full List of -for Scientific Papers-Contents

No. 2 September (1995)

	Title	Authors	Additional key words	page
1.	Supply and Demand Analysis for Rice in Peninsular Malaysia -With special reference to direct seeding in the Muda Area-	Minoru TADA and Yoshinori MOROOKA	rice, self-sufficiency rate, supply, demand, direct seeding, econometric model, simulation, Muda Area	1-11
2.	Damage of Rice Grains caused by the Rice Bug, <i>Leptocorisa oratorius</i> Fabricius (Heteroptera : Alydidae)	Atsushi SUGIMOTO and Lionel NUGALIYADDE	Sri Lanka, Stylet sheath	13 -17
3.	Improved Method of Determination of Membrane Thermostability for Screening Heat-Tolerant and Sensitive Varieties in <i>Brassica</i>	Mohammad Mofazzal HOSSAIN, Hiroyuki TAKEDA and Toshihiro SENBOKU	Temperature stress, EC, heat Killing time	19-27
4.	Fauna of Plant Parasitic Nematodes in the Temperate Region of Japan 1. Surveys in Shizuoka and Kagawa Prefectures	Emiko YAMAMOTO and Yukio TOIDA	plant parasitic nematodes, Shizuoka Pref., Kagawa Pref., vegetables, flowers, bonsai pine	29-36
5.	Fauna of Plant Parasitic Nematodes in Temperate Region of Japan 2. Survey in Chiba Prefecture	Emiko YAMAMOTO and Yukio TOIDA	plant parasitic nematodes, Chiba Pref., temperate region, vegetables, flowers	37-42
6.	Fauna of Plant Parasitic Nematodes in Temperate Region of Japan 3. Survey in Wakayama Prefecture	Emiko YAMAMOTO and Yukio TOIDA	plant parasitic nematodes, Wakayama Pref., temperate region, vegetables, flowers	43-48
7.	Screening of Bacteria Producing Vitamin B ₁₂ from Tua-Nao in Thailand	Noriyuki OKADA, Charan CHETTANACHITARA and Wiwut DAENFSUBHA	fermented soybeans, Natto, cell fusion	49-57
8.	Relation between Population Density of the Rice Bug, <i>Leptocorisa oratorius</i> Fabricius (Heteroptera: Alydidae), and Damage of Rice Grains	Atsushi SUGIMOTO and Lionel NUGALIYADE	<i>Echinochloa crus-galli</i> , weeds, Sri Lanka	59-64

9.	Anaerobic Direct Seeding of Rice in the Tropics	Minoru YAMAUCHI	coleptile, crop establishment, cultivar, lodging, seed aging, weeds	65-78
10.	Land Levelling under Direct Seeding Rice Culture in Malaysia	Hideto FUJII and Meng Chang CHO	Malaysia, Vacant spot, Motor grader, Tractor, Seedling establishment	79-86
11.	Proline Content in <i>Brassica</i> under High Temperature Stress	Mohammad Mofazzal HOSSAIN, Hiroyuki TAKEDA and Toshihiro SENBOKU	<i>Brassica oleracea</i> , <i>B. campestris</i> , heat tolerance, hybrids, proline, reproductive stage	87-93

No.1 November (1994)

	Title	Authors	Additional key words	page
1.	Role of Natural Enemies in the Regulation of Stored-Product Insect Populations in Rice Storages in Thailand	Porn-tip VISARATHANONTH, Hiroshi NAKAKITA, and Prasoot SITTISUANG	predators, parasites, ants, spiders, pseudoscorpion	1-7
2.	Prevention of Aflatoxin Contamination in Thai Maize 2. Distribution of maize with high moisture content and methods of control of <i>Aspergillus flavus</i> infection.	Shoichi KAWASUGI, Koji KAWASHIMA, and Prisan SIRIACHA	<i>Aspergillus flavus</i> , maize, hermetic storage	9-17
3.	Changes of Communal Ties among Rice Farmers in Group Farming -A case of <i>kelompok tani</i> in the Muda Area, Malaysia -	Kumi YASUNOBU, Yoshinori MOROOKA, and Hin Soon WONG	guess-who test, double-cropping, sociogram, direct seeding	19-27
4.	Effects of Forest Windbreaks deployed in Arid Lands, Turpan, Northwest China 1.Effect on climatic improvement	Taichi MAKI, Borong PAN, Mingyuan DU, Makoto NAKAI, and Kenji UEMURA	tamarisk, wind speed, air temperature, surface soil temperature, relative humidity	29-38
5.	Effects of Forest Windbreaks deployed in Arid Lands, Turpan, Northwest China 2.Effects on prevention of wind erosion and on crop growth	Taichi MAKI, Borong PAN, Mingyuan DU, Makoto NAKAI, and Kenji UEMURA	tamarisk, wind direction sand accumulation, plant growth	39-45
6.	Climatic Differences between an Oasis and its Peripheral Area in Turpan Basin, Xinjiang, China	Mingyuan DU, and Taichi MAKI	climate improvement, evaporation, heat balance, windbreak	47-55
7.	Detection of Mycoplasma-like Organisms Associated with White Leaf Disease of Sugarcane in Thailand using DNA Probes	Kazuo NAKASHIMA, Mitcha CHALEEPROM, Porn-tip WONGKAEW, and Pisan SIRITHORN	MLO, dot hybridization	57-67
8.	Function and Regulation of Genes that are Induced by Dehydration Stress in <i>Arabidopsis thaliana</i>	Kazuo YAMAGUCHI-SHINOZAKI, Takeshi URAO, Toshisuke IWASAKI, Tomohiro KIYOSUE, and Kazuo SHINOZAKI	signal transduction, abscisic acid, <i>cis</i> -acting element, transcription factor, transgenic plant	69-79

No. 10, 2002. 3

目 次

- 松本和馬, ジェームス・R・コトゥライ
*Azadirachta*属樹種とマホガニーの混合植栽による
マホガニーマダラメイガの被害防除試験…………… 1
- 中牟田潔, 松本和馬, ジェームス・R・コトゥライ
合成性フェロモンによるマホガニーマダラメイガ
*Hypsipyla robusta*の野外における誘引…………… 9
- 趙朝輝, 斎藤昌義, 吉橋忠, 中原和彦, 辰巳英三
電解水を用いた充填豆腐製造の微生物制御…………… 13
- 椛木信幸, 田村治男, 小松 隆, 三浦憲蔵, 森田弘彦, 田淵隆一,
片岡健治, タウインカン ワンカート, パイウイット ワタナビタワス
タイ東北部における土壌保全型畑作システムの開発…………… 21
- ジョン・S・コールドウェル, ソムサク・スクチャン,
ウィモンラト・オンオク, チュンポルン・サトラヴァハ, 小倉力,
山本由紀代, プラバトソム・プラピン
水状況, 浸蝕, および収量の関係に対する農家の捉え方…………… 31
- 鮫島良次, 唐立松
新疆のオアシス内外の気象条件とワタ圃場における水の利用…………… 43

Distribution Systems and Rural Development

Kazuyuki Tsurumi
Director, Development Research Division, JIRCAS

In West Africa

A few years ago, I had the opportunity to visit several countries in West Africa. As generally known, West Africa is an area where the income level is very low and where essential food products are in short supply, especially, compared to other developing areas. In addition, these countries are facing many problems such as limited water resources, degradation of soil, difficulty in increasing the production of foods, etc.

During my visit there, I was able to observe a farming village where farmers were actively tackling the production of farm products, especially, the production of vegetables under such difficult conditions. Actually, only part of the farmers were working actively in the village. However, they not only dug wells for themselves to ensure the water supply for their own use but also installed a fence neatly around the village to protect themselves from wild animals. Furthermore, their farmland was well-managed and they appeared to be full of life. According to them, very recently, an open market had been set up near the village and they began to deliver their products to the market. It is obvious that when cash income is readily available, farmers are strongly motivated to produce farm commodities. Although I heard that there was only one TV set in the village, it seemed that the TV supplied a great deal of information as well as a means of entertainment in the village. It is no exaggeration to say that the example of the village in West Africa described above suggests that the presence of markets strongly affects the regional economy and this is common throughout the world. Still, I would like to emphasize that the vitality I observed in the village I visited was remarkable, compared with other villages in the vicinity.

Agricultural promotion measures

Not only in Africa but also in many other regions, agricultural promotion measures are being implemented based on some development programs managed by each country or each region. Besides, international agencies and institutes in advanced and developing countries also have long been carrying out on a large scale studies on the development of new varieties of crops, pest control measures, effective policy and systems, etc. as well as conducting surveys on social and cultural trends. Moreover, these countries and institutes have been making utmost efforts to disseminate the newly developed technology by dispatching specialists or advisors. However, I must admit that the results of these efforts are not satisfactory when I see the actual situation of farmers working on their farmland. Although there must be many reasons for the poor results, one of the major reasons is that it is difficult to give an incentive to farmers only by introducing new technology and/or constructing facilities. Actually, even though the activities seem to be successful at the beginning while they are supported with subsidies and by advisors, these activities are likely to revert to the original state upon termination of the said support. From a short-range view, there must be, at least, a tangible output for the benefit of producers to some extent in order for producers to maintain the incentive. In other words, cash income from markets and purchase of assets must be greatly attractive for them. Of course, only the existence of markets will not solve all of the problems. Needless to say, the production activities are indispensable. At the same time, it is important to ensure means of distribution of crops for sale. In order to improve the income level of all of the farmers, in this case, monetary distribution in a wide area which involves as many regions as possible is necessary, because the transfer or return of wealth in a limited region will not enable to improve the standard of living of all.

Distribution systems

The existing distribution systems in developing regions have their own background based on traditions and social and economic conditions, respectively. In fact, the activities of official agencies and private distributors are closely related to support these distribution systems, and many actors operate between producers and retailers. What is important for agricultural promotion and the development of farming villages is not to totally remove the existing systems but to carefully review their advantages and disadvantages and to make full use of the existing advantages for necessary reforms. By maintaining fairness as a whole, it is more important in particular to orient private distributors toward a direction to let them play their role to their full capacity. In some countries and regions, due to the migration of populations to large cities, changes in food habits, etc., changes have already taken place in the distribution network and in the process of price formation.

Together with the reform of systems, it is important to construct well-organized infrastructures for the distribution systems since basic infrastructures are often rudimentary in many developing regions. Because of the lack of adequate infrastructures, transportation of the crops produced takes a long time, resulting in losses of large quantities of crops and deterioration in quality during the transportation, which are serious problems. To address these problems, development of wholesale markets, transportation networks, storage facilities, etc. are urgently required in addition to technological development for processing the crops and preservation of the crops in the distribution system. Obviously, technological development varies with the environment, economic conditions, etc. of each country, starting from the development of techniques to prevent losses of the harvested crops and drying, and extending to the development of techniques to process crops to products with value added, provided that these commodities can be purchased at a low price and are acceptable to most of the people in the country or the region.

For the development of efficient distribution systems

Since the distribution systems play an important role in the improvement of the income of farmers and the enhancement of the regional economy, development of distribution systems is required along with technological development and its dissemination. Therefore, approaches from both aspects are suggested for the development of an efficient distribution system: one from the view point of system or institution, and the other from the technology perspective. As for the former, it is necessary to identify the existing constraints in the current system, taking into account the social background, and for the latter, to determine the current technological level and the objectives. Then, it is essential to implement a policy related to the reform and improvement of the distribution system as well as to determine the need for the introduction of newly developed technologies and to consider the possible impact on farmers' economy and regional economy. Since a considerably large amount of investment, however, is required for the development of infrastructures for the distribution systems, plans for the promotion of distribution systems in the respective regions should be drafted carefully by setting up clearly priorities for the implementation of the programs.

The example in West Africa introduced at the beginning of this article shows only one aspect of the distribution systems in that region. However, such a trend certainly offers a good opportunity for more efficient rural development, even though in some cases, how to maintain a market in itself is a problem. Furthermore, I would like to underline the fact that due to the changes in the technologies and systems for the distribution of products, the structure of producing areas for many kinds of foods has changed a great deal even in Japan. Now, I do hope that studies on technologies and structure for the development of more efficient distribution systems will be promoted to accelerate rural development in the developing regions, which requires a close collaboration among related researchers in many fields.

Rice from Thailand, China, Vietnam, Bangladesh, and the U.S. for sale in Ghana, West Africa

Development of Technology for the Diagnosis and Prevention of Shrimp Viral Diseases in Malaysia

The collaborative project titled: • gDevelopment of technology for the diagnosis and prevention of shrimp viral diseases• h was conducted for five years from 1996 until 2002 in Malaysia. This JIRCAS project was planned to target Southeast Asia which is a major area for prawn production. The fisheries industry is extremely important for many Southeast Asian countries surrounded by the sea. Especially, the prawn industry is the key of all fisheries, because of the high value to obtain foreign exchange. Recently, prawn culture has expanded rapidly in these areas because of the development of culture technology (Fig. 1). At the beginning of the 1990s, prawn production in the world amounted to about 700,000 MT, with Southeast Asia accounting for the major part. However, the production of cultured prawns markedly decreased as a result of serious viral disease outbreaks in the first part of the 1990s. Yellow Head Virus (YHV) and White Spot Syndrome Virus (WSSV) were the main viral pathogens. At present, WSSV is the most serious problem for the prawn industry in Southeast Asia. This viral disease has occurred in most of the prawn farms in Malaysia since 1996. The increased severity of widespread viral infection is the most significant threat to stable aquacultural production. Therefore, in order to ensure stable production of cultured products, it is essential to adopt preventive measures against viral diseases. The aim of this project is the development of serological diagnosis, disinfection, and other control methods for the prevention of prawn viral diseases.

Fig. 1. Harvest of black tiger prawns from culture ponds.

Research was executed according to a four-phase plan. In the first phase, investigations of the present conditions and problems associated with shrimp viral diseases were carried out. In these studies, field work was conducted based on the collection of accurate epidemiological data. In the second phase, the pathogens were identified by polymerase chain reaction (PCR) and other methods, and concentrated and purified in the next step. In the third phase, methods for rapid diagnosis were designed, including the production of monoclonal antibodies to develop serological diagnostic methods (Fig. 2). In the last phase, disinfection methods for disease control were developed. Sterilization of facilities using disinfectants was used, and attempts will be made to prevent the occurrence of prawn viral diseases. For this project, JIRCAS collaborated with the Fisheries Research Institute (FRI), Department of Fisheries, Ministry of Agriculture of Malaysia. The institute consists of four research divisions, namely Aquaculture, Fish resources, Marine

ecology, and Food processing. Fish health section belonging to the Aquaculture division was selected as the counterpart of the project. This laboratory had just initiated fish virological research because of the increase in the incidence of many fish viral diseases during the development of marine fish aquaculture. As a result, the required equipment had been already provided for virological studies. The Pathology division, National Research Institute of Aquaculture (NRIA), Ministry of Agriculture Forestry and Fisheries of Japan, supported this project by sending experts in 1998 and in 2000. As a result of this project, a few clones of virus-specific monoclonal antibodies were obtained. Hereafter, these monoclonal antibodies will be used for the diagnosis of WSSV. On the other hand, the WSSV inactivation test indicated that halogenous disinfectants induced effective inactivation even at lower concentrations. In future, the application of effective methods of diagnosis and disinfection of WSSV should enable to achieve sustainable aquaculture in Southeast Asia.

Quantitative Analysis of 2-Acetyl-1-Pyrroline, a Strong Flavor Compound of an Aromatic Rice Variety, Khao Dawk Mali 105

A large quantity of rice is produced in many areas worldwide to meet the demand of consumers. In fact, aromatic rice varieties are very popular in Southeast Asia. Recently, they have gained a wide acceptance in Europe and the U.S.A. One of the major aromatic varieties, Khao Dawk Mali 105, is mainly produced in Northeast Thailand. The demand for this variety is increasing in both domestic and international markets due to the recognition of its good quality, i.e. pleasant aroma. Although an increase in production is urgently needed, cultivation is limited due to infertile and drought-stricken sandy soils. Erratic rainfall at the beginning of the rainy season and labor shortage for transplanting are other constraints on the production of this variety in Northeast Thailand. Since rice production is the most important activity in Northeast Thailand, where Khao Dawk Mali 105 is the main variety, it is essential to maintain the quality of this variety. It is assumed that the aroma quality depends on cultivation conditions and postharvest practices. However, there is no agreement with regard to factors controlling the aroma, and this could probably be related to the lack of objective methods for aroma evaluation of rice. Empirical methods include biting kernels, smelling tissue after warming, soaking in potassium hydroxide solution and organoleptic evaluations of cooked rice.

A • gpopcorn• h-like flavor compound, 2-acetyl-1-pyrroline (AcPy) (Fig. 1), has been reported to be an important flavor component of aromatic rice, which has a lower odor threshold than other volatile compounds in aromatic rice varieties. This compound also has been isolated and identified from pandan (*Pandanus amaryllifolius* Roxb.) leaves and popcorn. Moreover, this compound contributed to the aroma of roasted beef and crusts of wheat and rye breads. Quantification of this flavor compound in rice has been performed using a simultaneous steam distillation and solvent extraction. However, it is known that distillation leads to the loss of components during volatilization and also requires large amounts of samples. Consequently, quantification of AcPy in rice varied among the reports. Therefore, it is necessary to develop a method for quantification of AcPy in aromatic rice varieties using smaller samples and not employing steam distillation for extraction.

Fig. 1. Synthetic route leading to 2-acetyl-1-pyrroline and its labeled analog.

Isotope dilution method, the method using isotope-labeled compounds as an internal standard, is an ideal method for quantification of AcPy using gas chromatography-mass spectrometry-selective ion monitoring (GC-MS-SIM). In our laboratory, we synthesized its Carbon 13 analog, 2-acetyl- ^{13}C -methyl-1-pyrroline, for an internal standard following a straightforward synthetic route (Fig. 1). AcPy in rice was extracted with hot ethanol containing the standard compound, and analyzed by GC-MS-SIM. This improved method can enhance the sensitivity for quantification of AcPy in aromatic rice samples using small quantities (0.5 g) with a high specificity, linearity and reproducibility.

Market samples, including KDML 105 (known as • gJasmine• h) were analyzed to demonstrate the applicability of this method. In milled rice of Khao Dawk Mali 105, the concentration of AcPy was 286 • } 4.2 ppb (Fig. 2). Concentration of AcPy in brown rice, rice bran, husk and seedlings samples was relatively higher than in milled rice.

We hope that the quantitative analysis method for AcPy we have developed will facilitate the studies on the elucidation of the AcPy formation pathway, and will eventually lead to the identification of the factors controlling the flavor of aromatic rice.

Evaluation of Rainfall Station Network in Tropical Monsoon Area

When a field plot receives rainfall during the irrigation season, rainfall becomes effective for crop production if the water requirement can be properly estimated and water storage in reservoirs can be properly managed. For this purpose, it is necessary to monitor the average amount of rainfall over an irrigation system using a rainfall station network. The spatial variability of precipitation and accuracy of rainfall observation for water management should determine the rainfall station density. This study aims at proposing a method to evaluate the rainfall station density.

The study was carried out in the Muda Irrigation Scheme that is located in the northwestern part of peninsular Malaysia. It covers an area of 126,000 ha, of which 96,000 ha consist of rice fields.

First, the spatial variability of rainfall should be investigated. It is expected that in a large area the depth of rainfall tends to decrease. Depth Area (DA) analysis deals with the relationship between the rainfall amount and area. The Depth Area relationship can be described by many empirical equations. In this study the simplified Horton method was used.

$$P_l = P_0 \cdot \exp(-k \cdot l)$$

P_0 : Maximum rainfall in one rainfall area

P_l : Rainfall at the point l km apart from a rainfall center

k : Coefficient (km^{-1})

l : Distance (km)

Rainfall station with VHF radio

Values of coefficients k were obtained using 385 one-day rainfall events in a part of the target area with 10 rainfall stations. The location of the center for each rainfall event should be estimated at the same time. The coefficient of correlation between observed and estimated rainfall for each rainfall event was calculated. The average value of the correlation coefficients was 0.78. Although the equation is very simple, it describes the spatial variability of rainfall well because rainfall caused by convective lifting

predominates in the tropical monsoon area. Application of the equation to rainfall caused by frontal lifting or orographic lifting remains to be tested.

Values of coefficient k for 95% of the rainfall events ranged from 0 to 0.6, while in 5% of the rainfall events extreme values of coefficient k exceeding 2.0 were recorded. DA analysis results showed that the average amount of rainfall decreased rapidly when the area increased.

Next, rainfall events with specified coefficient k over an area in which rainfall stations were evenly scattered were simulated. Accuracy of observation for simulated rainfall events under the given station density was calculated. Relationship between the accuracy of observed rainfall and rainfall station density was obtained for the coefficient k of rainfall after appropriate simulations.

Finally, the rainfall station network was evaluated by combining the distribution of the coefficient k with the results of simulations. Standard error of rainfall events as a function of the station density in the Muda Irrigation Scheme is shown in Fig. 1. The evaluation of the rainfall station network implemented in Isohara by the Meteorological Agency of Japan is shown in the same Figure. It was considered that the rainfall station density in the Muda area should be higher because of the larger spatial variability of rainfall.

A: Present station density

B: Initial station density

Fig. 1. Standard error of rainfall events as a function of station density.

Rainfall data acquisition system began with 20 stations and has expanded to 61 stations in the Muda area.

The effect of this improvement and further investment was not apparent. The Figure shows that the expansion of the rainfall station network improved the accuracy of rainfall observations. However, a large number of rainfall stations are necessary for further improvements.

Traditional evaluation methods require many rainfall stations. In this study attempts were made to combine the evaluation of the rainfall station network with Depth Area analysis to reduce the number of rainfall stations for evaluation. The evaluation method proposed could be applied to irrigation systems in the flat plains of the tropical monsoon area.

World Aquatic Foods and Activities of JIRCAS

Yutaka Fukuda
Director, Fisheries Division, JIRCAS

Food production capacity of the hydrosphere

When seen from a spacecraft, the hydrosphere of the earth's surface appears as a beautiful blue region. It occupies 70% of the earth's surface and its deepest point is deeper than 10,000 meters. Therefore, the hydrosphere by far surpasses land in its capacity as a potential space where creatures could live. The world's oceanic region, however, despite its huge volumetric capacity, has a lower biological productive capacity than land due to its low nutrient content. As a potential place for food production, land provides cereal and other primary products that form the staple human diet. Unfortunately, it is difficult to utilize the hydrosphere's primary product, phytoplankton, as food. Instead, humans exclusively utilize fish, shellfish, and other higher-order products of the hydrosphere.

Trends in catch quantity

In 1999, the total catch of the world's fisheries reached 137 million tons. This amount was 1.3 times larger than that in 1990, with the increase being greater than the increase in production of cereal grains, which remained at the same level between 1990 and 1999. However, it is generally believed that the ocean's capacity to provide foods will probably run out in the near future. With respect to country-wise distribution of catch quantity in 1999, Japan landed 6.61 million tons, the third highest in the world. Japan's catch at one point was higher than any other country in the world, but it was ousted from its position by China in 1989. China, which landed 47.5 million tons, equivalent to about 35% of the world's entire catch in 1999, harvests more from the hydrosphere, by far, than any other country. Although some economists doubt China's catch statistics, the catch quantities, especially of the freshwater fisheries resources, are dramatically increasing, pushing up the world's total catch. Therefore, the inland water regions of the world are expected to become potential places for development of fisheries. Peru and Chile, South American countries where sardine is a major fisheries resource, landed 8.44 and 5.59 million tons, respectively, becoming the world's second and fifth highest ocean harvesters.

Predicted consumption of fishery products in year 2010 (FAO)

In year 2010, the world's population is expected to reach 7.03 billion. Accordingly, 100 to 120 million tons of aquatic food will be needed. Assuming that about 30% of the total catch is inedible, it is expected that there will be a shortfall of 10 to 40 million tons in aquatic foods. Japan and other Asian countries including China, India, Indonesia, the Philippines, and Thailand consume a particularly large amount of fish products. Various ichthyophagous cultures are now being practised in monsoon regions around Asia where the staple food is rice, while in European countries diets are mainly based on various meat products. Considering the significant increase in personal incomes of people in Asia in recent years, it is estimated that 69 million tons of aquatic foods will be needed around this region by year 2010. In other words, more than half of the world's fisheries products will be consumed in Asian countries (see figure).

Activities of JIRCAS Fisheries Division

In this context, the JIRCAS Fisheries Division is engaged in three international collaborative studies to secure fisheries products in Asia. The first is a study on sustainable production systems of aquatic animals in brackish mangrove areas, conducted in cooperation with the Philippines, Malaysia, and Thailand. This study aims to restore fisheries resources and develop the technology of environment-friendly aquaculture using natural nutrients and the environmental protection ability

of brackish-water mangrove forests. The second study is • gElucidation of reproductive mechanisms in the giant freshwater prawn, and research aiming to improve prawn-rice farming systems in the Mekong Delta. • h This study is being conducted in cooperation with Vietnam, and is aiming at the establishment of freshwater prawn aquaculture systems combined with rice growing as part of the conventional complex agriculture in the Mekong Delta of Vietnam. The third study is entitled, • gDevelopment of technology for utilization of freshwater fisheries resources. • h This study is being carried out in cooperation with China, and is aiming at the development of techniques to manufacture frozen minced fish meat (SURIMI) and fishmeal from freshwater fish.

Predicted pattern of consumption of aquatic foods in year 2010 (Total world consumption-115.3 million tons)

Collaborative Research in Vietnam: Development of Farming Systems in the Mekong Delta Area

The Mekong Delta was formed about 10 thousand years ago at the mouth of the Mekong River. Covering roughly four million hectares, the region, except for small hills near the Cambodian border, is less than one m above sea level (Fig. 1). Large-scale flooding follows the rainy season and washes away damaging salt and acid sulfate, providing fresh fertile soil and fish. Depending on the topography, the Delta's soils range from alluvial to acid sulfate to saline. Houses line the banks of the well-developed canal network due to the high elevation and the convenience of waterway transportation (Fig. 2). In addition, ponds are also dug for stocking fish and as a source of soil with which to expand the farm area (Fig. 3).

Fig. 1. Topology map of the Mekong Delta (Ministry of Irrigation, 1987).

Fig. 2. A typical farmer's house in the Mekong Delta with a pigsty and a fish pond.

Fig. 3. Farmer's fruit garden with a pond.

In the region, the *doi moi* economic renovation program, initiated in the late 1980s, has contributed to rapid economic growth through further development of the traditional and unique agricultural VACR systems (a Vietnamese acronym standing for fruits and vegetables, aquaculture, livestock and rice). They combine fruit and vegetable cultivation, animal husbandry and aquaculture and contribute to sustainable agricultural management by cycling products through several stages of production in order to minimize waste while maximizing benefits.

The major objective of the five-year research project (1999-2003), titled "Development of new technologies and their practice for sustainable farming systems in the Mekong Delta," is to promote agricultural practices that are not only economically profitable but also ecologically sustainable as farming systems. Research subjects included in

the project comprise the development of technology for components of farming systems in the areas of rice, livestock, fruit and aquaculture production. The project also aims to develop and evaluate sustainable farming systems that employ technology for environmental conservation and VACR farming systems and put these technologies into practice through the establishment of model VACR farming and extension systems. For this purpose, the studies have been carried out in collaboration with Cantho University (CTU), Cuu Long Delta Rice Research Institute (CLRRI) and the Southern Fruit Research Institute (SOFRI). So far, in the project, studies for the development of techniques for the breeding of salt-tolerant varieties and development of integrated pest management in rice and rice-based farming systems have been carried out. In the livestock area, techniques for feeding management for pig production and pathological diagnosis of porcine diseases have been improved. A model orchard was established for the improvement of fruit production at the on-farm trial site and basic technology for prawn seed production has also been developed (Fig. 4). Development of methods for the assessment of nitrogen cycling is currently being promoted. In the socio-economic area, farming systems at the research site were classified and the cause-effect relationship of the technical and economic factors in farming systems was analyzed.

The annual Workshop of 2001 was held at CLRRI, Cantho, Vietnam, during the period of November 27 - 29, 2001, to review the results already obtained and to examine the future research direction of the project (Fig. 5). The next annual Workshop of 2002 will be held at the College of Agriculture, Cantho University in November 2002.

On-Farm Trial to Develop Agropastoral Systems in the Brazilian Savannas

Since 1996, JIRCAS has been implementing an international collaborative project with Brazilian Agricultural Research Corporation (EMBRAPA), for developing agropastoral systems (sustainable crop-pasture rotation systems) in the Brazilian savannas. As a part of the project, an on-farm trial to transfer the technologies and knowledge of the experimental stations to private farms has been conducted. Here, the process and results of the trial are introduced.

The Agricultural Training Center of National Federation of Japanese Immigrant Agricultural Cooperation (JATAK-ATC) was selected as the experimental site of the on-farm trial. JATAK-ATC is located in the Guatapara district of the San Paulo State, which is approximately 300 km northwest from Sao Paulo City. It consists of 570 ha of upland fields and 450 ha of wetland, and is playing an important role to demonstrate and diffuse the advanced agricultural technologies to the small or middle holders in the district. The aims of this study are (1) selection of forage species suitable for intensive grazing on the upland fields, (2) selection of forage species suitable for the wetland pasture, and (3) establishment of key technologies to develop sustainable agropastoral systems in JATAK-ATC.

Grazing cattle on the wetland pasture during dry season.

When the on-farm trial was begun in 1997, most of the upland field area was utilized as sugar cane fields (Fig. 1). However, to avoid soil deterioration by mono-crop cultivation of sugar cane, JATAK increased the cultivated area of corn in 1998. The soil of the upland fields was an Oxisol, which had a very high sand content (80%), and low organic matter content (1.8%). Thus, an agropastoral system combining forage crops with sugar cane and corn seemed to be a good alternative to enhance soil fertility of the upland fields. Until 1997, *Brachiaria decumbens* was the only grass species planted in JATAK-ATC. It is known that *B. decumbens* has tolerance to low soil fertility, but its nutritive value is relatively low. Thus, a grazing experiment was conducted for two years, comparing *B. brizantha*, *B. dictyoneura*, and *Panicum maximum* with *B. decumbens*. Results of the experiment indicated that *B. brizantha* was most suitable for intensive grazing, from the points of view of dry matter productivity, forage quality and persistency of the pastures.

Fig. 1. Change of land use with time in the Agricultural Training Center of JATAK, the Guatapara district, San Paulo State.

On the other hand, in the wetland, a drainage system was constructed between 1994 and 1997, and the drained areas have been utilized as native pastures. The number of animals of JATAK-ATC also increased from 197 heads in 1994 to approximately 1,000 heads in 2001. Since 1998, several field experiments have been conducted to select grass species to improve pasture productivity of the wetland. Flooding tolerance was compared between *Brachiaria decumbens*, *B. brizantha*, *B. humidicola*, *Andropogon gayanus*, *Paspalum atratum*, and *Cynodon dactylon*. Only *B. humidicola* and *P. atratum* could survive the flooding during the rainy seasons. In Central Brazil, the producer can buy seeds of *B. humidicola* more easily than *P. atratum*. Thus, *B. humidicola* was considered to be the most suitable forage species for the wetland of JATAK-ATC. Moreover, results of the seeding experiments indicated that the suitable seeding period of the wetland was the beginning of the dry season when it became possible for a tractor to enter the wetland.

In the Guatapara district, 750 ha of the wetland owned by the small and middle holders remain unutilized. The pasture establishment technologies for *B. humidicola* tested in JATAK-ATC can be adopted by them. Results of this study also suggest that JATAK-ATC can develop sustainable agropastoral systems combining sugar cane and grain production and livestock production in future. Further research will be continued to improve the agricultural sustainability and to enhance the feeding resources of JATAK-ATC.

Tagging of Leaf Rust Resistance Genes, *Lr34* and *Lr46*, Using Microsatellite Markers in Wheat

Leaf rust, caused by *Puccinia recondita* Roberge ex Desmaz f. sp. tritici Eriks. & E. Henn. is the most serious disease in wheat. Resistant cultivars are very important for sustainable wheat production in developing countries for economic and environmental reasons. Most of the leaf rust resistance genes identified are race-specific, and since they may be overcome by genetic shifts or new virulence in the pathogen population, durable resistance, that is, race-nonspecific and/or slow rusting genes, may be of primary interest to wheat breeders. This resistance may be expressed best at the adult plant stage as a quantitative trait.

Slow rusting genes have small effects, and hence are easily affected by environmental conditions and are difficult to identify due to their race-nonspecificity. Tagging these genes with molecular markers increases the efficiency of selecting leaf rust resistance and facilitates marker-assisted selection.

A doubled haploid (DH) population was produced from cv. Fukuho-komugi × cv. Oligoculm by means of wheat × maize crosses. A full genetic linkage map was constructed using various kinds of molecular markers, such as microsatellite, RFLP, RAPD etc. A framework map with 343 markers was used to perform QTL (quantitative trait loci) analysis for leaf rust resistance in this population. Leaf rust severity was scored at adult plant stage in the field for two seasons, 2000 and 2001, at Cd. Obregon, Sonora State, Mexico (Fig. 1).

Fig. 1. Symptoms of leaf rust-infected leaves.

From left to right (two leaves each): Fukuho-komugi (*Lr34*), Oligoculm (*Lr46*), resistant and susceptible DH lines.

Two chromosome regions, 7DS and 1BL, for the putative QTLs were detected by composite interval mapping (CIM) (Fig. 2). These QTLs were considered to be due to the effects of the known slow rusting genes, *Lr34* and *Lr46*, according to their positions. The QTL analysis also indicated that *Lr34* was derived from the Japanese cv. Fukuho-komugi, while *Lr46*, from the Israeli cv. Oligoculm. These QTLs explained about 40% and 26% of the total variation.

Fig. 2. Likelihood ratio (LR) contour by composite interval mapping for QTL detection of leaf rust severity on chromosome 1B long arm and 7D short arm. Bold contour indicates LR by joint analysis of data for the years 2000 and 2001. LR thresholds, equivalent to LOD=2.5, are 11.5 for a single year and 13.8 for joint analysis. Short arms are toward the top. • ♦ @ indicates centromere.

Microsatellite markers, *Xgwm295.1* and *Xwmc44*, were linked to these QTLs on 7DS and 1BL, respectively. When the population was classified according to the genotypes of these markers, the mean differences in leaf rust severity for *Xgwm295.1* and *Xwmc44* were 40.1% and 25.5%, respectively. The mean severity of the lines, whose genotype was resistant for both *Xgwm295.1* and *Xwmc44*, was 11.3%; this was 61.6% more resistant than the mean of susceptible lines (Table 1), and 19.9% more resistant than the overall mean. Moreover, genotyping using these molecular markers aids in discriminating the lines with *Lr34* and *Lr46* from those with only *Lr34*.

Lr34 and *Lr46* classified as slow rusting genes are widely used in CIMMYT (International Maize and Wheat Improvement Center) breeding program. The results indicated that the molecular markers used in this study facilitate the identification of *Lr34* and *Lr46*, and contribute to pyramiding of the leaf rust resistance genes in the breeding program.

This study was conducted as part of a collaborative program between Biological Resources Division, JIRCAS and Applied Biotechnology Center, CIMMYT from Jan. 1998 to Jan. 2002.

Table 1 Genotypic effects of flanking loci on leaf rust severity (%)

Locus	Genotype ^a	2000	2001	Mean	
<i>Xgwm295.1</i> (7DS)	F	12.6	10.9	11.9	
	O	57.1	46.6	52.1	
	dif.	-44.5	-35.7	-40.1	
<i>Xwmc44</i> (IBL)	F	47.6	41.4	44.9	
	O	23.2	16.8	19.5	
	dif.	24.4	24.6	25.5	
<i>Xgwm295.1</i> / <i>Xwmc44</i>	F / O	12.6	10.1	11.3	a ^b
	F / F	11.6	12.5	12.5	a
	O / O	32.8	25.6	30.2	b
	O / F	80.4	66.4	73.0	c
	dif. (FO vs. OF)	-67.8	-56.3	-61.6	

a F, O and dif. indicate Fukuho-komugi, Oligoculm and genotypic difference between F and O genotypes. F and O are resistant and susceptible for *Xgwm295.1*, and susceptible and resistant for *Xwmc44*, respectively.

b Mean values with different letters are significantly different (P<0.05).

• gValue-Addition to Agricultural Produce and Products• h

- Towards increase of farmers• f income and vitalization of rural economy -

The 9th JIRCAS International Symposium on • gValue-Addition to Agricultural Produce and Products• h will be held October 16-17, 2002, in Tsukuba, Japan.

Background and Objectives

The current world population is about 6 billion and it is anticipated that the population will reach 7.5 billion and 8.0 billion by years 2020 and 2030, respectively, according to United Nations• f World Population Prospects. Global food production should be increased so as to meet the demands of the rapidly increasing population, with the limited water resources and arable land. Therefore, the roles of rural areas where agriculture and food industry greatly contribute to the production of agricultural produce and products will become more important, from the point of food security. Agriculture is still the largest sector of rural economies, and a majority of the rural population is engaged in agriculture, in developing countries. The incomes of rural people are much lower than the urban ones, and the population has been shifting from the rural to the urban areas seeking better incomes and convenient daily-life. These trends will lead to the reduction of rural potential as a base for food supply and the increase of the poorest in slums in big cities. On the other hand, it is difficult for small-scale rural food companies to compete with big companies of the urban and developed countries. In considering these facts, we have to make efforts to give rural people and enterprises tools to increase their income by adding value to the commodities, in order that they may stay in the rural areas and continue to be engaged in agriculture and food production.

Changes in urban life-style as a result of the increased income and the increasing number of working women have resulted in increased consumers• f demand for a more diversified diet, for processed and convenience foods and for animal products. When people overcome hunger, they become concerned about the quality and safety of what they eat. For example, they will avoid foods with contaminants such as pathogens, mycotoxins and pesticides, and prefer foods with physiological functions such as anti-carcinogenicity and anti-hypertension. It is important for rural farmers and enterprises to market products that meet the demands of urban consumers. We dealt with postharvest losses of grains in the 5th JIRCAS Symposium in 1998, and then started a research project to reduce postharvest losses of grains in Southeast Asia. It is worthwhile to review the demands of urban consumers, the role of rural food industry and the related research activities in developing countries. For this purpose, we will invite distinguished experts from Japan and overseas, to discuss problems associated with ensuring high quality/safety of, and adding value to agricultural produce and products, and explore directions for research on these topics in developing countries.

[JIRCAS Newsletter No.31 June 2002](#)

Dr. Yutaka Fukuda, was appointed Director of the Fisheries Division on March 1, succeeding Dr. Masachika Maeda who has joined Miyazaki University as Professor in the Department of Environmental Sciences. Dr. Fukuda is a fisheries scientist and, prior to joining JIRCAS, was Director of Food Processing and Preservation Division at the National Research Institute of Fisheries Science (NRIFS). From 1996 to 2000, as senior scientist of JIRCAS, Dr. Fukuda conducted research on efficient utilization of freshwater resources at Shanghai Fisheries University, as part of a JIRCAS collaborative research project with China. (See page 2 for his Feature Article and photo)

Dr. Masa Iwanaga, Director of the Biological Resources Division at JIRCAS, has been appointed new Director General of the International Maize and Wheat Improvement Center (CIMMYT) and will join CIMMYT in July 2002. Dr. Iwanaga is the first Japanese scientist to become director of a CGIAR Center. He has said that he will • gbuild on CIMMYT• fs strong mission to end hunger and poverty in the developing world through clearly focused research on maize and wheat. • h He added, • gCIMMYT has an impressive record in improving the livelihoods of hundreds of millions of poor people, in rural as well as urban areas. My task is to ensure that CIMMYT continues to play a critical role in developing new knowledge and science-based technologies that will help farmers and consumers overcome malnutrition, improve their incomes, and move from subsistence into an economy marked by globalization and interdependence. • h

Dr. Iwanaga holds a MS degree from Kyoto University and Ph. D. in Plant Breeding and Plant Genetics from the University of Wisconsin, USA. He has more than two decades of research and management experience in international development. He had worked for IPGRI, CIAT, and CIP for about seven, three, and ten years, respectively, before he joined JIRCAS in April 2000.

Okinawa Subtropical Station: Present and Future

Masaaki Suzuki
Director, Okinawa Subtropical Station, JIRCAS

Unique features

The JIRCAS Okinawa Subtropical Station has two unique features. First, it is the only national research institution located in the subtropical climate zone of Japan. This makes it possible to conduct experiments with many tropical and subtropical crops either in open fields or in slightly heated greenhouses of the Station. Similar climatic conditions can be simulated only in heavily heated greenhouses or climate chambers in other Japanese research institutions. The Station has, therefore, served as a center for conducting research on tropical and subtropical crops as well as the gateway for introducing and acclimatizing tropical crops. Second, the Station is located in Ishigakijima Island, a small coral island of which the environment typifies the subtropical and tropical insular regions of the world. Special socioeconomic and technological considerations are indispensable for the development of agriculture in these regions, and the Station has served as a key research station to develop agricultural technologies adaptable to these regions.

The Station, at present, consists of five laboratories as well as the International Collaborative Research Section. The Island Environment Management Laboratory is the leading laboratory and is expected to develop technologies for attaining sustainable agricultural production in insular environments. The Environmental Stresses Laboratory is studying mainly the mechanisms of heat tolerance in vegetable crops and evaluating useful genetic resources that could be utilized for domestic and foreign breeding programs. The Crop Breeding Laboratory is developing useful breeding materials for sugarcane and tuber crops using biotechnology and is producing breeding materials for rice and wheat crops by rapid generation advancement techniques using advantageous climatic conditions. The Tropical Fruit Crops Laboratory is developing technologies for culturing tropical fruit crops in subtropical conditions and evaluating the eating quality of fruits. This laboratory is also developing new technologies for the mass production of fruit tree seedlings. The Plant Protection Laboratory is developing technologies for controlling important tropical pests and diseases such as citrus greening disease by introducing an integrated pest management method. Finally, the International Collaborative Research Section serves as a receiving office for research fellows from tropical and subtropical countries. At present, 10 post-doctoral fellows have been invited from Indonesia, China, Egypt, etc. and are conducting pioneer research in the above-mentioned laboratories.

An air view of insular environment and technology development facilities.

Future prospects

More collaborative work within the Station is essential to contribute more effectively to the development of technologies for small islands in developing regions. We are now constructing a new building with a large-scale lysimeter, where the transpiration of crops, evaporation and infiltration of soil water, and the water movement in a soil-crop continuum can be measured accurately. Furthermore, by using the runoff plots, the mechanism of erosion can be studied more precisely and countermeasures can be proposed. The addition of these new facilities is expected to give a boost to the research in the Station and would hopefully lead to a better understanding of the tropical and subtropical island environments. One of the major problems facing such islands is the sustainable production of food. The JIRCAS Okinawa Subtropical Station hopes to contribute toward alleviating and solving this problem.

Farm land in Ishigakijima Island.

Physiological Mechanism of Crop Heat Tolerance and Development of Heat-Tolerant Crops

Heat stress is one of the most important constraints of crop production in tropical and subtropical regions, and the severity of the situation is growing worse each year due to increasing global warming. The JIRCAS Okinawa Subtropical Station has conducted research on physiological responses to high temperature conditions in various crops such as snap bean, adzuki bean, and tomato. Our research is financed in part by Japanese Bio-oriented Technology Research Advancement Institution (BRAIN).

Physiological characteristics of heat-tolerant snap bean • eHaibushi• f

Flower and pod abscission occur easily under high temperature conditions in snap bean. The Station has successfully developed a heat-tolerant cultivar • eHaibushi• f by screening more than 350 accessions of germplasm. • eHaibushi• f was able to produce more fertile pollen and higher yield under high temperatures than other existing cultivars. The cultivar keeps withdrawing and transpiring water under high temperature and intense light conditions, and this seems to be a main reason why it is able to exhibit an excellent performance. The cultivar also lowered water potential in floral organs under high temperature conditions more gradually than a heat-sensitive cultivar. The cultivar was registered in the National Catalogue of Agricultural Crops in 1998.

Utilization of heat-tolerant germplasm for breeding programs

Wild plant germplasm generally exhibits a wide range of genetic diversity including responses to various environmental stresses. We found that Southeast Asian wild adzuki bean *Vigna minima* could set pods and produce viable seeds under high temperature conditions and can hybridize with adzuki bean. We are now developing isogenic lines of heat-tolerant adzuki bean cultivar by recurrent backcrossing and selection, and plan to conduct comparative research on these isogenic lines.

**Heat-tolerant snap bean • eHaibushi• f
developed by the JIRCAS Okinawa
Subtropical Station.**

Function of small heat shock protein

Plants usually produce small heat shock proteins (sHSPs) in response to heat stress. Mitochondrial (MT)- and endoplasmic reticulum (ER)-located sHSP genes have been successfully cloned from tomato, and it was observed that both genes worked specifically in stigmas under heat stress at the flowering period. In tomato flowers, MT-sHSP was produced more quickly at 40°C treatment as compared with ER-sHSP. These sHSPs have a molecular chaperon function which can enhance the renaturation of chemically denatured citrate synthase *in vitro*. We have also successfully produced transgenic tobacco and tomato plants by introducing MT- and ER-sHSP genes, and found that the MT-sHSP transgenic tobacco plants enhanced heat tolerance during vegetative growth stage. We are now evaluating how MT-sHSP gene works during reproductive growth stage.

Transgenic tobacco lines introduced with MT-sHSP gene.

The First Report of a Sodium-Pump (Na^+ -ATPase) Gene in Plant Cells

Salinity is a major abiotic stress in agriculture worldwide and more than 40% of irrigated lands are affected by salinity. Breeding of salt tolerant crops through genetic engineering is considered as one of the effective methods of solving salinity problems especially when land reclamation is very difficult.

Recently, several genes have been proved to be crucial for salt tolerance in plants. We have conducted research to develop a salt tolerant plant by introducing a gene related to Na^+ -pump which can prevent the accumulation of sodium ions in the cytoplasm. However, Na^+ -pump has been identified only in animal cells so far, and it used to be considered that higher plant cells would not have Na^+ -pump. The marine algae *Heterosigma akashiwo*, which we have studied, usually live in brackish water and have a function of expelling sodium ions. Recently, we detected Na^+ -ATPase activity in the plasma membranes of algae (Figs. 1, 2).

Fig. 1. Na^+ -transporter model in the plasma membrane of *Heterosigma akashiwo*.

Fig. 2. Na^+ -transporting activity in the plasma membrane of *Heterosigma akashiwo*.

Moreover, we succeeded in the world's first cloning of cDNA of membrane-bound enzyme Na^+ -ATPase (HANA) from these algae. The full-length HANA cDNA was 4,467-bp long and coded for a 1,330-amino acid protein with a molecular

weight of 146,306. HANA is a member of P-type ATPases; it has 10 deduced transmembrane domains and conserved domains including phosphorylation sites and ATP binding sites. It showed 40% identity in amino acids with animal Na^+/K^+ -ATPase α -subunits. A hydrophilic sequence with 285 amino acid residues existed between the 7th and 8th transmembrane domains. This sequence has not been found in animal cells. Studies on the sequence indicate that HANA has monomeric composition and does not have a β -subunit which animal Na^+/K^+ -ATPases usually have. The amounts of cDNA and HANA did not vary when *H. akashiwo* cells were cultured for one week at various concentrations of NaCl solutions ranging from 0.3 to 0.5 M.

The phylogenetic tree of a P-type ATPase family was established by using the neighbor-joining method in GrowTree Phylogram of Wisconsin GCG DNA sequence analysis software. Sequences of ATPases were obtained through the GenBank, EMBL, and SWISS-PROT databases. The tree consists of three major clusters, Ca^{2+} -ATPases, H^+ -ATPases, and Na^+/K^+ -ATPases, HANA is included in the 3rd cluster (Fig. 3). Therefore, HANA is similar to Na^+/K^+ -ATPases of invertebrates such as *Artemia*, *Drosophila*, and *Hydra*. It can be indicated that both HANA and yeast Na^+ -ATPases are Na^+ -pumps, but that the latter is classified in the cluster of Ca^{2+} -ATPases. This difference indicates that the origin of Na^+ -transport system in alga is different from that in yeast. We are now trying to incorporate HANA cDNA into higher plants such as tobacco, and study how Na^+ -transporting activity works in these transgenic plants.

Fig. 3. Phylogenetic tree of P-type ATPases family.

Control of Microbial Contamination by Electrolyzed Water in Tofu Manufacturing

Tofu is a popular processed food in Asia, and recently, it has become popular worldwide as a health food containing high contents of essential amino acids and isoflavone. Since the consumption of tofu is gradually increasing, it becomes very important to maintain hygienic conditions during its manufacture. Especially, the control of heat-resistant spore-forming bacteria, which are predominant on the surface of soybean, is an essential part of tofu manufacturing. This report describes the potential of electrolyzed water to control microbial contamination in tofu manufacturing.

Electrolyzed water

Electrolyzed water can be produced by electrolyzing sodium chloride solution or dilute hydrochloric acid. Electrolyzed water is classified into 3 types: acidic electrolyzed water (germicidal, used for hygienic purposes), alkaline ionized water (having medical effects; drinking water), and alkaline electrolyzed water (lipid-detergent). Scientific evidences concerning electrolyzed water increased in the 1990s and some industrial applications were also developed. Nowadays, acidic electrolyzed water is used to sanitize food-processing equipment and fresh-cut vegetables in food industries.

The electrolyzed water generator introduced in China Agricultural University.

Utilization of electrolyzed water for soaking soybeans

Microbial contamination could be effectively eliminated by using acidic electrolyzed water. We soaked soybean in 3 types of electrolyzed water: acidic electrolyzed water at pH 2.1, 1185 mV oxidation-reduction potential (ORP) and 100 ppm chloride, alkaline electrolyzed water at pH 11.7, -120 mV ORP, and a mixture (weak acidic electrolyzed water) of both waters at pH 6.5, 891 mV ORP, and 50 ppm chloride. Microbial population of the water became negligible after only 30 min. of treatment in acidic electrolyzed water and 1 hour in the mixture, while physico-chemical characteristics of tofu and milk made from soybean thus treated were not changed at all. Electrolyzed water is however very unstable and should be prepared only at the time of use. Moreover, acidic and weak acidic electrolyzed water are easily inactivated when polluted by organic matter; therefore, it is necessary to always protect them from pollution and to preliminarily wash the manufacturing lines with electrolyzed water before use. In order to apply electrolyzed water in processing of other foods, similar analyses of the efficiency, stability, and reactivity (safety) of electrolyzed water in the presence of other organic materials are needed.

Changes in viable bacteria populations in soybeans soaked in electrolyzed water.

Effects of electrolyzed water on soybean, soybean milk, and tofu

	Alkaline EW*	Acidic EW	Weak acidic EW	Sterilized water
Water absorbency of soybeans (%)	120.6	112.6	114.0	116.1
Solid content in soaked water (%)	0.51	0.47	0.37	0.32
Yield of soybean milk (ml**)	232.9	230.6	229.1	227.4
Solid content in soybean milk (%)	10.85	11.04	10.60	10.64

A Differential System for Rice Blast Disease

IRRI-Japan Collaborative Research Project has been implemented with financial assistance from the Japanese Ministry of Agriculture, Forestry and Fisheries (MAFF), and researchers from Japan International Research Center for Agricultural Sciences (JIRCAS) have continued joining the project since 1984. Phase IV of the project • Physio-genetic studies on yield determination and ecological adaptability for sustainable rice culture • f was initiated in October 1999 and will continue until September 2004.

Among our activities, I describe our major progresses in the genetic studies of rice blast resistance.

Blast research now

Blast caused by *Pyricularia grisea* Sacc. is one of the most serious diseases of rice (*Oryza sativa* L.) all over the world. In the lowland areas of tropical Asia, tungro virus and bacterial leaf blight are the most important, and blast used to be considered as the 3rd most important. However, the introduction of new cultivars without blast resistance genes has caused an increased occurrence of this disease. Moreover, as rice production in upland and rainfed areas has become more important, blast has become a more serious problem.

Japan has accumulated a lot of knowledge and technology on rice blast. However, the blast pathogen has a wider genetic variability in pathogenicity in tropical areas, and that requires more comprehensive research. Especially, a differential system of blast, which was developed in Japan, was not adaptable to blast isolated in the tropics, indicating that additional genes are associated with blast resistance.

Since the prevention of pests and diseases using resistance genes is the most important method in developing countries where pesticides are not sufficiently available, the differential system of blast is a very important research area to accelerate the use of resistance genes in rice breeding programs and pest control.

Approach of IRRI-Japan Project

We have developed differential lines, which are useful tools in understanding the pathogenicity of blast isolates. The lines were developed as a result of continuous backcrosses between Japanese differential varieties as donors of resistance genes and three recipient cultivars Lijiangxintuanheigu (LTH), CO 39, and US 2 as recurrent parents as shown in the Table. Since Japonica type cultivars LTH and US 2 have no resistance gene and Indica type cultivar CO 39 has only one gene *Pia*, the pathogenicity of blast isolates can be easily determined using near isogenic lines (NILs) developed from these lines.

Target resistance gene	Genetic background • including resistance gene • j			
	Monogenic lines (-)	LTH NILs(Lijiangxintuanheigu) (-)	CO 39 NILs (<i>Pia</i>)	US 2 NILs(Non)
<i>Pia</i>	BC1F15	BC6F8, BC6F9	-	BC6F2
<i>Pib</i>	BC1F13	BC6F8	BC6F9	BC6F2
<i>Pii</i>	BC1F15	-	-	BC4F1
<i>Pik</i>	BC1F14	BC6F8	BC6F9	BC6F2

Four kinds of differential variety series, namely, monogenic lines, LTH NILs, CO 39 NILs, and US 2 NILs have been developed. A total of 24 monogenic lines were derived from backcrossing one to three times with LTH, and self-pollinating at F₁₁ to F₁₅ generations. Morphological traits of LTH, LTH NIL, and a donor line are shown in Fig. 1. A total of 17 LTH NILs were developed at generations BC₆F₈ to BC₆F₁₀. LTH NILs still segregate in some morphological characteristics and will need further fixation processes. A total of 18 Indica-type CO 39 NILs were developed and attained relatively uniform traits. Although there still exist some morphological variations, these monogenic lines, LTH NILs, and CO 39 NILs could be used as differential varieties. Unfortunately, seed production using these lines is limited under tropical conditions, and a high yielding line such as US 2 is being developed.

Fig. 1. Monogenic lines and donor variety parents.

- A: LTH (long day condition: LDC),
- B: LTH (natural [short] day condition: SDC),
- C: Monogenic line, IRBL19-A (LDC),
- D: IRBL19-A (SDC),
- E: Donor variety, Aichiasahi (SDC)

The differential varieties we developed have already been distributed to national institutes and colleges in China, India, Japan, Korea, the Philippines, Thailand, and Vietnam, and pathologists and plant breeders are working with them for blast isolate determination and breeding of resistant cultivars.

Our research provides the possibility of a future global research network for a better understanding of blast disease and resistance genes and enhancing the development of a more concrete differential system and blast-resistance breeding program in related countries.

9th JIRCAS International Symposium

• gValue-Addition to Agricultural Products• h --Towards increase of farmers• f income and vitalization of rural economy--

Date: October 16 and 17, 2002

Venue: Epochal Tsukuba

Organized by: JIRCAS

Incooperation with: National Agricultural Research Organization

National Food Research Institute

Fisheries Research Agency

PhAction

Food Forum Tsukuba

PROGRAM

Day 1 (Wednesday, October 16)

Opening Session (9:30-10:00)

Opening address and welcome remarks

Keynote addresses (10:00-11:00)

1. Status of postharvest development and the potential future contribution of value addition to rural economy (Geoffrey Mrema, FAO)
2. Linking farmers to markets - PhAction Initiative (Guy Poulter, Chair of PhAction, NRI, UK)

Session 1 (11:15-15:20)

Current status of rural economy and measures for increasing farmers• f income and vitalization of rural economy

1. China (Li Suoping, CAAS, China)
2. The Philippines (Nerlita M. Manalili, SEARCA, The Philippines)
3. Vietnam (Le Van To, Post-Harvest Technology Center, Vietnam)
4. Indonesia (Made S. Mahendra, UNUD, Indonesia)
5. South Asia (Andy Hall, CPHP, India)
6. Latin America (Bernard Ospina, CLAYUCA, Colombia)
7. Africa (Shaun Ferris, IITA, Uganda)

Session 2 (15:35-17:55)

System forensuring high quality and safety

1. Codex standards and food safety (Yukiko Yamada, NFRI, Japan)
2. Systems for ensuring production quality and safety for small rural agro-enterprises - the way forward (Linda Nicolaidis, NRI, UK)
3. Grain Quality-storage to market (Joseph Rickman, IRRI, The Philippines)
4. Safety of feed and animal products (Andrew Speedy, FAO, Italy)
5. Extension of fish pre-rigor state by enhancing mitochondrial ATP synthesis (Shugo Watabe, Univ.Tokyo, Japan)

Day 2 (Thursday, October 17)**Session 3 (9:00-12:30)**

Research on value-addition and novel utilization

1. Application of value adding technologies in Thailand (Gassinee Trakoontivakorn, IFRPD-KU, Thailand)
2. Present status and problems of traditional fish products in Southeast Asia (Tan Sen Min, SEAFDEC, Singapore)
3. Development of intermediate foodstuff from freshwater fish in China (Wang Xi Chang, SFU, China)
4. Inventory of indigenous plants and minor crops in Thailand based on bioactivities (Kazuhiko Nakahara, JIRCAS, Japan)
5. Functionalities of traditional foods in China (Li Lite, CAU, China)
6. Functionalities of foods and their utilization in Japan (Makoto Shimidzu, Univ.Tokyo, Japan)

Poster Session (12:30-14:30)**Session 4 (15:00-16:30)**

General Discussion

1. What needs to be done to make postharvest research and development serve the needs of the poor farmers in their efforts to find markets for their products? (Chair: Geoffrey Mrema, FAO)
2. Changing focus of postharvest research - from postharvest losses towards value- addition - re-evaluation of indigenous products and traditional foods (Chair: Toru Hayashi, JIRCAS)

Closing Address (16:30-16:45)**Secretariat:**

The 21st Annual Group Meeting on Agricultural Science and Technology Exchange between China and Japan at Kunshan, China

The 21st Annual Meeting on Agricultural Science and Technology Exchange between China and Japan was held at Kunshan, China, from June 3 to 5, 2002. Nine Japanese delegates led by Mr. Akihiko Ohmori, Senior Councilor for Technical Affairs from Ministry of Agriculture, Forestry and Fisheries, and 12 Chinese delegates led by Ms. Jin Sisheng, Deputy Director-General from Department of International Cooperation (DIC), Ministry of Agriculture discussed the results of the previous year's activities, future strategy and direction of agricultural research and technology development, and extension work in both countries. Dr. Y. Morooka, Vice-President of JIRCAS joined the Meeting and also attended the 7th research coordinating meeting, which was held in order to discuss substantial issues on the ongoing comprehensive research project entitled "Development of Sustainable Production and Utilization of Major Food Resources." The coordinating meeting was chaired by Mr. Liu Zhangwei, Acting Director of the Asia and Africa Division of DIC, and members from both countries agreed that the project has achieved satisfactory results. Moreover, they exchanged views on suitable topics and schedules for the next project to be prepared, and subjects such as an early prediction and warning system of weather hazards and dietary functions of Chinese traditional foods were suggested. Special emphasis was placed on strengthening the coordinating functions of institutions which were likely to join the upcoming project. The next annual meeting will be held in Tokyo next May.

Masanori Inagaki
Research Planning & Coordination Division, JIRCAS

Visitors

JIRCAS welcomed Dr. Joachim Voss, Director General of Centro Internacional de Agricultura Tropical (CIAT) on April 25, Dr. Peter Hartmann, Director General of International Institute of Tropical Agriculture (IITA) on June 17, and Dr. Marc Cohen, Special Assistant to the Director General of International Food Policy Research Institute (IFPRI) on July 17. Our staff members have had very fruitful discussions with them.

PEOPLE

Dr. Ryoichi Ikeda joined JIRCAS on June 1, 2002, as Director of Biological Resources Division, succeeding Dr. Masa Iwanaga who left JIRCAS and now is Director-General of El Centro Internacional de Mejoramiento de Maiz y Trigo (CIMMYT). Dr. Ikeda has been serving as a rice breeder and research director for 21 years in National Agriculture Research Center, Tohoku National Agricultural Experiment Station and Central Agricultural Experiment Station, all of which now belong in the competence of the newly established independent administrative institute of the government, National Agricultural Research Organization. He was also engaged in international research work as International Research Coordinator in JIRCAS from 2000 to 2001 and a plant breeder in International Rice Research Institute from 1988 to 1993. His new assignment in JIRCAS covers various crops and regions, and he wishes to make every effort to attain the goal of JIRCAS by amalgamating activities of fellow researchers within the division and accelerating collaborative research work with various national and international agricultural research centers.

Message from the JIRCAS Okinawa Subtropical Station

Steps towards a new era

Masaaki Suzuki
Director, Okinawa Subtropical Station, JIRCAS

The G-8 meeting was held in Okinawa at the dawn of the 21st century. For a brief moment, the world's eyes, and the nation's eyes were turned to this group of islands in the southwestern part of the Japanese archipelago that is known as the Ryukyu Islands. In the southernmost end of the Ryukyu Islands is a group known as Yaeyama Islands. One of these islands is Ishigaki, and this is where, 30 years ago, the Okinawa Subtropical Station of JIRCAS (formerly Tropical Agriculture Research Center (TARC)) was established.

Ishigaki Island is only 230 km² in area, but it is a beautiful island surrounded by coral reefs and lying in the path of the Black Stream that brings warm water from the south to mainland Japan. The climate is humid subtropical with an average temperature of 24 and an annual precipitation of 2,100 mm.

The organization of the Station consists of the International Collaboration Research Section, and the Laboratories of Crop Introduction and Cultivation, Crop Breeding and Rapid Generation Advance, Tropical Fruit Tree, Plant Protection, and Soil Fertility. The staff consists of 24 researchers and 14 members in the administration and field management sections. In addition, ten outstanding scientists are invited each year from developing countries under the "JIRCAS Visiting Research Fellowship Program at Okinawa." They work closely with each other to develop technology on optimum utilization of bio-resources and the promotion of sustainable agricultural production in the tropics and subtropics.

JIRCAS will be reorganized as an agency in April, 2001. Our Station is fortunately blessed at present with several important factors for conducting research. First is the high ability of the young staff including the highly qualified researchers from abroad. Second is the ideal environmental factors that come naturally with the location of this island. The third one is the existence of good facilities such as buildings and fields and modern laboratory equipment as well. Last, but the most important factor, is the

availability of sufficient funds. I do hope that these conditions will prevail even after the reorganization.

We successfully implemented many important projects in the past 30 years and contributed to the development of agricultural technologies in the tropics and subtropics. For example, the low input hydroponics system, a new device for crop cultivation was developed at this Station. The system was applied to the efficient production of sugarcane seedlings, and has contributed to a large extent to the development of mechanization in sugarcane production in Okinawa. A procedure was developed here for successful cryopreservation of shoot meristems of taro cultured *in vitro*. A heat-tolerant variety of winged bean "Urizun" and a heat-tolerant variety of snap bean "Haibushi" were released in 1986 and in 1995, respectively from this Station. In another research project conducted here, it was revealed that soil loss from pineapple fields could be prevented by planting weeping lovegrass at the lower edge of the slope.

Next year, our projects will be much more oriented to sustainable agricultural production in small tropical and subtropical islands in order to contribute to the agricultural development of these islands. One of our major projects will be a study on the evaluation of the factors causing unstable crop production under tropical and subtropical conditions in connection with meteorological and soil conditions, and studies on the methods of control. How to minimize the use of water and fertilizers will be important issues in the project from the viewpoint of stable production and environmental protection.

The development of crops resistant to environmental stresses such as heat and salt will be another important field of study. The demand for crop production under unfavorable conditions seems to increase due to the increase in the population of the developing countries. The project is implemented not only by the use of traditional breeding methods, but also by using biotechnology in combination with physiological analyses.

Citrus greening disease occurs widely in Thailand, Vietnam, Taiwan and also in Okinawa. The disease brings serious damage to citrus production and is very difficult to control. The Asian citrus *Psylla* is known as the vector insect and a kind of wasp is known to be its natural enemy. However, the wasp can not be utilized to control the Asian citrus *Psylla*, because the wasp is also known to have another wasp as its natural enemy. These complex ecosystems must be clarified one by one to develop the technology for controlling citrus greening disease.

Tropical fruits such as papaya and mango will be studied to enhance the quality, in terms of color, flavor and taste, etc., because fruit trees are very important in tropical countries for improving farmer's livelihood and for soil conservation.

Last, but not the least, the rapid generation advance of hybrid populations of rice and wheat, and the breeding of sugarcane using biotechnological methods, taking advantage of the subtropical conditions of Ishigaki Island, are also important projects to be continued further.

Close cooperation among the researchers, the effective utilization of the facilities of the Station in the unique environment provided by Ishigaki Island will hopefully lead to the solution of many of these problems.

Development of Low-Input Technology for Reducing Postharvest Losses of Staples in Southeast Asia

Akinori Noguchi

Director, Crop Production and Postharvest Technology Division, JIRCAS

The first collaborative research project for the reduction of postharvest losses was launched on September 18, 2000 by the signature of a Memorandum of Understanding (MOU) among the Department of Agriculture (DOA), Institute of Food Research and Product Development (IFRPD) at Kasetsart University, School of Energy and Materials (SEM) at King Mongkut's University of Technology Thonburi (KMUTT), the Royal Thai Government and JIRCAS. This project is titled: "Development of low-input technology for reducing postharvest losses of staples in Southeast Asia" and will be continued for five years from 2000.

The increase in the world population and limited cultivated area emphasize the issue of food security as one of the global problems facing humans worldwide. While the production of food resources should increase, special attention must be paid to the reduction of postharvest losses in developing regions through the development of low-input and appropriate technologies.

Due to the fact that the climate in the Southeast Asian countries is typically hot and humid, postharvest losses have been estimated at about 30%, caused mainly by improper drying techniques and insect infestation during crop storage.

It was recognized that the widely used fumigant in the world, methyl bromide, is characterized by ecocidal and environmental disruption and contributes to the depletion of the ozone layer. Therefore, it will be strictly banned from use by 2015. On the other hand, an alternative pesticide, phosphine, induces tolerance and shows a marginal insecticide activity. As a result, developing countries have attempted to develop proper technologies for reducing postharvest losses.

Far too often the problem of feeding the world hungry is conceived in terms of producing a sufficient amount of food. Equally pressing problems related to preservation and distribution issues that affect food products between harvest and consumption, are frequently neglected.

While agriculture is obviously affected by the surrounding environmental conditions, there are many constraints on the rapid increase of food production. Therefore, it is very important to develop techniques for reducing postharvest losses as well as improving the quality and nutritional value of agricultural produce, prior to consumption.

The following technologies can be selected as appropriate solutions for common issues of postharvest losses in developing regions; drying and maintenance of freshness of products from harvest through transportation to storage. Safety assessment, product selection prior to processing and improvement and development of processing to meet the cultural food traditions should also be considered. The former two fields correspond to preventive technology for postharvest losses and the latter corresponds to technology for quality evaluation.

While harmonized development of these technologies is required to achieve a stable food supply and

improve farmer's income, the infrastructure and laws relevant to food and other agricultural products have not been updated to meet new challenges in developing regions. Therefore, we must adapt selected technologies to the conditions in developing regions, keeping in mind how agricultural productivity can be enhanced through incentives to the farmers.

In this project, the objectives are to develop low-input drying technology using natural energy sources such as sunlight, husks and straw. Preservation technology will employ natural enemies and products such as neem and pheromones. Achievement of effectiveness and development of lower-cost technology systems for the reduction of postharvest losses at the farmer level or in small-scale farming, are other objectives of the present project.

The scope of the studies can be summarized as follows; 1) Survey of postharvest losses of staple crops such as rice and maize and identification of causes of quality deterioration, 2) Analysis of the dynamic status of major stored products insects and the mechanisms of damage and possible alleviation, 3) Development of low-input drying technology and biological control of stored products insects using natural enemies and products, 4) Development of environment-safe technologies for reducing postharvest losses of staples.

Signature of Memorandum of Understanding at the DOA office

Development of a Cable Logging System for Low-Impact Timber Harvest in Tropical Natural Forests

Shozo Sasaki
Forestry Division, JIRCAS

Because of its high productivity and versatility, the ground skidding system has been commonly used for timber harvest in tropical natural forests. However, since the heavy crawler tractors used in the operations can easily damage residual trees and the forest floor, it is difficult to achieve sustainable forest management with this harvesting system. This is especially true in the operations in hilly areas, where current logging activities are increasing. It is necessary for tropical forest management to develop low-impact, socially and economically acceptable logging techniques that can be used in the steep, rugged and fragile forest environment.

Cable logging system has an advantage over the ground skidding system in that it is not necessary to bring heavy machinery into forest stands. However, because a few heavy logs are scattered in a broad forest area, the cable system may not be suitable in terms of cost and benefit. Therefore, we are developing a new cable logging system that is suitable for selective cutting in tropical natural forests in many aspects.

The cable system is a combination of standing skyline system and running skyline system. For quick installation, operations and dismantling, we selected a wire rope 20-mm in diameter for the skyline, which is rather smaller for heavy logs in tropical natural forests. To ensure safety with the smaller skyline, the cable is installed very loosely, with a maximum mid-span deflection (sag) value of 0.1. The cable tension and sag values can be controlled according to the log weight. Fig. 1 shows the results of some examinations in trial operations. For light logs less than 2 t in weight, with a sag value of 0.04, we observed that the cable system could totally lift up the logs all the way in the span. With the 0.08 sag setting, heavy logs up to 5 t could be totally lifted in the middle of the skyline over a stream buffer zone. On a slope, logs could be extracted by dragging with one side lifted up. The calculated and measured maximum cable tension values were 7,500 and 7,000 kgf, respectively, which is compatible with the skyline safety factor. Based on logging impact data, the ratio of disturbed area in the cable system is much smaller (1/10) than that of the ground system.

Fig. 1. Comparison of carrying load and cable sag values in trial operation.

Our target specification of the system is as follows: 6 t carrying load, 500 m working span, and 50 m lateral working range. We are currently conducting several trials in a 30 ha research plot in a hill forest in Peninsular Malaysia. Eight cable corridors are selected based on cable installation conditions, maximum accessibility to cutting trees, and minimal road construction. We plan to further improve the system, techniques, ground preparation work and operational procedures for efficient and lower-impact harvest.

A trial operation of the cable logging system

Characterization of Vegetation Status in the Sub-Saharan Region Using Remote Sensing

Satoshi Uchida

Environmental Resources Division, JIRCAS

In the southern part of the Sahara desert, there are vast areas under semi-arid climatic conditions that form a belt zone. These areas are prone to a decline of the soil productivity and to desertification. Although monitoring of nutrient conditions over a long period of time would be required to estimate the soil productivity, this method can not cover areas out of experimental stations. Alternative method to estimate the soil productivity within a spatially wide range is to examine the vegetation status in relation to the soil productivity. Remote sensing is a suitable method for identifying the vegetation density at every pixel within the coverage of an observed scene and for monitoring the temporal changes. In this study, low spatial resolution (1 km) satellite data were used to characterize the vegetation status in association with physical environmental factors and high spatial resolution (20 m) satellite data were used to discriminate agricultural land use around the study site.

Normalized Difference Vegetation Index (NDVI) calculated by the combination of near infrared spectral band data and visible red spectral band data can be used to estimate the vegetation status. Fig. 1 shows the changes in the 1 km mesh 10-day composite NDVI derived from NOAA/AVHRR data during the period from October 1992 to September 1993, where 10-day composite denotes the maximum value recorded during 10 days in order to remove the effects associated with cloud cover. Each item in this figure represents averaged NDVI over land unit, which was defined by overlying soil (Regosols) and annual rainfall maps in Burkina Faso.

Fig. 1. Temporal changes of 10-day composite NDVI for unit areas depending on annual rainfall ranges. Areas are located on the same soil type, Regosols, in Burkina Faso.

As the rainy season started in June, NDVI began to increase from the unit with the largest amount of annual rainfall to the unit with a smaller amount. The difference in the level of maximum NDVI was mainly caused by the proportional existence of vegetation components and not by the difference in the status of the vegetation. The Figure indicates that the landscape in the rainy season in the area with more than 700 mm annual rainfall was distinctively different from that in the area with less than 500 mm. In other words, annual rainfall in the range from 500 to 700 mm was identified as the critical level to maintain the vegetation reproductivity.

Spatially detailed information on actual land use was analyzed by using SPOT/HRV data with a spatial resolution of 20 m. Annual rainfall at the study site, Kolbila village, is about 700 mm. In terms of land use, millet was generally cultivated in the surroundings of house clusters while wide fallow areas could also be observed. In this study, the author attempted to discriminate cropped area and fallow from other land use types by applying the decision tree method for multi-temporal NDVI obtained from SPOT/HRV data. This method is based on the difference in the characteristics of the vegetation coverage depending

on the land use types; i.e., both cropped area and fallow showed relatively low NDVI values compared with forest or bush during the post-rainy season and the cropped area showed a distinctively high NDVI value during the crop growing period.

Fig. 2 displays the estimated land use in 1992 and 1993 over the Kolbila village, in the center of the image, and its surroundings. Cropped area in the southeastern part was located around the river course, where the conditions of cultivation were considered to be more suitable in terms of soil moisture level than in the Kolbila village. This figure characterizes the variation of the cropped area in the Kolbila village as follows; 1) about half of the cropped area in 1992 was cropped subsequently in 1993, 2) continuously cropped area occurred mostly in the range within a distance of about 500 m from the center of the village.

Fallow shown in Fig. 2 could include the deforested area. According to the estimated land use for the extensive area around the Kolbila village, fallow appeared widely mixed with bare land. These land use features should be examined in relation to the location conditions, e.g., topography, accessibility to road or river, for the purpose of analyzing the changes in the soil productivity.

 Cropped in 1992&1993  Center of Kolbila village
 Cropped in 1992

Fig. 2. Distribution of cropped area in Kolbila village and its surroundings in 1992 and 1993 estimated by using multi-temporal NDVI of SPOT/HRV data.

Characteristics of Rainfall Kinetic Energy and Raindrop Size Distribution on Ishigaki in the Subtropical Zone of Japan

Kenji Banzai
Okinawa Subtropical Station, JIRCAS

It has been recently observed that a large amount of red soils flows out from the rivers to the seacoast in the southwestern islands of Japan, particularly Okinawa. This phenomenon exerts a considerable effect on the natural ecosystems and endangers the coral reefs and seaweed habitat in this subtropical area. High rainfall intensity and large raindrop size have been known to contribute to this severe soil erosion. Using current rainfall energy equations, energy values can be calculated to predict soil loss which in turn can be very useful in formulating remedial measures. However, the distribution of the actual rainfall energy values is often wide and the characteristics of the rainfall energy in each zone have not been elucidated.

The filter paper method in which a filter paper with eosin powder is exposed to rain for several seconds to measure the raindrop diameter is not practical and prevents rapid and accurate determinations.

To gain a basic understanding of rainfall energy values, we examined the characteristics of the rainfall energy and raindrop size distribution in the subtropical area using a disdrometer. The device transforms the vertical momentum of the raindrop impact into an electric pulse, whose amplitude is a factor in the function of the drop diameter. Rainfall energy values were calculated from the observations obtained with the device, which enables to measure the raindrop size distribution continuously and automatically. The device however can not measure raindrops below 0.3 mm, hence rainfall energy values may show an error of about 2.48%.

Fig. 1. Relationship between rainfall intensity and energy.

Measured kinetic energy vs. rainfall intensity data revealed a wide distribution between the upper limit equation of Wischmeier and the lower limit equation of Mihara (Fig. 1). Kinetic energy above the Wischmeier equation which was also observed below 30 mm/h rainfall corresponded to the excess zone. On Ishigaki, there were large-sized raindrops at a rainfall intensity below 30 mm/h. The distribution of the raindrop size on the points shown in Fig. 1, was wide, ranging from 1-5 mm in diameter compared with the data recorded in Tsukuba where the raindrop size was mainly in the range of 1-2 mm (Fig. 2).

This study highlights the higher rainfall kinetic energy and larger raindrop size observed in the subtropical area compared with the temperate area. Rainfall energy values derived from disdrometer measurements can also be used effectively for the calculation of the rain coefficient in the USLE equation, estimation of the amount of splash erosion and elucidation of the processes involved in soil crust formation.

Fig. 2. Properties of raindrop diameter distribution.

Annual Workshop on 'Mekong II Project' Held in Cantho, Vietnam

The comprehensive project entitled "Development of new technologies and their practice for sustainable farming systems in the Mekong Delta (Mekong II)" has been implemented since last year, 1999, after a high degree of success was achieved in the phase I project entitled "Evaluation and improvement of farming systems combining agriculture, animal husbandry and fisheries in the Mekong Delta." The Mekong II project focuses on the production of commodities through the material circulation of by-products and/or wastes generated in the VACR farming systems. VACR is a Vietnamese acronym standing for fruits and vegetables, aquaculture, livestock and rice. For this purpose, the studies have been carried out in collaboration with Cantho University (CTU) and Cuu Long Delta Rice Research Institute (CLRRI) since 1999, respectively, and with the Southern Fruit Research Institute (SOFRI) since 2000.

The annual workshop on the comprehensive 'Mekong II' project was held at the Mekong Delta Farming Systems Research and Development Institute (MDFSRDI), CTU, Cantho, Vietnam during the period of November 14-17, 2000. The main purpose of the workshop was to review the results and to examine the future research direction of the project.

There were more than 80 participants from Vietnamese organizations, including local authorities such as agricultural extension departments and Tan Phu Thanh village representatives (the research site for the on-farm trial of the project), as well as CTU and CLRRI, in addition to 12 Japanese participants.

After the greeting address delivered by Prof. Dr. Le Quang Minh, Vice Rector of CTU, followed by the opening addresses given by Prof. Dr. Vo-Tong Xuan, Director of MDFSRDI, and by Dr. Osamu Ito, Director of Environmental Resources Division, JIRCAS, 52 reports were presented in 9 sessions during the first three days. In Session A, an outline of the on-farm trial site of the project was introduced. Technical report on rice cultivation was presented in Session B. In Session C, integrated pest management in rice cultivation was reported, and topics on upland crops such as soybean with rice cultivation and on drying technologies were discussed in Sessions D and E, respectively. After the discussion on fruit production in Session F, the results of pig production were presented in Session G. In Session H, 12 reports were presented on aquaculture production including fish and freshwater prawn. After Session I which covered the development and evaluation of farming systems, future direction and development for closer collaboration for the studies were discussed comprehensively in Session J. On the last day, November 17, a field trip to Tan Phu Thanh village was organized for all the participants. The workshop was successful due to the strong commitment of the experienced staff of the MDFSRDI, CTU. The Proceedings of the Workshop were published by JIRCAS.

Participants exchanged views on the progress of the project and confirmed the importance of such studies. During the workshop, it was eventually concluded that the development of sustainable farming systems which combine rice cultivation, fruit production, animal husbandry and aquaculture is definitely important, and may enable the organizations involved in the project to devise new strategies for developing techniques for the improvement of farming systems in the Mekong Delta. The next annual workshop for the project will be held at CLRRI in late October, 2001. (*Testushi Hidaka*)

People

Dr. Takahiro Inoue, a soil scientist, was appointed Director General of JIRCAS on January 6, 2001 after the retirement of Dr. Nobuyoshi Maeno. Dr. Maeno who had been assigned to CIAT from 1977 to 1981 as a TARC (predecessor of JIRCAS) member, eventually joined JIRCAS in August 1994 as Director of the Research Planning and Coordination Division and became Director General of JIRCAS in August 1996. Dr. Inoue had briefly assumed the position of Director of JIRCAS* Research Planning and Coordination Division from April 1, 1998 until August 31, 1998. He then joined Tohoku National Agricultural Experiment Station where he became Director General on April 1, 1999. As a TARC member, he had the opportunity to carry out "Studies on the Increase of Productivity of Upland Soils in Thailand" in collaboration with the researchers of the Department of Agriculture of Thailand from 1980 to 1984.

JIRCAS Fellowship

JIRCAS Fellowship Program: Welcoming New Visiting Researchers

Eighteen Visiting Researchers are participating in the JIRCAS 2001 Visiting Research Fellowship Program to carry out collaborative research at Tsukuba and Okinawa.

Tsukuba: Long-term (2 years at JIRCAS HQ.)		
Donghe Xu	Tianjin Agricultural Academy of Sciences, P. R. China	Mapping of resistance genes to fusarium head blight (FBH) in wheat
Nguyen Van Dong	Agricultural Genetics Institute, Vietnam	Fine-mapping of tms-4(t) and marker-aided selection for thermosensitive genetic male sterility in rice
Nguyen Thi Thu Huong	Institute of Chemical Technology, Vietnam	Quality analysis and evaluation of food resources for better use
Subbarao V. Guntur	International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India	Physiological studies on nitrification inhibition and nitrogen absorption in <i>Brachiaria humidicola</i>
Tsukuba: Short-term (5 months at National Institute of Agrobiological Resources)		
Zhenbo Tan	Beijing Academy of Agricultural and Forestry Sciences, P. R. China	Isolation of cDNAs clones encoding proteins that regulate freezing of cold-hardy plant tissues
Shahid Masood	Plant Genetic Resources Institute, Pakistan	Molecular evaluation of rice varieties collected from Pakistan
Chongjian Hong	China Agricultural University, P. R. China	Induction of high quality mutants and analysis of the mutation mechanism in sweet potato
Wong Boonsuebsakul	Kasetsart University, Thailand	Establishment of rapid and reliable method for the diagnosis of bacterial wilt disease of curma, ginger and other economic crops in Solanaceae plants by immunological and molecular techniques
Okinawa: Long-term (1 year at JIRCAS Subtropical Station)		
MD. Khalilur Rahman	University of Dhaka, Bangladesh	Subsurface drip irrigation of some vegetable crops
Le Van Hoa	Can Tho University, Vietnam	Physiological and biochemical studies on aluminum-resistant pineapple
Md Abudul Awal Howlader	Bangladesh Agricultural Research Institute, Bangladesh	Molecular mechanism of biosynthesis and metabolism of metabolites related to heat tolerance of crops
Jalal Ud din	Land Resources Research Institute, Pakistan	Physiological, biochemical and molecular basis of heat tolerance in transgenic tomato (MT-sHSP) at the reproductive growth stage
Vijay K. Yadav	Rajasthan Agricultural University, India	Cloning of salinity gene(s) in <i>E. coli</i> and characterization
Arifin N. Sugiharto	University of Brawijaya, Indonesia	Cloning of useful genes and transformation in sugarcane
Lawrence M. Aboagy	Plant Genetic Resources Center, Ghana	Characterization and evaluation of factors for early growth in sugarcane

Xiaochuan Liu	China National Rice Research Institute, P. R. China	Comparison of salt-tolerance QTLs in different RI populations of rice (<i>Oryza sativa</i> L.)
Yunxia Liu	Institute of Biological Control, P. R. China	Development of regeneration system of sweet potato for utilizing anthocyanin transcriptional activator genes
Jiang Ling	Huazhong Agricultural Institute, P. R. China	Development of genetic transformation technique in papaya plant

Message from the President of JIRCAS

"New JIRCAS" - Structural Reorganization -

Within the framework of the administrative reform enacted by the Japanese Government for the reorganization of government-affiliated research organizations, on April 1, 2001, Japan International Research Center for Agricultural Sciences (JIRCAS) became an Independent Administrative Institution (a semi-autonomous agency) under the supervision of the Ministry of Agriculture, Forestry and Fisheries of Japan (MAFF).

President : Takahiro Inoue

The introduction of the new system of Independent Administrative Institutions (IAI) is at the core of the administrative reform. This system has been introduced to enhance the effectiveness, quality and transparency of technological development by separating the administration functions into an implementing function and a planning and drafting function, by transferring the implementing function of the national research institutions to the IAI, each of which has its own independent judicial status. Therefore, under the new system, JIRCAS should implement not only autonomous and flexible programs, but also commit itself to a strict *ex post facto* evaluation and review of its performance, and disclosure of various issues.

In many developing countries, although the demand for food is increasing due to population increase and the improvement of the dietary habits, agricultural production remains at a low and unstable level. As a result, hunger and poverty are still important problems. Moreover, concern about the deterioration of the global environment has generated the need for sustainable development of agriculture, forestry, and fisheries, in harmony with the natural ecosystems. The mandate given to JIRCAS by the Japanese Government does not change fundamentally from the previous one in which JIRCAS was entrusted with the mission of promoting sustainable development of agriculture, forestry and fisheries compatible with the preservation of the environment in developing regions of the world through the implementation of integrated collaborative research programs.

The most distinctive feature of the new IAI is the semi-autonomy with limited prior control from outside and the *ex post facto* evaluation by which the IAI itself strictly evaluates its own performance to apply the results of the evaluation for subsequent activities. In the new system, MAFF defines JIRCAS mid-term objectives, which "New JIRCAS" should achieve during a five-year period. The mid-term objectives include issues related to the enhancement of the efficiency of the research activities, improvement of the quality of the research programs and of financial performance. Based on the mid-term objectives, the IAI drafts a mid-term plan to achieve these objectives autonomously.

The performance of the research activities evaluated by the IAI itself will be periodically evaluated additionally by the IAI Evaluation Committee established in MAFF which is composed of experts who do not belong to the public sector. Each fiscal year, the IAI Evaluation Committee will investigate and

analyze the achievements of the mid-term objectives during the given fiscal year. The results of the evaluation will be subjected to structural modifications in terms of operational and financing systems for the next fiscal year.

Since the research activities need to be fully executed, the Government will allocate, within budgetary limitation, most or all of the financial resources required to carry out the defined objectives. Moreover, JIRCAS should make utmost efforts to receive financial support from either any other governmental offices or the private sector, etc. to fulfill the mid-term objectives.

Role and Research Strategy

Since the role of JIRCAS is to promote the development of agriculture, forestry and fisheries in developing regions of the world through integrated collaborative research programs, the priorities identified by "New JIRCAS" for the research strategies are as follows: 1) Development of production and utilization systems for sustainable agriculture, forestry and fisheries in harmony with the environment by carrying out research on the development of stress-tolerant crops, technologies for preserving arable land environments, new farming systems for ensuring profitability for the producers and technologies for efficient postharvest management and utilization, and 2) Rehabilitation, maintenance, improvement and utilization of the natural environmental resources, with emphasis placed on tropical forest and coastal ecosystems.

In order to complete the mid-term objectives within the above research strategy, "New JIRCAS" carries out its main activities through the implementation of 1) International collaborative research programs in developing regions by sending researchers on a long-and short-term basis, 2) Collaborative research with researchers invited from developing regions, 3) Research in Japan to further enhance international collaboration, 4) Accumulation and analysis of research information for supporting the collaborative work, 5) Organization of international symposia, workshops and seminars, 6) Technical assistance for food and environmental issues, 7) Advice to national organizations involved in overseas development assistance as a think tank function.

In conclusion, the reorganization of JIRCAS into an IAI should enable JIRCAS to gain more flexibility in the implementation of its research programs, in the hiring procedures since it will be possible to recruit researchers from universities or institutes which do not belong exclusively to the public sector and in financial aspects since funds could be obtained from both the public and private sectors. At the same time, the strict evaluation of the performance of the Center may contribute to the enhancement of the quality of the research programs and to a more efficient utilization of the financial resources to further promote collaborative activities compatible with the needs of the developing regions.

Biological Functions of Proline in Osmotolerance Revealed in Antisense Transgenic Plants

Proline (Pro) is a major organic molecule that accumulates in many plants exposed to environmental stresses such as drought, high salinity, high temperature, freezing, UV radiation, and heavy metals. Under stressed conditions, Pro has been considered to play an adaptive role in mediating osmotic adjustment and protecting the subcellular structure. In particular, many studies in plants have focused on the roles of Pro in defense mechanisms against impairments caused by osmotic stress. Some reports have indicated a positive correlation between the accumulation of Pro and stress tolerance in plants. However, in other reports, it was suggested that the increase in the free Pro level merely resulted from stress. Thus the roles of Pro in osmotolerance in plants still remain controversial, and there have been few practical demonstrations of the function and the mechanism of action of Pro throughout plant growth. In higher plants, Pro is synthesized via both the glutamic acid (Glu) and ornithine (Orn) pathways. The former is considered to be a major pathway, especially under osmotic stress. In the Glu pathway (Fig. 1), Pro is synthesized from Glu via 2 intermediates, glutamic- δ^1 -semialdehyde (GSA) and δ^1 -pyrroline-5-carboxylate (P5C). Two enzymes catalyze this pathway, P5C synthetase (P5CS) in the first step and P5C reductase (P5CR) in the final step. Genes encoding P5CS and P5CR have been isolated from various plants, and their expression and the functions of their products have been characterized. As a result, it has been shown that P5CS is the rate-limiting enzyme in Pro biosynthesis in higher plants. On the other hand, Pro is metabolized to Glu via P5C and GSA. Two enzymes catalyze this pathway, proline dehydrogenase (ProDH) in the first step and P5C dehydrogenase (P5CDH) in the final step.

Fig. 1. Metabolic pathway of Pro in plants (the Glu pathway). GSA, glutamic- δ^1 -semialdehyde; P5C, δ^1 -pyrroline-5-carboxylate; P5CS, P5C synthetase; P5CR, P5C reductase; ProDH, proline dehydrogenase; P5CDH, P5C dehydrogenase.

Arabidopsis accumulates Pro in response to osmotic stresses due to drought, high salinity, and chilling. Stress-induced Pro accumulation in *Arabidopsis* is caused by the activation of Pro biosynthesis, and by the inactivation of Pro degradation. The elevated expression of an *AtP5CS* gene encoding the P5CS protein in *Arabidopsis* precedes the accumulation of Pro in response to these stresses. In contrast, the expression of the *AtProDH* gene is repressed during the stress conditions. Gene expression of *AtP5CS* and *AtProDH* corresponds well to Pro accumulation, suggesting that metabolic regulation is essential for the control of endogenous Pro level.

To investigate the function of Pro biosynthesis and degradation in the accumulation of Pro and to further elucidate the roles of Pro in growth and stress tolerance in plants, we generated antisense transgenic *Arabidopsis* plants with an *AtP5CS* and an *AtProDH* cDNA, respectively. The *AtP5CS* antisense transgenic plants exhibited morphological changes and were susceptible to osmotic stress. Mutated phenotypes in both morphology and osmotolerance were suppressed by the application of exogenous L-Pro but not by that of D-Pro, suggesting that Pro plays other roles in addition to being a compatible osmolyte in terms of osmotolerance in plants. We further investigated the specific effect of Pro deficiency on protein biosynthesis in the *AtP5CS* antisense transgenic plants. We observed a significant reduction in the Pro and hydroxyproline (Hyp) contents in hydrolysates of a purified cell wall fraction but not in the Pro content of hydrolysates of soluble proteins in transgenic leaves. These results show that Pro deficiency specifically leads to a defect in biosynthesis of the cell wall structural proteins in the transgenic plants. That is, Pro may act as a major constituent of structural proteins of cell walls in osmotolerance as well as morphogenesis of plants.

On the other hand, the *AtProDH* antisense transgenic plants showed an enhanced accumulation of Pro, providing evidence for a pivotal role of ProDH in Pro degradation. These transgenic plants were tolerant to freezing and high salinity, indicating the efficiency of suppressing Pro degradation in Pro accumulation, and the contribution of Pro to stress tolerance in higher plants (Fig. 2).

Fig. 2. Salinity tolerance of the *AtProDH* antisense transgenic plants. Phenotype of plants exposed to salinity stress for 0.5 h. Plants used for the analysis were wild-type (WT) and anti-*AtProDH*-12 transgenic plants.

In our study, we not only confirmed the key roles of two enzymes, P5CS and ProDH, in the regulation of Pro accumulation, but also revealed a positive correlation between Pro and osmotolerance in higher plants using transgenic technologies. Moreover, we identified a new function of Pro in growth and osmotolerance in plants.

Biological Resources Division, JIRCAS

Utilization of *Panicum maximum* in Agropastoral Systems in the Brazilian Savannas

Since the 1970s, *Brachiaria* spp. of African origin, such as *B. decumbens* and *B. brizantha* have been rapidly introduced into the Brazilian savannas. However, extensive pasture utilization without fertilizer application has led to the degradation of more than 50% of the pastures into which the grasses had been introduced. Recently, the adoption of agropastoral systems (sustainable crop-pasture rotation systems) has been considered to be an alternative for pasture renovation in the savanna regions. The major improvement in agropastoral systems for forage production is the residual effect of fertilizer applied to the preceding crops. Moreover, it is also expected that the residual effect of fertilizer applied to annual crops will enable to utilize high quality forage species even in the savanna soils with a low fertility. *Panicum maximum* is a promising forage species with a high productivity and high nutritive value. Therefore, in this study, the suitability of the use of *P. maximum* in agropastoral systems was examined in the Brazilian savannas.

Photo: Grazing experiment on the *Panicum maximum* pastures established after 4-year cultivation of soybean (front) and 4-year rotation of summer soybean with winter millet (back)

At first, a greenhouse experiment was conducted to compare the growth response of *B. decumbens*, *B. brizantha*, and *P. maximum* to different P (0, 25 and 50 kgP/ha) and N (25, 150 and 300 kgN/ha) application rates. P application increased the dry matter yield of the 3 species, and their response to the P application was very similar. On the other hand, an increase of N application up to 300 kg/ha resulted in the increase of the dry matter yield of *P. maximum* linearly, while the dry matter yield of *B. decumbens* and *B. brizantha* reached a plateau at 150 kgN/ha. Their external N requirement was in the following order: *P. maximum* > *B. brizantha* > *B. decumbens*. It appears that the high N external requirement of *P. maximum* may be associated with its high soil fertility requirement.

Furthermore, a grazing experiment was conducted at the National Beef Cattle Research Center of the Brazilian Agricultural Research Corporation in Campo Grande, Brazil. *P. maximum* pastures were established after 2 different cropping sequences: in one previous cropping sequence, soybean had been cultivated for 4 years in summer (SO-PM), and in the other, a 4-year rotation of summer soybean with winter millet for grazing (SO/MI-PM) had been adopted. The average soybean yield in the previous 4 years was 2,559 kg/ha. During a period of 253 days, herbage samples were harvested at 6-week intervals, and the dry matter productivity was evaluated. Table 1 shows the average value of total biomass (plant top + existing litter) during the experimental period. The average biomass in the SO-PM system was significantly higher than that in the SO/MI-PM system. Total dry matter production in the SO-PM system was much higher than that of the SO/MI-PM system. During the investigation period, leaf samples were taken 2 times to evaluate the nutritive value. Significant differences were observed in the contents of

crude protein and nitrogen. *In vitro* digestibility of SO-PM was also higher than that of SO/MI-PM. These data indicated that dry matter productivity and forage quality of SO-PM were much higher than those of SO/MI-PM. Based on the soil analysis, it is considered that, in the rotation of summer soybean with winter millet, soil nitrogen was immobilized into the plant residues of millet, and that *P. maximum* after the rotation could not utilize the soil nitrogen. Thus, the growth and forage quality of *P. maximum* were limited after the rotation of soybean and millet, because of its high nitrogen requirement.

However, in farming practices, rotation of summer soybean with winter millet is more rational than continuous soybean cultivation from the point of view of economic profit, weed management, and sustainability of the soil nitrogen content. Therefore, to achieve a high productivity and enhance the nutritive value of *P. maximum* even after the rotation of soybean with millet, application of a small amount of nitrogen fertilizer could be effective. It is also considered that the use of species other than *P. maximum* (such as *Brachiaria* spp. with a lower external N requirement) could be an alternative for the development of a sustainable agropastoral system.

Table 1. Average biomass, dry matter production and nutritive value of *Panicum maximum* pastures established after 4-year cultivation of soybean and 4-year rotation of summer soybean with winter millet

•@	Average biomass	Dry matter production	Crude protein	In vitro digestibility	Nitrogen
•@	(DM t/ha)	(DM t/ha/253 days)	(%)	(%)	(%)
After soybean	12.7	16.6	12.7	56.0	1.92
After soybean+millet	9.0	10.3	8.6	51.8	1.31

Technology Selection in Mekong Delta Project

For the implementation of research projects dealing with technology development, attention should be paid to the kind of technology required for meeting farmers, needs. In particular, in the case of comprehensive research projects, component technology should be integrated. In our project, in order to meet farmers, needs for technology development and to integrate component technology within the whole farming systems, we applied a farming systems research and extension approach for selecting the technologies to be developed in the project. The study site is representative of the irrigated alluvial soil area in the Mekong Delta, Vietnam. In the above approach, the first step is the diagnosis stage and the second step, the design stage. In the first step, problems and requirements were identified and compiled. In the second step, we applied the AHP-Method for evaluating the technology. In the AHP-Method (Analytic Hierarchy Process), the decision-making process is applied when there are options with some of the criteria conflicting with each other.

The results were as follows. As shown in Table 1, among the problems, those related to the farming systems were as follows: 1) "Difficulty in adoption of VAC systems," "Difficulty in crop selection and combination," 2) Optimum waste disposal," 3) Waste pollution," and 4) " Optimum way of selecting chemicals." Besides these problems, there are various kinds of individual problems in each component such as rice-fish, livestock, fruit trees and fisheries.

Based on the above data, we listed up the technology required to address these problems. We compared each technique with the criteria. The criteria suitable for technology assessment (evaluation) included "effects," "technology level" ("possibilities"), "ease of adoption for farmers (to learn technology)," and "research cost." For each criterion, the respective techniques were scored. Fig. 1 shows the results of the analysis.

In this figure, IPNM technology was evaluated. IPNM stands for integrated pest and nutrient management. IPNM technology includes: "Comparison of sustainability of double and triple rice cropping," "Development of measures to maintain or improve soil fertility," "Development of fertilizer application methods," "Utilization of resistant varieties," "Renewal of varieties," "Utilization of natural enemies," "Protective methods associated with labor-intensive management," "Development of rice-duck system," "Development of rice-fish system." IPNM technology is one of the important technologies for farming systems and one of the possible solutions to address problems such as "Optimum waste disposal" and "Optimum way of using chemicals." Among the IPNM techniques, "Development of measures to maintain or improve soil fertility (fruit tree gardens and paddy fields)" includes manure production and composting technology, evaluation of fish pond and canal deposits as fertilizer, and evaluation of fermented liquid from bio-digester as fertilizer. "Protective methods associated with labor-intensive management" refer to the development of water control methods which include land leveling and deep water management for weed control. "Development of rice-fish system" aims at weed control and reduced use of chemicals. "Development of rice-duck system" aims at the control of the golden apple snail. Among these, "Development of measures to maintain or improve soil fertility" had the highest total score. Especially the scores of effects and technology level were much higher compared with others.

On the other hand, we obtained the results of evaluation from farmers. As it is too difficult for farmers to answer in the form of AHP-Method, we decided to ask them to score each research topic. As a result, "Development of measures to maintain or improve soil fertility" had a higher score. Therefore, we

selected this technology for development in the project. Likewise, we also selected technologies in other research fields.

In the above process, we identified the technologies to be applied in the Phase 2 of the Mekong Delta project. The objective of the project is to develop sustainable farming systems by technology development for environmental conservation, including bio-digester technology, technology for soil fertility preservation, and water control technology. At the same time, component technology will be developed as follows: 1) In the rice component, direct seeding technology, IPM technology, rotation technology, and drying technology, 2) In the pig component, feeding technology by using local resources and disease control technology, 3) In the fruit tree component, IPM technology, 4) In the aquaculture component, farming technology and seed production technology. These technologies were selected based on farmers, requirements identified at the diagnosis stage. At the design stage, we considered four important criteria such as "effects," "technology level" ("possibilities"), "ease of application for farmers (to learn technology)," and "research cost." The procedure described above may enable to minimize the risks of failure of technology development and to increase the possibility of integrating each technology for the implementation of the comprehensive research project.

Table 1. Main problems relating to farming systems

1 <Difficulty in VAC systems adoption / Difficulty in crop selection and combination>

It is difficult to adopt VAC systems due to the lack of resources / capital. I do not know how to select and combine components. It is difficult to invest due to the difficulty in borrowing money.

2 <Optimum waste disposal>

I do not know what is the optimum amount of wastes in ponds and ditches. There are problems about the decrease in soil fertility. But, there is neither enough knowledge nor enough materials to make manure.

3 <Waste pollution>

Livestock wastes cause environmental problems such as decrease of water quality and bad smell. On the other hand, it is difficult to use the bio-digester.

4 <Optimum way of using chemicals>

I do not know the optimum way of applying fertilizers and of spraying pesticides and herbicides.

Fig. 1. Technology evaluation by AHP (IPNM).

International Symposium on "Lignocellulose - Material of the Millennium: Technology and Application"

A joint international symposium between JIRCAS and Universiti Sains Malaysia (University Science Malaysia, USM) was held at Penang, Malaysia, during the period of March 20 ~ 22, 2001. The symposium was titled: "Lignocellulose - Material of the Millennium: Technology and Application." The purpose of the symposium was to exchange information on the latest achievements in research works on lignocellulose and related materials through paper presentations and discussions.

More than 100 participants attended the symposium, including 20 from Japan, 60 from Malaysia, and others from Europe, North America and Asian countries. There were 39 oral presentations, including 5 lectures and 40 posters.

Professor Mohd. Azemi Mohd Noor (Chairman of the Symposium, USM) and Dr. Terunobu Suzuki (Director of Forestry Division, JIRCAS) delivered the opening addresses, followed by the declaration of official opening of the symposium by Y. Bhg. Dato, Professor Dzulkifli Abdul Razak (Vice Chancellor, USM). Session I included 5 presentations on pulp, paper and cellulose derivatives. Session II was held in the afternoon with 7 papers relating to food, feed and medical applications of lignocellulosic materials (Session II-A) and 7 presentations on lignocellulose-based composites (Session II-B). On the morning of the second day, Session III-A dealt with the properties and characterization of lignocellulose materials and products (6 papers), while Session III-B with lignocellulose composites (8 papers). Sessions II-B and III-B differed in terms of processing and utilization of lignocellulosic fibers, namely fiber-reinforced composites (II-B) and chemical reaction on fibers (III-B). After Session III, a poster session with 40 papers was held. Session IV included 6 presentations on new technological developments in lignocellulose research, followed by the closing ceremony with a speech by Professor Azemi and closing remarks by Dr. Suzuki. On the last day, March 22, a visit to a wood-based board factory, including briefing of Penang Island, was organized for all the participants. The symposium was very successful due to the strong commitment of the experienced staff of USM.

During the symposium, participants exchanged views and opinions on a wide range of research works related to wood and non-wood lignocellulosic materials. A large number of papers presented during the symposium involved studies on the extraction of lignocellulose materials from plant by-products such as oil palm wastes, rubber wood and banana fibers, which are often discarded after collection of the main products. The current project between JIRCAS and USM, indeed, dealt with such materials, especially by-products from oil palm. The presentations indicated that there is a great potential for the utilization of these wastes as raw materials for the production of pulp, paper, composites and plastics in addition to food and feed resources. It was also noted that the relationship between JIRCAS and USM had been strengthened through this joint symposium.

Workshop

International Workshop on Nitrogen Fertilization and the Environment in East Asian Countries

The use of nitrogen fertilizers has significantly contributed to the remarkable increase of the production and yield of various staple crops since the Green Revolution. However, in recent years, the beneficial effect of nitrogen fertilization on crop production has been somehow offset by the occurrence of adverse effects on the environment. Excessive use of nitrogen fertilizers often induces pollution of soils, water and the atmosphere by the emission of nitrogen compounds. Such environmental problems have recently become serious in the countries of East Asia, namely China, Korea and Japan, which are characterized by intensive agriculture with high input due to recent economic development and high population density.

The international workshop on "Nitrogen Fertilization and the Environment in East Asian Countries" held on February 5-9, 2001 addressed the issues related to nitrogen fertilization and the environment in East Asian countries and aimed (1) to exchange views on the issues, (2) to identify gaps in knowledge, and (3) to discuss future research needs and possible forms of cooperation. The workshop hosted by the Environmental Resources Division of JIRCAS included an international symposium, a planning meeting for the environmental component of the JIRCAS China project, and a field excursion tour.

A total of 100 scientists from 15 countries participated in the 2-day,s international symposium. After the opening address delivered by Dr. T. Inoue, Director General of JIRCAS, Dr. A. Mosier of USDA-ARS and three other leading scientists from China and Japan presented keynote lectures to outline the issues in East Asian countries and the world. Then followed 6 general sessions with 25 reports by researchers from Japan, China, Korea, UK, Germany and USA. The symposium was closed by discussion sessions both in the break-out groups and synthesis and closing remarks by Dr. Minami, Director General of the National Institute for Agro-Environmental Sciences.

During the 4th planning meeting for the environmental component of the JIRCAS China project titled: "Evaluation and development of methods for sustainable agriculture and environmental conservation," discussions were held on the results and future plans of the project with participants outside of the project in addition to the counterparts. During the excursion tour, the participants visited JIRCAS experimental fields, Shizuoka Prefecture Tea Experiment Station, and Shizuoka Prefecture Agricultural Experiment Station and exchanged views on recent studies conducted in Japan and technologies applied for minimizing the impact of nitrogen fertilization on the environment.

This was the first international workshop focused on nitrogen fertilization and environment in East Asia. We consider that this workshop gave a good opportunity to promote the development of technologies or policies that maximize the use of land, water, soil, and biota resources without exerting an adverse impact on the environment, by the development of research networks in East Asian countries and the world.

Shift in Environmental Research at JIRCAS Following Restructuring

•@Characterization of environmental resources has been one of the key research activities of JIRCAS and has been carried out mainly on a large scale by applying remote sensing techniques within the framework of geographic information systems (GIS). These activities are closely associated with the major comprehensive projects that JIRCAS is implementing in different parts of world. The outcome is utilized by other scientists in the projects for their own research as basic information about their study area. These activities are expected to contribute to prioritization of research needs and integrated analysis of individual results in the projects. Due to the high expectation of stronger linkages with socio-economic analysis, it was eventually decided to transfer this part of activities to the Development Research Division at the time of the reorganization of JIRCAS. This functioned as a trigger for major changes in the divisional concept of the former Environmental Resources Division from macro-analysis of environmental resources to micro-analysis of production environments including not only abiotic but also biotic components. Beside the analyses using GIS/remote sensing, the Division had been dealing with the nutrient flow in agro-ecosystems and abiotic stress management under unfavorable conditions, indicating that the main focus of the Division had been placed on abiotic components among various environmental resources relating to agricultural production. Incorporating research groups specialized in the management of crops, water resources, and pests and diseases, the new Division (Crop Production & Environment Division) is now ready to start research, focusing more on the development of integrated technologies required for the improvement of productivity and sustainability in a cropping environment.

•@The majority of the research themes documented in the mid-term plan of JIRCAS for the next five years will be conducted through so-called comprehensive projects as driving vehicles. The projects have been merged into five groups based on the type of activity and/or target region. The projects will be managed by the JIRCAS scientists under long-term assignments as core researchers, assisted by scientists not only from JIRCAS but also from other research organizations who will be sent under short-term assignments. More than half of the scientists in the Division are stationed at a project site and conduct their activities under the management of a two-way matrix with one axis for the Division and one for the project. The other half of the scientists in the Division carry out research mainly at the Headquarters. As long as they participate in a comprehensive project, however, they operate within the matrix frame as in the case of the scientists in secondment. In most of the cases, these scientists are under the supervision of the Division Director and the project coordinator. Although the matrix system tends to increase the complexity of the operations within the organization, it certainly contributes to enhancing the transparency of the management and the interaction among staff scientists with different backgrounds,

which is necessary for multidisciplinary projects. Especially for research aiming at technology development for cropping systems in different agro-ecosystems, which should be the major task for the new Division, tighter linkage among the scientists is most important to achieve the objectives since any technologies applicable to the field conditions should result from the integration of various scientific disciplines. Through the grouping of scientists with similar disciplines and active interaction among the groups, we hope to generate more in-depth discussions on the subjects and more systematic integration of the research plan and results from different groups.

Osamu Ito

Director, Crop Production & Environment Division, JIRCAS

Shift in the divisional thrust from environmental resources to production environments

Collaborative Research Project

Comprehensive Studies on Soybean Improvement, Production and Utilization in South America and Mid-Term Evaluation Meeting

•@In 1997, the comprehensive collaborative project titled: "Comprehensive studies on soybean improvement, production and utilization in South America" was initiated in the MERCOSUR countries. The project is focusing on the development of sustainable and more efficient systems of soybean production in the MERCOSUR countries such as Brazil, Argentina and Paraguay, because soybean production in this area accounts for approximately one-third of the total world production, and unstable production of soybean in these countries may hamper the supply of soybean worldwide. However, soybean production in South America has often been carried out under environmentally vulnerable conditions in arid and acid soils characterized by a low fertility. On the other hand, since the history of soybean cultivation in this area is relatively short, there is a growing concern that continuous cropping, pest and disease outbreaks, and soil erosion may adversely affect future soybean production.

•@This comprehensive project focuses on research in five areas: genetics and breeding, soil management and pest control, crop management and production, postharvest technology, and socio-economic analysis. The project is executed in collaboration with several South American research organizations, such as National Center for Soybean Research (CNPSO) and National Center for Beef Cattle Research (CNPGC), Brazilian Agricultural Research Corporation (EMBRAPA), Center for Agricultural Technology in Paraguay (CETAPAR), Japan International Cooperation Agency (JICA) and Ministry of Agriculture and Livestock, Paraguay (MAG), and Marcos Juarez Agricultural Experiment Station (EEA-MJ), National Institute of Agricultural Technology, Argentina (INTA). Presently, in 2001, three researchers on a long-term basis are carrying out studies on genetics and breeding, soil management, and drought tolerance of soybean cultivars, respectively at CNPSO, Brazil. One researcher on a long-term basis is conducting studies on soybean diseases at EEA-MJ, Argentina. Studies on plant parasitic nematodes are being carried out at CETAPAR/JICA, Paraguay. In addition, one scientist currently stationed at CNPSO is in charge of the coordination of the project.

•@The seminar on soybean research conducted between CNPSO and JIRCAS was held at CNPSO on December 11, 2000 for the preparation of the mid-term evaluation meeting. Some of the reviews and results obtained in this project were presented and discussed during the seminar.

JIRCAS researcher collecting soil samples for isolation of plant parasitic nematodes in a no-tillage soybean field in Paraguay.

Greenhouse experiments for the evaluation of the micronutrient status in soybean plants at CNPSo, EMBRAPA.

•@A mid-term evaluation meeting for this project was organized on March 22, 2001 at Tsukuba by JIRCAS. The main purpose of the meeting was to evaluate the results and to examine the future research orientation of the project. Dr. Peter Kerridge, Coordinator, International Center for Tropical Agriculture (CIAT)-Asia, CIAT, Prof. Dr. Kazuo Kawano, Kobe University, and Dr. Shinji Sakai, Director of Department of Crop Breeding, Tohoku National Agricultural Experiment Station were invited as commentators for the meeting.

•@After the opening address given by Dr. Takahiro Inoue, Director General of JIRCAS, the researchers of JIRCAS and related institutes presented the results and future research plans for each subject as follows: 1) Genetic improvement of chemical constituents in soybean seeds, 2) Production of DNA markers, Breeding methods for insect-resistant soybean plants in South America, 3) Identification of soybean genes for resistance to *Phytophthora sojae* using molecular markers, 4) Improvement of soil management practices, 5) Improvement of methods of control of diseases and insects in Paraguay, 6) Ecology and control of major diseases of soybean in Argentina, 7) Morphological and physiological characterization of drought-tolerant soybean cultivars and identification of selection criteria for drought tolerance, 8) Analysis of soybean supply and demand, and 9) Socio-economic evaluation of new technologies.

•@After the presentations, several critical comments on the studies were presented and the participants discussed solution strategies and future plans for the studies. They also exchanged views on the progress of the project during the meeting. Finally, the framework, future plans and orientation of the project were approved in general. Particular issues raised by one reviewer were as follows: 1) To define more clearly how this project could contribute to overall research on soybean improvement in South America, 2) To give a high priority to the development of soybean for consumption as food as well as to carry out research common to all soybean production, 3) To continue to promote a close collaboration with national scientists.

•@A workshop on soybean will be held in November 2001 in Brazil during which feedback of the current studies and the future orientation of the program will be discussed.

JIRCAS Research Highlight

Diagnosis and Prevention of Shrimp Viral Diseases in Southeast Asia

•@Southeast Asia including Thailand, Malaysia, Indonesia, and so on, is a significant area for world shrimp culture. However, in recent years, the production of cultured shrimps has markedly decreased as a result of serious viral disease outbreaks. The increased severity of widespread viral infection is the major constraint on stable aquaculture. Therefore, in order to ensure sustainable production of cultured products, it is essential to adopt preventive countermeasures against viral diseases. Therefore, the development of rapid diagnosis and inactivation methods for White Spot Syndrome Virus (WSSV), which is the most serious problem in Southeast Asia, was promoted.

•@Serological diagnosis using monoclonal antibodies is one of the most rapid and accurate methods, in addition to the low cost and simplicity. The use of monoclonal antibodies resulted in a higher sensitivity to the virus than the use of polyclonal antibodies, because monoclonal antibodies give a very specific reaction against a particular part of the virus. The methods of monoclonal antibody production involve four steps. First, the virus antigen to mice was prepared by artificial injection of the wild pathogen virus to healthy prawns. The hemolymph containing a large amount of virus was collected from diseased prawns, and then the virus was concentrated and purified by high speed centrifugation and ultracentrifugation. In the next step, mice were immunized. The virus antigen prepared in the previous step was injected intraperitoneally into the mice, and then a few more viral injections were performed as a booster after three weeks. In the third step, cell fusion took place. After the final immunization, the spleens of immunized mice were removed and the spleen cells were fused with myeloma cells, because the spleen cells can not survive over a long period of time, while the hybridomas (fused spleen and myeloma cells) can grow and produce antibodies. In the final step, screening and culture were performed. The cells, which produced the specific antibodies against WSSV were selected by screening from many hybridomas using the immuno-fluorescence technique (Fig. 1).

•@After screening, they were cultured and they produced antibodies used as monoclonal antibodies. A few strains producing virus-specific antibodies were obtained from more than 100 strains of hybridomas, which were selected by antibody production tests. Hereafter, virus-specific strains will be further selected and used for the diagnosis of the disease caused by WSSV.

•@Viral inactivation was tested using chemicals, such as formalin and halogenous disinfectants, including sodium hypochlorite and IsodineR (povidone-iodine was an effective ingredient). The concentrations of formalin were 0, 0.1, 0.25, 0.5 and 1% (V/V), while 0, 0.5, 1.0, 2.5 and 5.0 ppm of effective chloride in sodium hypochlorite, and 0, 2.5, 5.0 and 10.0 ppm of effective povidone-iodine in IsodineR were used for the inactivation test. These chemicals were mixed with equal volumes of the virus and then made to react together at 25°C for 10 minutes. After the reaction, the resultant products were injected intramuscularly to 10 healthy prawns at the dose of 0.1 ml/prawn. The mortality was monitored for 2 weeks after the injection. The experiments showed that mortality was not recorded at concentrations above 0.25%, 0.5 ppm, and 2.5 ppm for formalin, effective chloride in sodium hypochlorite, and effective povidone-iodine in IsodineR, respectively (Fig. 2). These data indicated that halogenous disinfectants induced an effective

inactivation even at lower concentrations. It was suggested that these disinfectants were extremely useful for the inactivation of WSSV.

•@The studies on the diagnosis and disinfection of WSSV should enable to prevent pathogen intrusion into aquaculture farms, and, therefore, should contribute to sustainable aquaculture in Southeast Asia.

JIRCAS Research Highlight

Agro-Environment and Land Use in Different Farming Systems in West Java, Indonesia

- @Farming Systems (FS) in Indonesia have been implemented and developed in harmony with physical and socio-economic conditions through a long history of human activities. In this country, FS comprise a variety of types associated with the great diversity in the geographic and cultural environment of more than 17,000 islands. This study focused on the spatial analysis of agro-environmental factors for typical FS in West Java in association with land use changes, by using satellite data, thematic maps and statistical data.
- @Two specific FS implemented in a flat area and mountainous area, Kecamatan (Sub-district) Binong in Kabupaten (Regency) Subang and Kecamatan Cibinong in Kabupaten Cianjur, respectively, were characterized in this study. In order to describe the characteristics of FS clearly, methods to quantify the distribution pattern of land use and to identify the planting time and cultivation pattern of rice fields were developed.
- @Land use maps in Binong and Cibinong were obtained by supervised classification of LANDSAT/TM data acquired on June 26, 1997. The map showed that most areas in Binong were occupied by paddy fields, while in Cibinong two dominant land use types characterized by upland fields and forests were observed. Entropy, which is the index of randomness of distribution, indicated that the land use in Cibinong was more dispersive than that in Binong. The value of entropy calculated for Cibinong was 1.921, whereas 1.291 for Binong. Entropy value depending on land use categories was the lowest, 0.333 for paddy fields in Binong, suggesting that the distribution of paddy fields in Binong was very concentrated. In contrast, in Cibinong, paddy fields showed the highest degree of dispersion with the highest entropy value of 2.598 (Fig. 1).
- @Topographic factor analysis using Digital Elevation Model indicated that Binong was very flat with a low elevation and topographically homogeneous. On the other hand, the Cibinong location showed a wide range of elevations and consisted of a steep sloping area. These topographic features affected the distribution pattern of agricultural land use at each site. Analysis of the location of land use in Cibinong showed that upland fields were mainly distributed in the area where the elevation ranged between 200 and 600 m and the soil type consisted of Yellowish Red Podsollic soil, while forests were located in areas around 1,000 m in elevation with two soil types; 1) a combination of *Yellowish Red Podsollic*, *Yellow Podsollic* and *Regosol*, and 2) an association of *Brown Andosol* and *Brown Regosol*.
- @In the irrigation area located in the northern plain in West Java, the cropping pattern of rice was analyzed using the Normalized Difference Vegetation Index (NDVI) data, which were provided as 10 day-composite maximum values with 1 km mesh. The analysis of the temporally sequential NDVI data set showed that the time of planting of rice, which started from the upper part to the lower part of the irrigation network, could be spatially represented. These findings suggest that the progression of planting can be estimated by the multi-temporal data obtained at appropriate times, although the planting time of rice changed year by year. The pattern of planting and growing of rice in Binong was analyzed in greater

detail by using NDVI of LANDSAT/TM data, which showed a higher spatial resolution (30 m) and could be compared with the data from the irrigation planning map issued by the Provincial Office. The results indicated that the TM data enabled to detect the variation in cropping time in smaller land units than the units shown in the irrigation planning map (Fig. 2).

•@From 2001 onward, studies on vegetable-based FS will be initiated in addition to those on contrasting FS of Cibinong and Binong, to identify the constraints on sustainable and efficient production of vegetables in West Java.

Note:Reddish part shows higher values of NDVI of LANDSAT/TM. Based on the irrigation planning map, the time schedule of irrigation was divided into 4 periods, S1 to S4, and the area with identical symbols should be irrigated during the same period.

Workshop & Meeting

Economic Analyses of Agricultural Technologies and Rural Institutions in West Africa: Achievements, Challenges and Application to Rice Farming Research

- @The international workshop titled:"Economic Analyses of Agricultural Technologies and Rural Institutions in West Africa," with emphasis placed on rice farming research in the region, was held at JIRCAS on July 12-13, 2001.
- @In 1998, JIRCAS initiated a collaborative research project with the West Africa Rice Development Association (WARDA). Rapid demographic expansion and urbanization in Africa have shifted food preferences from traditional foodstuffs to rice and bread, and the demand for rice in sub-Saharan Africa is growing faster than that for any other major food staples. These patterns are especially evident in West Africa. In collaboration with WARDA, JIRCAS is conducting an economic study, focusing mainly on rice farming in lowland regions of Cote d'Ivoire and Ghana. Factors such as land tenure management through local organizations, market access and access to capital through informal financial systems are recognized to play important roles in farmers, capacity to adopt and use improved technology, including such developments as land improvement through investment in water control mechanisms, utilization of improved varieties, chemical inputs, and related cultural practices. Furthermore, it has been observed that the systems by which individuals gain access to land and capital may be discriminatory toward an individual,s social origin and gender. Therefore, the objective of this project is to assess how the institutional and economic environment affects the farmers, capacity to effectively adopt new technology.
- @The value of economic analysis has already gained clear recognition in the field of agricultural research in developing countries. Its potential value is expected to be even greater for the assessment of the impact of technology systems as well as policy/institutions on the welfare of agricultural households and the regional economy. Session I reviewed socio-economics research activities in CGIAR Centers (i.e. ICRISAT, IITA and WARDA) and JIRCAS in West Africa and the roles of economic analyses in the field of agricultural research were discussed. Session II was focused on the rice farming-related research of the JIRCAS-WARDA project and details of the schemes and methodology of economic analysis were discussed. The workshop, with 53 participants, provided an excellent opportunity to discuss the role of economic studies in addressing the problems related to agriculture and rural livelihood in West Africa. It was also pointed out that the effective interaction between economic studies and technological studies based on a multi-disciplinary approach was essential to facilitate agricultural research and development in the region.

Discussion at the workshop

Workshop & Meeting

Sixth China -Japan Annual Research Coordination Meeting

•@Following the 20th Annual Group Meeting on Exchange of Agricultural Science and Technology between China and Japan held in Tokyo, the Chinese delegation led by Mr. Tang Zhengping, Director-General, Department of International Cooperation, Ministry of Agriculture, PRC, visited JIRCAS on May 31, 2001 in order to attend a research coordination meeting for discussing substantial issues relating to the ongoing comprehensive research project "Development of sustainable production and utilization of major food resources in China." This coordination meeting has been organized alternatively in China and Japan and this year, the sixth annual meeting was held. Both parties appreciated the favorable evaluation of the project conducted during the mid-term research review meeting held in February 2001. JIRCAS expressed its gratitude for the appropriate procedures implemented for duty-free import of research materials sent to China and the granting of visas to the Japanese scientists. This year, the main discussions focused on the orientation of international research collaboration after the reorganization of JIRCAS into an independent administrative institution (semi-autonomous agency) and the appropriate allocation of the budget for supporting the collaborative research project. Next annual meeting will be held in Beijing in May 2002.

8th JIRCAS International Symposium

Water for Sustainable Agriculture in Developing Regions -More crop for every scarce drop-

Date: 27 - 28 November 2001

Venue: Epochal Tsukuba, Tsukuba Science City, Japan

Background and Objectives

- @Many observers have pointed out the dangers of future food shortages and famine due to impending global water shortages. Already, one-third of the world's population faces water shortages, and this proportion is expected to rise to two-thirds by the year 2025 (report by U.N. Secretary-General Kofi Annan, March 2000). Competition for water between urban and rural areas, increased demand for water due to rising living standards, and changes in annual precipitation and rainfall patterns as a result of environmental change all indicate that water demand and supply are in the process of major change.
- @In the past, when water was insufficient for agricultural production, irrigation systems based on the construction of dams and canals had been put in place. However, the number of areas where new irrigation infrastructure is economically viable is becoming limited. Concerns have also increased about the negative impacts on the environment. New approaches are especially needed for water-limited semi-arid and arid environments, as well as in other environments with unreliable rainfall and uncertain water availability for agriculture.
- @For these reasons, development of drought-resistant and stress-tolerant crops coupled with small-scale but effective technologies to make efficient use of limited water resources on a regional basis are needed. Ecological approaches, breeding, and transgenic genetic improvement can provide crop resources to help make resource-efficient technologies go further. These technologies include farm and watershed-based water collection and storage, improved agronomic practices that use soil water more efficiently, and water-saving crop production techniques. Such technologies are adapted to both the environmental conditions and the production practices of farmers in the area for which they are developed. Development of such technologies and establishment of stable and sustainable agricultural production systems, and ultimately living environments, are essential to maintain a world environment in balance.
- @For this purpose, we have invited distinguished experts from within Japan and other countries, to discuss problems associated with water availability and use in developing regions, with a focus on water-limited semi-arid and arid environments, as well as other environments with unreliable rainfall and uncertain water availability, and to explore directions for research on water for sustainable agricultural production.

PROGRAM

Day 1 (Tuesday, November 27)

KEYNOTE ADDRESSES

- @
 - œ Global Water Resources Assessment and Future Projections
Prof. Katumi Musiake, *Institute of Industrial Science, University of Tokyo*
- @
 - œ Meeting the Water Needs for Food and Environmental Security
Dr. David Molden, *IWMI*
- @
 - œ Global Evolution and Future Directions of Water Use in Agriculture
Prof. Yoshihiro Kaida, *SCEAS, Kyoto University*

SESSION I - Increasing Drought Resistance and Water Stress Tolerance through Ecological and Genetic Approaches

- @
 - œ Reducing Water Stress through Ecology and Crop Characteristics
Prof. Shinobu Inanaga, *Tottori University*
- @
 - œ Development of Drought-Resistant and Water Stress-Tolerant Crops through Traditional Breeding
Dr. Rodomiro Ortiz, *IITA*
- @
 - œ Development of Drought-Resistant and Water Stress-Tolerant Crops through Biotechnology
Dr. Kazuko Shinozaki, *JIRCAS*

SESSION II - Agronomic Approaches for Improved Crop Water Use

- @
 - œ Soil Water Balance and Crop Water Use Efficiency
Dr. Rony Wallach, *The Hebrew University of Jerusalem*

Day 2 (Wednesday, November 28)

SESSION III - Transforming Agricultural Production in Water-Stressed Areas of Developing Regions

- @
 - œ Improving Water Availability and Use in Rainfed Systems
Dr. Osamu Ito, *JIRCAS*
- Commentators:
 - Dr. John S. Caldwell, *JIRCAS*
 - Dr. Yoshiyuki Shinogi, *NIRE*
 - Dr. Chayasit Aneksamphant, *Land Development Dept., Thailand*
- @
 - œ Water Management and Crop Production in Semi-Arid and Arid Environments - Successes from technical cooperation projects -
Mr. Ryuzo Nishimaki, *Managing Director, JICA*
- Commentators:
 - Prof. Ali A. Al-Jaloud, *KACST*
 - Mr. Yoshiaki Kano, *Managing Director, TBIC, JICA*

POSTER SESSION

- @
 - œ Summary of major themes and issues from each session
 - œ JIRCAS's goals and areas of contributions
 - œ Examples of research from Thailand and Laos
 - œ Needs and contributions of partners
 - œ Developing collaborative partnerships with public institutions, international research institutions, non-governmental organizations, and users of research results

For further information, please contact:

Role of New Division --- Food Science and Technology Division

Toru Hayashi

Director, Food Science & Technology Division, JIRCAS

Establishment of new Division

The Food Science and Technology Division was established on April 1, 2001, when JIRCAS was reorganized from a governmental institution into an Independent Administrative Institution (IAI, semi-autonomous agency), under the supervision of the Ministry of Agriculture, Forestry and Fisheries of Japan. The Division is to be engaged in research activities in the field of postharvest technology to contribute to food security, poverty alleviation and sustainable development on a global scale through research collaboration with scientists in developing countries, while another IAI, National Food Research Institute, is mainly engaged in research for and development of food science and technology relevant to the interests of the Japanese consumers and the Japanese food industry. Postharvest research covers a wide range of fields in the harvest-consumption chain: harvesting, handling, drying, storage, grading, packaging, processing, transport, disease and insect control, quality/safety evaluation and inspection, and marketing.

Food security

Food security is one of the major global problems facing humans today. The world population reached about 6 billion in 2000 and it is anticipated that the population will exceed 7.5 billion in 2020, according to United Nations' World Population Prospects. Because agriculture is influenced by the environmental conditions and global arable land is limited, global food production may not increase sufficiently to meet the demand of the rapidly increasing population. On the other hand, postharvest losses of grains have been estimated at 20-30%, caused mainly by insect infestations and microbial infection in developing countries. Therefore, the products once harvested should be consumed with minimum loss during handling, transportation and storage. Developing techniques to reduce postharvest losses of agricultural products and to maintain their quality will contribute to global food security.

Poverty alleviation

Agriculture is still the largest sector of rural economies, and a majority of the rural population is engaged in agriculture, in developing countries. The income of urban people is much higher than that of the rural ones, and population has moved from the rural to the urban areas, seeking higher income and more convenient living conditions. Against this background, we must make utmost efforts to give rural people the means to increase their income, so that they may stay in the rural areas and continue to cultivate their land and rear their livestock. The prices of agricultural commodities are declining and their percentage in the final consumer price is decreasing, which indicates the necessity of value addition to the commodities. Consumers are concerned about the quality and safety of what they eat. Changes in the urban life-style associated with increased income and women's work have resulted in increased consumers' demand for a more diversified diet, for processed and convenience foods and for animal products.

It is important for rural farmers to market products that meet the demand of urban consumers. Therefore, studies to ensure high quality/safety of agricultural commodities and to enhance their value will contribute to the improvement of rural income.

Sustainable development

Postharvest technologies to be developed should be environment-friendly in order to promote environmental sustainability. Since technologies less dependent upon chemicals are preferable from the viewpoint of not only food safety but also environmental preservation, the development of alternative methods to chemical treatment is highly required. For example, the world's most widely used fumigant, methyl bromide, is to be phased out by 2015 due to its ozone-depleting potential, and worldwide scientists have been making efforts to develop alternative methods for disinfesting agricultural products such as grains and fruits and vegetables.

Research activities

We are currently conducting a research project titled: "Development of low-input technology for reducing postharvest losses of staples in Southeast Asia" in collaboration with Thai organizations, to develop low-input drying technology using natural energy sources such as sunlight, husks and straw and to develop insect-controlling technology employing natural enemies and bioactive botanicals. The technologies will result in effective and lower-cost systems that are also environment-friendly to reduce postharvest losses of rice. We investigate the bioactivity of indigenous plants in Southeast Asia such as ginger as well as the characteristics of Thai aromatic rice in order to promote value-adding utilization of these commodities.

We are also involved in other research projects, including the improvement of the process for the production of Chinese traditional foods such as soybean milk curd (tofu) and rice noodles (miefun) in China and the development of technology for the utilization of soybeans for non-feed purposes in Brazil. In Indonesia, we have successfully isolated white-spored mutants from the koji molds for the production of Kecap, an Indonesian soy sauce, to discriminate the koji molds from mycotoxin producers.

All these research activities are expected to contribute to global food security, rural poverty alleviation and environment sustainability.

Contribution of JIRCAS to the Development of New Rice Varieties for Africa

In the middle of the 1990s, West Africa Rice Development Association (WARDA, based in Bouake, Cote d'Ivoire) had succeeded in producing fertile progeny lines from the interspecific cross of *Oryza sativa* (Asian rice) and *O. glaberrima* (African indigenous rice). These hybrid lines have attracted considerable attention because they are expected to be better adapted to crop management with limited resource input, compared with Asian varieties that cover almost 100% of the rice area in this region. WARDA has been the major organization involved in the Africa/Asia Joint Research Project (Interspecific Hybridization between African and Asian Rice Species), a South-South Cooperation Project funded by UNDP/TCDC since 1997. In early 1998, JIRCAS joined the project with an independent budget and started a 5-year collaborative research program with WARDA to analyze the genetic and eco-physiological characteristics of the interspecific hybrids. For the project, JIRCAS had been assigned to conduct research on drought and soil acidity, which are the major constraints on rice production in the resource-limited rainfed ecosystems in West Africa.

During the first half of the project (1998-2000), JIRCAS dispatched a crop physiologist to WARDA. He was assigned to the Molecular Biology Laboratory of the Breeding Unit, headed by Dr. Monty Jones, who had successfully conducted studies on interspecific hybridization. The laboratory aims at tagging genes responsible for important traits of the interspecific progenies through QTL analysis, on the basis of which superior marker-aided selection systems could be developed. With substantial assistance from Dr. Cadalen, a molecular biologist, and the technical assistance extended by Cornell University, a molecular analysis scheme for polymorphism among rice varieties/lines was effectively developed in the laboratory. The main activity of the crop physiologist sent by JIRCAS was centered on the development of screening methods and quantitative criteria applicable to QTL analysis of drought and soil acidity tolerance.

For drought tolerance, field experiments were conducted during a dry spell at Mbe, in an upland field near Bouake, using several African and Asian lowland and upland rice varieties. Growth analysis showed that upland rice varieties displayed a much higher tolerance to drought than lowland varieties. It was interesting to note that the growth of the African rice varieties was significantly reduced by drought stress at the early vegetative stage. Another finding on the physiological response of *glaberrima* rice to drought was that CG20, an African rice variety originating from Casamance (Senegal), showed a much higher reduction rate in transpiration than in photosynthesis. Though it is not necessarily true for all African rice, the drought-tolerance mechanism of CG20 was associated with a rapid closure of the stomata leading to a reduction in the amount of transpired water. This was confirmed by the larger increase in the $\delta^{13}\text{C}$ value (carbon isotope discrimination rate) in CG20, compared with other *glaberrima* varieties. Therefore, it was assumed that there would be a wide range of variation among African rice varieties in the response to drought stress.

The ability of water uptake by roots is another determinant for drought tolerance at the vegetative growth stage of rice plants. With the technical assistance of Dr. Ookawa, Associate Professor, Tokyo University of Agriculture and Technology, during a short-term visit to WARDA, several parameters of water relations were examined. Among them, the rate of xylem exudation from the cut section of stem was well correlated with drought tolerance. Due to the simplicity of this measurement, the xylem exudation rate could be adopted as a quantitative criterion for QTL analysis of drought tolerance at the vegetative growth stage.

Emphasis was also placed on the genotypic variation in soil acidity tolerance among *O. glaberrima* varieties. We conducted an experiment in an upland field at Man, an acidity-prone area in the western part of Cote d'Ivoire, using several Asian and African rice varieties. As phosphorus deficiency is the main limiting factor in acidic soils in this area, the studies were focused on the response to P-application. The responsiveness to P-application in *glaberrima* rice was as high as that of *sativa* rice. IG10, an African rice variety from Cote d'Ivoire gave the highest yield under P-deficiency. After confirmation of the reproducibility of the results, it was suggested that new interspecific crosses could be made for breeding a variety with outstanding tolerance to soil acidity and P-deficiency.

Forest Conversion and Road Construction - A Case Study in a Rubber Village in Sumatra, Indonesia -

Indonesia has the third largest area of tropical forests in the world. According to FAO, about one million ha of forests are being lost each year in this country. Historically, shifting cultivation had been considered to be the primary cause of deforestation. However, subsequent studies have paid more attention to profitable tree crops and found that smallholder tree crop production, rubber in particular, contributes to the deforestation rather than shifting cultivation. Rubber earns the highest agricultural income in Indonesia. Rubber is the dominant smallholder crop in much of Sumatra and Kalimantan.

The construction of roads is well known to accelerate forest conversion to agricultural land. Previous studies on road and deforestation revealed that closer distance from roads and higher density of roads likely lead to a higher rate of deforestation. However, little is known about how road construction affects farmers' behavior in forest clearing.

Collaboration work between JIRCAS and International Centre for Research in Agroforestry (ICRAF) focused on the impact of road construction on forest conversion to agricultural land in a village of rubber smallholders in Sumatra. The village named Talang Sungai Bungo was chosen for the farmer survey. Swidden-based rubber cultivation is the dominant economic activity in the village. The farming system is a combination of shifting cultivation and traditional rubber planting. Our fieldwork was conducted in 1999-2000. A survey was conducted for 40 randomly selected households in the study village through two interviews. The first interview was made in May-June 1999, to obtain information about land acquisition and land tenure and the second was performed in February-March 2000, to analyze the household economy.

The economic development policy of President Suharto (period: 1967-1998) had accelerated the improvement of the infrastructure in Indonesia. The road related to the transport of rubber from the village to the market had been substantially improved and paved by the government in 1974 and 1978. The road construction enabled to lower the cost and shorten the time of transport of rubber remarkably. As the market price of rubber remained constant, the villagers were able to sell rubber at a higher price and the profitability of rubber increased.

To identify changes in farmers' behavior in terms of forest clearing after road construction, the following data were analyzed: data-1) Land ownership of the households, data-2) Acquisition methods of the land owned by the households, data-3) Forest clearing implemented by the households, (1) distance from the village center to the plots of forest clearing, (2) year when the plots were cleared, (3) size (ha) of the plots, data-4) Number of total households in the village, based on statistical data of the district.

Results of analysis of data-1) showed that a household owned an average of 16 ha of land, including rubber gardens (9.7 ha) and bush fallows (5.8 ha). Analysis of data-2) indicated that the main method of land acquisition involved the clearing of primary forests (73% of the plots of land). According to the custom law, the person who clears a primary forest can acquire the land. Other methods of land acquisition included inheritance and purchase. Results of data-3) analysis showed that forest conversion to agricultural land in the village had been sharply accelerated in the late 1970s and has been stable since then. Analysis of data-4) showed that population growth had been stable and ranged between 1 and 3% during the period of 1970-2000. Analysis of data-3) (2)-(3) indicated that the area of forest cleared per household had doubled in the late 1970s and has been stable since 1980. As a result of the analyses of data-3) and -4), it was found that the expansion of agricultural land in the 1970s was mainly associated with the increase in forest clearing per household and that the contribution of population growth was not significant.

Based on this study, we observed that expansion of agricultural land occurred not because of local population growth, but because smallholders cleared a larger forest area, reflecting farmers' behavior in response to road construction. Road construction which had improved the transport of rubber and raised the profitability of rubber in the village, enhanced farmers' incentive to expand the farm size.

This study indicates that road construction is effective for local people to improve their living standard in the short term. However, excessive clearing of forests may result in inequality of the land area among local people in addition to all the adverse effects associated with deforestation, including the loss of biodiversity. It is thus important to strike a balance between forest conservation and the welfare of the local people in this area.

Complete Nucleotide Sequence and Genetic Organization of Papaya Leaf Distortion Mosaic Virus* RNA

Papaya (*Carica papaya* L.) is one of the most important fruit trees in tropical and subtropical areas. Papaya leaf distortion mosaic virus (PLDMV) and *Papaya ringspot virus* type P (PRSV-P) have been reported to cause papaya diseases in Japan. Out of them, PLDMV is the most destructive factor in papaya production in Japan (Fig. 1). The viruses belong to the genus *Potyvirus*. They are similar to each other in several properties including characteristic symptoms that appear on papaya plants, host range, transmission mode of aphid and physical properties.

Fig. 1. Ringspot and distortion symptoms on a papaya fruit caused by PLDMV.

Information on the nucleotide sequence of PLDMV-RNA is necessary to identify similar viruses, as mentioned above, and to develop methods for their control. The complete nucleotide sequence of the RNA genome of the PRSV-P Hawaii isolate was reported in 1992. On the other hand, only the 3' terminus of that of PLDMV was reported in 1996.

In this study, the complete nucleotide sequence of the RNA genome of PLDMV was analyzed to determine the genomic organization of PLDMV and to classify PLDMV based on molecular taxonomy.

The sequence was determined from 6 overlapping cDNA clones and by primer extension. The genomic RNA was 10 153 nucleotides (nt) in length, excluding the poly(A) tract, and contained one large open reading frame that started at nucleotide positions 135 to 137 and ended at positions 9942 to 9944, encoding a polyprotein of 3269 amino acids. The 5' untranslated region (5'UTR) of PLDMV preceding the ORF was 134 nt and contained box a-like (ACAAAACCTT) and box b-like (TCAATACA) sequences which were highly conserved sequences in the other reported potyviruses. The 209 nt of the 3' untranslated region (3'UTR) was present downstream of the ORF.

The polyprotein was cleaved by viral proteinases into smaller proteins. Cleavage sites were predicted by analogy with the other potyviruses. The genetic organization of PLDMV RNA was defined as follows: P1, the first proteinase, a protein with a proteolytic activity; Hc-Pro, helper component proteinase, a protein with aphid transmission helper component activity and proteolytic activity; P3, the third protein, function unknown; 6K1, 6kDa protein 1, function unknown; CI, cytoplasmic inclusion protein, a protein with RNA helicase activity; 6K2, 6kDa protein 2, function unknown; NIa, nuclear inclusion protein "a" including the VPg (NIa-Vpg), genome-linked viral protein covalently attached to the 5' terminal nucleotide and NIa proteinase (NIa-Pro); NIB, nuclear inclusion protein "b", the RNA polymerase and CP, coat protein (Fig. 2). The proteins were not assembled into virus particles, but they were nonstructural virus-encoded host-alien proteins except for CP.

The genetic organization of PLDMV was similar to that of the other potyviruses. Predicted amino acid sequences of PLDMV proteins were compared with those of PRSV-P and other 23 distinct potyviruses. The overall percentages of amino acid sequence identity ranged from 46.4% with *Potato virus V* (PVV) to 50.5% with *Plum pox virus* (PPV). PLDMV exhibited the highest percentage of amino acid identity (65.6%) in its NIB with PPV. The region with the lowest identity among the potyviruses was the P1 protein, with identity ranging from 18.4% with *Bean yellow mosaic virus* (BYMV) to 29.2% with *Bean common mosaic virus* (BCMV). CP amino acid sequence identities, which are the criteria used for the taxonomy of potyviruses, ranged from 61.9% with *Potato virus Y* (PVY) to 52.1% with *Tobacco vein mottling virus* (TVMV). These molecular characterizations confirmed that PLDMV is a distinct member of the genus *Potyvirus*.

The PLDMV and PRSV-P also shared the highest sequence identity value (63.0%) in their NIb, and the lowest (22.8%) in their P1 protein. Since the P1 protein of the potyviruses is the most variable, it is considered to be a very important protein for the identification of individual potyviruses. It might be useful for the distinction between PLDMV and PRSV-P by RT-PCR. The information on the complete sequence will be used for the development of technology for the transformation of PLDMV-resistant papaya in the near future.

Fig. 2. Proposed genomic map for PLDMV RNA.

P1, the first proteinase; Hc-Pro, helper component proteinase; P3, the third protein; 6K1, 6kDa protein 1; CI, cytoplasmic inclusion protein; 6K2, 6kDa protein 2; NIa, nuclear inclusion protein "a" including the VPg (NIa-Vpg), genome-linked viral protein and NIa proteinase (NIa-Pro); NIb, nuclear inclusion protein "b"; CP, coat protein.

APEC/JIRCAS Joint Symposium and Workshop on Agricultural Biotechnology

The Asia-Pacific Economic Cooperation (APEC) Agricultural Technical Cooperation Working Group and JIRCAS joined hands to organize the "Joint Symposium and Workshop on Agricultural Biotechnology" in Bangkok during September 3-7, 2001. The first day was open to the public, attracting more than 300 participants. Discussion was focused on "The Future of Biotechnology in World Agriculture." Several internationally known experts gave keynote speeches followed by a panel discussion. It became clear that agricultural biotechnology would have a significant impact on future agriculture and world trade, especially through the safe and prudent application of transgenics (genetically modified organisms, GMOs) in both developing and developed countries. Public acceptance of biotechnology applications was considered to be the key for current and future society to benefit from biotechnology applications.

Subsequently, APEC organized a workshop focused on "Policy and Regulations on Biotechnology Applications." Special attention was directed towards food safety and environmental safety in relation to GMOs. APEC member economies are sharing information and experience in this very sensitive area in order to achieve a more regionally coherent approach. Many developing economies requested further support for their capacity building in policy, regulatory and technical areas for the active and safe implementation of biotechnology to address their agricultural production and use problems.

JIRCAS' workshop, which was organized from 5 to 7 September, was titled: "Genetic Engineering of Crop Plants for Abiotic Stress." The reasons why abiotic stress was chosen as theme are threefold. First of all, poor farmers in marginal areas are more vulnerable to the impact of abiotic constraints (e.g. drought) on the production of food crops. Second, most of the transgenics that are already present in farmers' fields or in the pipeline for future release are related to herbicide resistance, disease/pest resistance, postharvest or nutritional quality. These are important traits for high-income countries and high-input agriculture. Unfortunately, no transgenics with abiotic stress tolerance are anticipated for commercial use. This is probably because poor farmers in marginal areas are not the prime targets of biotechnology research by the private sector. Poor farmers of developing countries are deprived of the benefits from transgenics adapted to their growing conditions. Thirdly, JIRCAS believes that recent developments in basic biological science (genomics in particular) can lead to a much better understanding of the biological mechanisms of abiotic stress response and tolerance. Moreover, knowledge and DNA obtained through research in one crop can be used for other crops since the biological mechanisms for abiotic stress response are considered to have common features (functional synteny) among higher plants.

More than 10 prominent scientists gave lectures on the basic biological mechanisms for tolerance to drought, high temperatures, low temperatures and high salinity, as well as on recent progress in the development of transgenics in cereals, legumes, tropical fruits and root and tuber crops. Dr. J. M. Ribaut of CIMMYT and Prof. K. Watanabe of Tsukuba University reported on successful transformation with abiotic stress tolerance in wheat and potatoes, respectively, presenting the promise of future production of crops with abiotic stress (such as drought, low temperature) for use by poor farmers in marginal areas. They used DREB (drought responsive element binding protein) genes provided by Dr. Shinozaki of JIRCAS, demonstrating that the genetic mechanisms controlling the biological response to drought, low temperature and high salinity that were originally found in *Arabidopsis* can also be used for those important economic plants.

Participants benefited from the joint symposium and workshop organized by APEC and JIRCAS since they could attend sessions dealing with policy aspects (APEC's main interest) as well as scientific progress (JIRCAS' main interest). Policy and science should go hand-in-hand, but there had not previously been any opportunity for policy authorities and science experts to get together. Proceedings of the JIRCAS workshop will be published as a JIRCAS Working Report in early 2002.

Seminar on "Multifunctionality of Agriculture"

On October 17-19, 2001, an international seminar on the multifunctionality of agriculture was held at JIRCAS. The seminar was organized by the Food and Fertilizer Technology Center for the Asian and Pacific Region, a Taiwan-based international organization, and co-sponsored by four Japanese research institutes, including JIRCAS.

The purpose of the seminar was to gain a better understanding of the multiple functions of agriculture through the exchange of information and to determine whether information gaps exist and how these can be filled, for the benefit of those involved in agricultural research and policy formulation. The participants came from eight Asian countries, and 17 papers were presented. The keynote speech on "Agriculture and the Environment" was delivered by Dr. K. Minami, President of the National Institute for Agro-Environmental Sciences, Japan, followed by four sessions: Food security, Environmental protection, Other externalities, Evaluation of multifunctionality.

During the discussion, the multifunctionality of agriculture, one of the key topics being currently debated at forums, especially in developed countries, was found to be an important issue for developing countries' agriculture, of which roles need to be recognized from a broader viewpoint in order to obtain stronger support. There was a wide consensus among the participants that paddy rice production, which is a common agricultural activity in the region, has positive externalities in several aspects. However it was also concluded that the definition of multifunctionality needed additional clarification, and that the methodologies used for evaluating externalities, in general, should be improved by further promoting the research network and research collaboration among the Asian countries.

On the third day of the seminar, the participants made a field trip to "Kasama Kleingarten" located north of Tsukuba, a small community where city dwellers are able to rent simple cabins with vegetable and flower gardens.

Water for Sustainable Agriculture in Developing Regions

- More crop for every scarce drop -

Opening address by Dr. T. Inoue,
President of JIRCAS

For its 8th International Symposium, JIRCAS chose the theme, "Water for Sustainable Agriculture in Developing Regions - *More crop for every scarce drop* -." This theme was chosen because of impending conflicts among agriculture, human livelihood, and the environment for scarce water, and the real danger of future food shortages and famine. Over 200 participants exchanged research results and ideas on ways to address this pressing problem during the two days of the Symposium, November 27-28, 2001.

The symposium presented current knowledge and state-of-the-art research in three sessions, moving from the global to the user-based level. In the opening session, three keynote speakers presented key elements of the problem and directions towards solution. Prof. A. Musiaka, University of Tokyo, presented results of global modeling of water supply and demand until 2050, using a $0.5^\circ \times 0.5^\circ$ grid and specific river basins, showing projected water scarcities driven by population increase. Dr. D. Molden, International Water Management Institute, explained that to meet environmental water needs, reduction in irrigation use will require productivity increases of 60% in irrigated agriculture and 35% in rainfed agriculture. Prof. Y. Kaida, Kyoto University, presented a framework for solution and numerous real-world examples based on individualized, communalized, and regionalized ecotechnologies. This framework proposed moving from engineering approaches that characterized the Green Revolution era to environmentally formative and adaptive approaches, with the goal of "more welfare for every drop." The following three sessions examined concrete ways to achieve the goals of productivity increase and environmentally formative water management. *Session 1* presented new genetic and ecological approaches to increasing drought resistance and water stress tolerance. Prof. S. Inanaga, Tottori University, presented examples of crop ecological adaptation using mechanisms of escape, avoidance, tolerance, and recovery, and approaches to enable crops to better use these mechanisms, including conservation tillage, deep tillage, fallow, mulching, and intercropping. Dr. R. Ortiz, International Institute of Tropical Agriculture, presented a model for decentralized plant breeding based on expansion of the phenotype concept adding management, farmers, institutions, and policy to genotype-environment interaction. He supported this with concrete examples of maize, cowpea, groundnut, and soybean breeding, including recent advances using genetic markers. Finally, Dr. K. Yamaguchi-Shinozaki, JIRCAS, described recent progress in transferring drought stress genes and promoter proteins in model plants, and explained plans being developed with other public institutions and the private sector to extend these new methods to economic crops.

Session 2 presented new agronomic approaches for improved crop water use. In terms of Dr. Ortiz model, this moved from the genotype side to the environment side of the phenotype model. Prof. R. Wallach, Hebrew University of Jerusalem, explained results of detailed studies of water movement demonstrating how water flux from the soil to the plant, measured by unsaturated hydraulic conductivity, is the real determinant of soil water depletion, rather than tension or water content alone. Dr. S. Hasegawa, Hokkaido University, showed the importance of macropores for crop deep water exploitation, and presented techniques for reducing soil impedance of root penetration developed in Northeast Thailand, including hardpan fracture and organic amendments in trenches. Finally, Dr. P. Thornburn, CSIRO, explained how soil wetting patterns using trickle irrigation depend on structure and hydraulic properties of specific soils, and not simply on soil structure, and illustrated this with a new decision-support tool.

Session 3 examined concrete examples of approaches to transforming agricultural production in water-stressed areas, through two series of presentations and comments. In the first series, Dr. O. Ito, JIRCAS, presented two models of comprehensive

research in rainfed agriculture in Northeast Thailand, the first focused on crop-livestock integration, and second which will develop small-scale watersheds through toposequence management and small-scale irrigation, starting in 2002. Three commentators provided additional perspectives relevant to the new project. Dr. W. Pichai, Department of Land Development, Thailand, explained the national policy background which the new project will support. Dr. Y. Shinogi, NIRE, presented an example of small-scale watershed management, the cascade system of Sri Lanka. Dr. J. Caldwell, JIRCAS, through comparisons between small-scale watershed research in Northeast Thailand and Mali, West Africa, showed the potential for cross-regional research interaction. These included participatory methods, future adaptation of small-scale ponds for long *bas-fonds* in West Africa, and strategic weather prediction for crop management decision-making being developed in Mali. In the second series, Mr. R. Nishimaki, JICA, using an example from Kenya, explained how JICA has integrated participatory approaches into its development programs, combining water management with support to other needs of users. Paralleling the concept of "more welfare for every scarce drop," evaluation of its programs examines relevance, sustainability, and impact, as well as efficiency and effectiveness. Two commentators provided additional perspectives. Dr. A. Al-Jaloud, King Abdulaziz City for Science and Technology, Saudi Arabia, showed how well-integrated management practices have enabled that country to achieve remarkable increases in food production in an arid environment. Mr. Y. Kano, JICA, presented a case study of how community forestry in Senegal, led by beneficiaries themselves, has increased sustainable reforestation. The Symposium concluded in *Session 4* with an introduction to the World Water Forum, a summary of JIRCAS' achievements in water-focused research over the past 10 years, and general discussion of research needs, contributions, and potential partnerships for achieving more crop and more welfare from every scarce drop.

Socio-Economic Studies Related to Agricultural Development in Developing Regions

Kazuyuki Tsurumi
Director, Research Information Division, JIRCAS

The Research Information Division conducts research projects on socio-economic development and promotes the implementation of comprehensive multidisciplinary research projects including studies on socio-economic aspects and natural sciences in developing regions. The comprehensive projects have been implemented by JIRCAS as a whole in order to address complex issues like poverty alleviation. Scientists belonging to several Divisions at JIRCAS join the project to carry out research related to their respective fields and develop new technologies. Up to now, eight comprehensive research projects have been implemented (Table 1). On the other hand, socio-economic studies have been mainly carried out by scientists from the Research Information Division itself (Photo). Research subjects cover the situation of the supply and demand of food worldwide and in specific developing regions, as well as the impact of agricultural policies and systems, including extension systems, on agriculture and rural development, and the relation between agricultural development and changes in the natural environment.

Table 1. International comprehensive projects at JIRCAS

Title of the project	Target area
Comprehensive studies on soybean improvement, production and utilization	Brazil, Argentina, Paraguay
Comprehensive studies on the development of sustainable agro-pastoral systems in the subtropical area of Brazil	Brazil
Evaluation and improvement of regional farming systems	Indonesia
Improving food security through increased productivity in rainfed rice systems	West Africa
Comprehensive studies on sustainable agricultural systems in Northeast Thailand	Thailand
Development of new technologies and their practice for sustainable farming systems in the Mekong Delta	Vietnam
Development of sustainable production and utilization of major food resources	China
Productivity and sustainable utilization of brackish water mangrove ecosystems	Malaysia

In the comprehensive research projects, socio-economic studies play two major roles. One is to identify issues to be addressed and the another is to evaluate the results of research activities. Prior to the implementation of the research projects, usually a kind of baseline survey mainly related to socio-economic aspects has been conducted, including agricultural production, consumption, distribution systems, foreign trade, and even social customs. From these results, several issues to be tackled for achieving sustainable agricultural development can be identified along with the technologies and systems to be newly developed. In general, the most serious problem in developing regions has been the low production of food, especially of grain. In this case, major factors should be considered, such as soil conditions, water management, cultivation technologies, farming systems, and even farmers' association structure. Once the most important technologies

required have been identified, scientists can initiate research. The purpose of the baseline survey should be very clear and indicate some direction. The second role of the socio-economic studies is to evaluate the technologies newly developed. Even if some technologies and systems may contribute to the increase of agricultural production or the reduction of production costs, they must be adapted to the farmers' management level. When farmers have to invest a large amount of money in order to introduce the new technologies, the outcome may not be successful.

Apart from the role in the comprehensive research projects, socio-economic studies are closely related to policy and administration aspects. For decision-makers, it is important to evaluate the impact of the new policies and systems they plan to introduce. Econometric simulation models may enable to forecast the supply and demand situation of food, agricultural trade development and farm household economy when, for example, trade liberalization and price support policies are introduced. Moreover, through economic studies, to a certain extent, the impact of agricultural activities on the natural environment can be evaluated. Usually, since the relations between these two aspects are discussed in qualitative terms, there is a need to add a quantitative dimension. From the socio-economist viewpoint, in these simulations, for the development of methodology for estimation of impacts in more realistic terms, research results will be important.

It is important to emphasize that the socio-economists should carefully consider the scope of their studies and clearly indicate the objectives since the results are more closely linked with policies developed by decision-makers than in the case of research covering natural science disciplines. In other words, the results of socio-economic studies themselves might contribute to changes in policy direction. However, at the same time, to preserve the objectivity of the studies, the socio-economists should avoid to be too strongly influenced by the decision-makers.

Collaborative Research Project with CIMMYT for the Development of an Effective Selection System for Disease Resistance in Wheat by Using DNA Markers

Kazuhiro Suenaga

Biological Resources Division, JIRCAS

The Headquarters of the International Maize and Wheat Improvement Center (CIMMYT) are located at El Batan, a suburb of Mexico City. CIMMYT focuses its activities on increasing the productivity and sustainability of maize and wheat production in developing countries in the world. Major activities include the development and worldwide distribution of improved varieties, the conservation of genetic resources, and the production of documentation related to new knowledge about these crops.

There has been a long collaboration between CIMMYT and JIRCAS (formerly Tropical Agriculture Research Center (TARC)). In 1993, a JIRCAS researcher was sent to CIMMYT on a long-term basis to carry out collaborative studies on the development of wheat x maize crosses for producing and utilizing wheat haploids for breeding purposes and genetical analyses.

Since January 1998, a JIRCAS researcher has been involved in collaborative studies on the development of an effective selection system for wheat varieties harboring resistance genes to Fusarium head blight (FHB) and yellow rust using DNA markers.

Indeed, biotic and abiotic stresses to plant production are major issues in developing countries. Although important diseases may differ depending on the region/country, Fusarium head blight (FHB) and yellow rust are among the most serious diseases in wheat production areas. In Japan, due to the high rainfall during the maturation season of wheat, wheat production often experiences serious damage by FHB, especially the southern and northern parts of Japan (Kyushu and Hokkaido). Moreover, since recent abnormal weather has caused an epidemic of FHB worldwide, it is important to develop efficient breeding systems for wheat cultivars resistant to FHB.

In order to breed disease-resistant cultivars efficiently, an appropriate system for the selection for the disease is essential. Accuracy of evaluation of the disease or the resistance genes may vary depending on the year or other environmental conditions. A considerable amount of labor may be required to evaluate certain kinds of diseases. Recently, we have developed a method in which molecular markers are used for the selection, instead of selecting resistant lines in breeding fields. That is, differences in the DNA level between resistant and susceptible lines are used for the selection. Once molecular markers for resistance genes are identified, it is possible to perform a very reliable selection, because molecular markers themselves are never affected by environmental conditions.

Emphasis is currently placed on the development of molecular markers for FHB and yellow rust diseases in wheat. There are various types of resistance genes for yellow rust. The most important genes in the breeding program at CIMMYT are those which exert relatively small effects and confer a resistance at the adult plant stage. Most of these genes are considered to confer a durable resistance and they are race-non-specific. Therefore, the use of molecular markers is considered to be more effective than for major genes.

Evaluation for FHB is often affected considerably by the environmental conditions. Resistance to FHB is classified into at least three types, as follows: 1) resistance to fungal penetration into wheat tissues, 2) resistance to fungal spread within spikes and 3) ability to degrade the toxin produced by the fungi. Each type of resistance requires different and laborious evaluation systems.

Since FHB damage has been a major problem in Japan for many years, Japanese wheats are one of the several resistance sources to FHB in the world. Many highly resistant cultivars have been identified among Japanese cultivars, and we are using such resistant cultivars to tag the resistance genes in the collaborative studies at CIMMYT. As one Japanese wheat played an important role in the Green Revolution, another Japanese wheat germplasm may again contribute to the breeding of FHB-resistant wheat cultivars for developing countries.

Water Quality and Carbon and Nitrogen Budgets in Intensive Prawn Farms in Freshwater Areas of Thailand

Junya Higano and Phongchate Pichitkul*²*

**Fisheries Division, JIRCAS and *²Faculty of Fisheries, Kasetsart University, Thailand*

The Giant Tiger Prawn (*Penaeus monodon* Fabricius 1798) is Thailand's major export commodity: annual production exceeded 280,000 tons in 1995. However, extensive discharge of organic substances from prawn farms is causing environmental damage to surrounding areas, resulting in decreased production and increased frequency of disease outbreaks. Uneaten feed and feces are key problems since they are the major sources of organic effluent and sediments. It is necessary to evaluate the carbon and nitrogen cycles in conventional prawn farming practices to promote the development of sustainable aquaculture techniques. The purpose of this study was to analyze the changes in water quality and their correlation with the carbon and nitrogen budgets in a closed pond system.

The field survey was conducted in two earthen ponds in a private prawn farm in Bang Len District, Nakhon Pathom Province, Thailand. Pond 1 was 6,400 m² in area and square-shaped, and Pond 2 was 3,200 m² in area, with an irregular shape. The initial stocking densities for Pond 1 and Pond 2 were 52 and 69 individuals/m², respectively. Prawn culture period extended from mid-January to the end of May 1998. Pond water consisted of concentrated salt water transported from salt fields, diluted with fresh water from irrigation canals. The pond water was not replaced or discharged until prawn harvest.

Throughout the culture period, the water temperature, salinity, pH, amount of dissolved oxygen and turbidity were measured weekly at the center and the edge of the pond and the contents of inorganic nitrogen, phosphorus, etc. were also analyzed. Feed, prawn and sediment samples were dried and pulverized prior to chemical analysis. The carbon and nitrogen contents were measured using an NC analyzer.

The water temperature gradually increased from January - February (the cool season) to March - May (the hot season). The temperature in the afternoon was 1 - 3 °C higher than in the morning. This difference tended to decrease in the last two months. During the culture period, the highest temperature exceeded 35 °C. The initial salinity of the water was 7 - 10 (psu), which decreased upon the addition of fresh water until the intended salinity level of 2 was reached. At the start, the pH value was stable at 7.5 - 7.6 in both ponds throughout the day. After two weeks, the pH in the afternoon was higher than in the morning and this trend became more pronounced after March. In the center of the ponds, fluctuation of pH was greater than at the edge, occasionally exceeding a value of 9. The changes in the dissolved oxygen level followed the same pattern as those of the pH: close to saturation in the morning and showing supersaturation in the afternoon under a working paddle wheel. Chlorophyll concentration rapidly increased after two months, ultimately exceeding 500 µg/l. The type of phytoplankton bloom observed was strongly associated with the changes of the pH and amount of dissolved oxygen. Total ammonia concentration exceeded 1 mg-N/l at the start. After the second week, the concentration decreased except for abrupt increases caused by phytoplankton mortality.

The survival rates of prawn in Pond 1 and Pond 2 were 80% and 43% and production rates were 0.75 kg/m² and 0.53 kg/m², respectively. Whereas the commonly used Feed Conversion Ratios (FCRs) expressed as wet weight were 1.58 and 1.71, the FCRs expressed as dry weight were 5.49 and 6.62 (Fig. 1). The results of the element analysis indicated that 16 - 19% of the carbon composition of feed was converted into prawn, 60 - 72% was converted into sediments, and the loss to water and air was 12 - 21%. The rate of nitrogen composition of feed was 25 - 30% converted into prawn, 46 - 54% into sediments, with a loss to water and air of 21 - 24%.

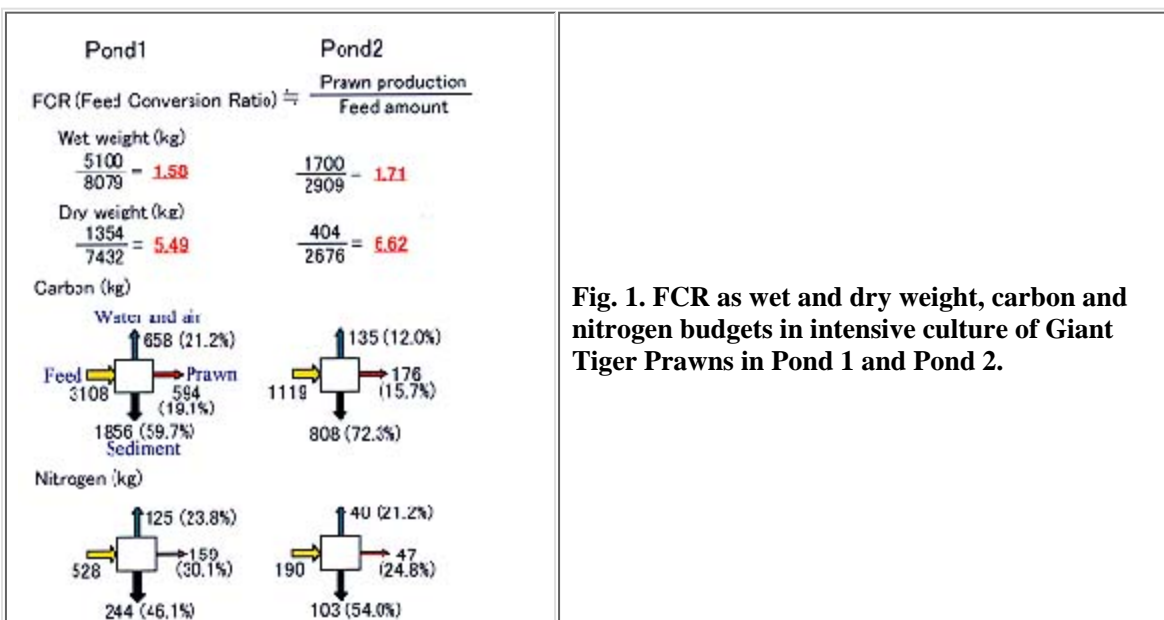

Fig. 1. FCR as wet and dry weight, carbon and nitrogen budgets in intensive culture of Giant Tiger Prawns in Pond 1 and Pond 2.

These results indicated that the production of 280,000 tons of *P. monodon* also led to the production of 138 - 156,000 tons of carbon and 20 - 23,000 tons of nitrogen that were discharged into the environment as wastewater and contaminated soil. We need therefore to consider the fate of these wastes and develop effective ways of reducing them. We have started a polyculture experiment between *P. monodon* and bivalves which are assumed to act as biofilters.

Note: prawn culture in freshwater areas was banned at the end of December 1998 as a result of its damaging effects on agricultural land, specifically damage caused by salinity.

**Discharge of water by pumping
water when *P. monodon* was
harvested**

Mitigating NO Emission from Soils by Deep Application of Fertilizers

Yasukazu Hosen and Kazuyuki Yagi
Environmental Resources Division, JIRCAS

To increase food production, the rate of chemical fertilizer application to arable land has been rising rapidly in developing regions, which could lead to harmful effects on the environment. For example, China has been the largest consumer of chemical fertilizer in the world since 1989 and many environmental problems have resulted due to the excessive load of nutrients on agricultural land, in particular nitrogen. To address such problems in China, JIRCAS launched a 7-year collaborative research project entitled "Evaluation and Development of Methods for Sustainable Agriculture and Environmental Conservation" since 1997. This project covers four major agricultural regions in China and both field experiments and local analyses are conducted at representative sites of each study area.

To support this project, experiments have also been carried out at JIRCAS in Japan. The objectives of these experiments are (1) to develop methods for quantifying total nitrogen cycling in arable land, including gas exchange between the pedosphere and the atmosphere, and soluble nutrient exchange between the pedosphere and the hydrosphere, and (2) to develop key technology for minimizing the impact of agricultural activities on the environment. As for (2), the possibility of mitigating nitric oxide (NO) emission from soil was suggested.

NO is known to be a cause of photochemical atmospheric pollution, acid rain, and is linked to increased tropospheric ozone, one of the major greenhouse gases. Arable land should not be overlooked as a source of NO, because global annual NO emissions from soil are in the order of 10 Tg NO-N, about half the amount contributed by fossil fuel combustion processes to the annual global NO-x budget. We focused our studies on the effect of depth of fertilizer placement in an attempt to develop a method for mitigating NO emission from upland fields.

Firstly, a numerical model was designed based on pre-existing survey data of soil NO concentration profiles in Andisol upland fields. Based on this model analysis, the possibility of deep application of fertilizer to mitigate NO emission was pointed out. Secondly, the estimated results were verified in a laboratory experiment with soil columns. Topsoil from an Andisol whose moisture weight percentage was 49 (± 0.9)% was put in cylindrical PVC tubes, 1.03 m in height and 0.194 m in internal diameter, at the bulk densities of 0.60 and 0.75 Mg m⁻³ and at the depths of 0-20 and 20-100 cm, respectively. As nitrogen fertilizer, ammonium sulfate (200 kgN ha⁻¹) was applied at the depths of 0-10, 5-15 or 10-20 cm in soil columns in duplicate. No water had been supplied to the soil columns for 15 days after fertilizer application. Then, the groundwater level was set at the depth of 100 cm. Soil gas was collected from sampling tubes installed in each soil column at intervals of 5 cm. Gas emission rate from the soil surface was determined by the closed-chamber method. This experiment was carried out in a thermostatic chamber (22.2 \pm 0.6°C). The results obtained from this experiment supported well our findings from model analysis. All the NO concentration profiles in soil showed a sharp peak at each fertilized site within 29 days after fertilizer application. Fig. 1 shows that the NO concentration in soil decreased abruptly as the distance from the fertilized site increased at 15 days after fertilizer application. These findings imply that NO is produced mainly at the fertilized site, but does not diffuse widely in the soil columns, because of the high NO-uptake by soil. As a result, the NO concentration gradient near the soil surface decreased when the depth of the fertilized site increased (Fig. 1). Consequently, the NO emission rate from soil columns fertilized at 10-20 cm depth during a period of 29 days after fertilization was reduced to almost the same rate as that of the unfertilized one, which was equivalent to 0.9-20% of the value from the fertilized columns at the depth of 0-10 cm (Fig. 2). These results indicated that a lower amount of NO was emitted from soil when the distance between the fertilized site and the soil surface increased.

Our findings demonstrate that NO emission from arable land could be mitigated by applying fertilizer deeper into the soil, in other words, by designing an unfertilized soil layer near the soil surface. We carried out field experiments to verify our findings from the laboratory experiment and to examine the possibility of application to field management as a mitigating technology, by using a system to monitor nutrient leaching in soil as well as gas emissions. The system enables to evaluate the effects of fertilizer treatment on the impact on the environment and to develop new technologies for mitigating the impact while sustaining crop yield. The environment-friendly technologies developed in this study will be applied to agriculture in developing regions.

EMBRAPA/JIRCAS Joint Workshop on Agro-Pastoral Systems in South America

The research project entitled "Comprehensive Studies on the Development of Sustainable Agro-Pastoral Systems in the Subtropical Area of Brazil" has been implemented since 1996. This research project is focused on the development of sustainable farming systems with high productivity in environmentally degraded areas in the subtropical zone of Brazil, with emphasis placed on land utilization through the adoption of crop-pasture rotation systems. For this purpose, the studies are being carried out in collaboration with the National Center for Beef Cattle Research (EMBRAPA-CNPGC) and Japan International Research Center for Agricultural Sciences (JIRCAS).

The workshop titled: "EMBRAPA-CNPGC/JIRCAS Joint Workshop on Agro-Pastoral Systems in South America" was held in Campo Grande, Brazil on December 7 and 8, 1999. After Dr. A. Boock, Director General of CNPGC, delivered the opening address, 10 papers were presented in research areas covering crop and pasture management, maintenance of soil fertility and economic evaluation of the systems. In a field tour which was organized during the meeting, the participants observed the experimental fields of CNPGC for the "Agro-Pastoral" project. From 5 countries, 35 scientists participated and reviewed the results obtained until now during the implementation of the project as well as other related studies, and discussed the future strategy and orientation of the project. In the closing remarks, Dr. N. Maeno, Director General of JIRCAS, reminded the participants of the potential of agro-pastoral systems to alleviate the food problem and environmental concern on a global scale and emphasized the importance of the multidisciplinary approach to achieve the objectives of this project. The proceedings of this workshop will be published this year.

JIRCAS Fellowship

JIRCAS Fellowship Program: Welcoming New Visiting Researchers

Eighteen Visiting Researchers are participating in the JIRCAS 2000 Visiting Research Fellowship Program to carry out collaborative research at Tsukuba and Okinawa.

Tsukuba: Short-term (5months at National Institute for Agrobiological Resources)

Yoon Mun Sup	National Seed Management Office, Rural Development Administration, Republic of Korea	Genetic diversity in the <i>Vigna angularis</i> complex
Badraddin Ebrahim Sayed-Tabatabaei	University of Tehran, Iran	Genetic variation of wild (<i>H. vulgare</i> ssp. <i>spontaneum</i>) and cultivated (<i>H. vulgare</i> ssp. <i>vulgare</i>) barley from Iran based on a DNA region linked to the <i>vrs1</i> locus
Liu Qingchang	China Agricultural University, P. R. China	Production of cell-induced sweet potato mutants for table and vegetable uses
Natalya v. Alpatyeva	N. I. Vavilov Research Institute of Plant Industry, Russia	Genetic diversity of cereal crops revealed by DNA polymorphism

Tsukuba: Long-term (2 years at JIRCAS HQ.)

Malik Ashiq Rabbani	National Agricultural Research Centre, Pakistan	Analysis of plant responses to environmental stresses and gene expression
Yin Changbin	Institute of Natural Resources and Regional Planning, P. R. China	Studies on regional food production, marketing and consumption in China
Najeeb S. Alzoreky	Sanaa University, Yemen	Analysis and evaluation of biological activity of indigenous edible plants
Thanawan Boonpunt	Kasetsart University, Thailand	Studies on changes in the physicochemical properties of rice grain during post-harvest processing

Okinawa: Long-term (1 year at JIRCAS Subtropical Station)

MD. Khalilur Rahman	University of Dhaka, Bangladesh	Subsurface drip irrigation of some vegetable crops
Lauro Gumasing Hernandez	Soils Research and Development Center, Philippines	Effect of subsurface "drip fertigation" on Chinese cabbage tipburn
Sayed Fathey El-Sayed	Cairo University, Egypt	Genetic studies on heat tolerance in snap bean (<i>Phaseolus vulgaris</i>) plants
Nguyen Thi Lang	Cuulong Delta Rice Research Institute, Vietnam	QTL mapping for rice salt tolerance genes and their evaluation
Werapon Ponragdee	Field Crops Research Institute, Thailand	Intergeneric crossing in sugarcane for higher environmental tolerance
Lin Tong-Xiang	Institute of Subtropical Pomology Fujian Agricultural University, P. R. China	Analysis of DNA markers in <i>Dimocarpus longan</i> and development of test kit
Liu Xiaochuan	China National Rice Research Institute, P. R. China	Tagging heterosis traits with molecular markers in rice

Ishwar Singh	Indian Institute of Sugarcane Research, India	Physiological and molecular characterization of heat tolerance in tomato and tobacco (transgenic of sHSP)
Maribel Regla Quintana Sanz	Institute of Pastures and Forages Research, Cuba	Sucrose phosphate synthase gene expression in sugarcane
Fan Shuguo	South China Institute of Botany, P. R. China	Molecular analysis of NaCl-tolerant and LiCl-tolerant suspensions of rice (<i>Oryza sativa</i> L. cv. Taipei 309)

Overview of JIRCAS

■ Objectives and Past Accomplishments

Global problems are increasingly impacting world food security. These include continued world population growth, deterioration of environments, and destruction of cultivated lands. Even more intensive efforts than ever before are essential to solve these problems. The promotion of sustainable agriculture, forestry and fisheries in harmony with natural ecologies is a critical need.

The demand for food is increasing in a large number of developing countries due to both population increase and improved diets. At the same time, where agricultural and fisheries productivity has remained low, food supplies remain unstable and serious problems of hunger and poverty continue to persist. To address these critical needs, the Japan International Research Center for Agricultural Sciences (JIRCAS) promotes research aimed at achieving a stable global food supply and ensuring sustainable agriculture, forestry and fisheries in harmony with the environment. It carries out interdisciplinary research on biological and social aspects of agriculture, forestry and fisheries, and undertakes collaborative projects with institutions of developing countries as well as international organizations.

JIRCAS was established on October 1, 1993, through the reorganization of the former Tropical Agriculture Research Center founded on June 1, 1970. From this year, on April 2001, it has become an independent administrative institution. JIRCAS is making many active contributions internationally to address the agricultural, forestry, fisheries, food and environmental problems of the world, with a focus on developing regions.

■ Main Activities of JIRCAS

1. Conducts collaborative research with developing countries, primarily through sending JIRCAS researchers.
2. Conducts experimental research in Japan to support research topics of international relevance.
3. Creates opportunities for scientists in developing countries to do collaborative research in Japan, by inviting research fellows from countries collaborating with JIRCAS.
4. Collects, analyzes and publishes information of relevance for research in developing regions.
5. Organizes international symposia and workshops.
6. Participates in research planning and offers technical support, counseling and aid to developing countries.
7. Serves as a think-tank for technology research focused on food supply, environmental problems, and related issues.

Message from the President

President
Takahiro Inoue

A new JIRCAS-structural reorganization

Implications of the new organization

On April 1, 2001, under the Japanese Government's administrative reform calling for the reorganization of government-affiliated research organizations, the Japan International Research Center for Agricultural Sciences (JIRCAS) became an Independent Administrative Institution (a semi-autonomous agency) under the supervision of the Ministry of Agriculture, Forestry, and Fisheries of Japan (MAFF).

The introduction of the new system of Independent Administrative Institutions (IAI) is at the core of the administrative reform. This system has been introduced to enhance the effectiveness, quality, and transparency of technological development by splitting the administration into its implementation functions and its planning and drafting functions. By converting the implementation functions of the national research institutions to the IAI system, each institution has gained its own independent judicial status. Therefore, under the new system, JIRCAS will conduct not only autonomous and flexible programs, but also commit itself to a strict ex post facto evaluation and review of its performance, as well as disclosure of various institutional issues.

The new mandate given to JIRCAS by the Japanese Government does not fundamentally change the previous mandate, in which JIRCAS was entrusted with the mission of promoting the development of sustainable agriculture, forestry, and fisheries compatible with environmental preservation in developing regions of the world. Although the demand for food is increasing due to population increases and improvements in dietary habits, agricultural production remains at a low and unstable level in many developing countries. As a result, hunger and poverty remain prominent issues. Moreover, concern for the deterioration of the global environment has generated the need for the development of sustainable systems of agriculture, forestry, and fisheries that are non-destructive to natural ecosystems.

The most distinctive features of the new IAI system are, first, semi-autonomy with limited control from outside institutions, and second, ex post facto performance evaluations, the results of which each IAI uses to plan subsequent activities. Under the new system, MAFF presents to JIRCAS mid-term objectives, a list of goals that the "New JIRCAS" is expected to achieve during a five-year period. The mid-term objectives include issues related to the enhancement of the efficiency of research activities, improvement of the quality of research programs, and financial performance. Based on the mid-term objectives, the IAI drafts a mid-term plan to achieve these objectives autonomously.

The IAI Evaluation Committees, established under MAFF and composed of experts not belonging to the public sector, will also periodically review the performance of IAI research activities. Each fiscal year, an IAI Evaluation Committee will investigate and analyze the progress made on the previous year's mid-term objectives. The results of evaluation will be subjected to operational and financial modification the following fiscal year.

Since the research activities need to be fully executed, the government will allocate, within budgetary limitations, most or all of the financial resources required to carry out the defined objectives. In addition, JIRCAS will make utmost efforts to gain supplementary financial support from such sources as other governmental offices or the private sector to fulfill the mid-term objectives.

Roles and research strategy

Given that the role of JIRCAS is to promote the advancement of agriculture, forestry, and fisheries in developing regions of the world through integrated collaborative research programs, the "New JIRCAS" has established the following priorities for research strategy. The first is to develop production and utilization systems in sustainable agriculture, forestry and fisheries in harmony with the environment by conducting research on such topics as stress-tolerant crops, technologies for preserving arable land environments, new farming systems for ensuring profitability of producers, and technologies for efficient postharvest management and utilization. The second priority is to rehabilitate, maintain, and improve the utilization of natural resources, with emphasis placed on tropical forest and coastal ecosystems.

In order to complete the mid-term objectives adhering to the above research strategies, the "New JIRCAS" plans to conduct and take full advantage of (1) international collaborative research programs in developing regions, dispatching researchers on long- and short-term bases, (2) collaborative research with researchers from developing regions, (3) domestic research that will further enhance international collaboration, (4) accumulation and analysis of research information for supporting collaborative work, (5) international symposia, workshops and seminars, (6) technical assistance relating to food and environmental issues, and (7) functioning as a think tank for advisory committees of national organizations involved in overseas development.

In conclusion, the reorganization of JIRCAS into an IAI makes it possible for JIRCAS to gain more flexibility in the implementation of its research programs. The reorganization will also transform hiring procedures, enabling JIRCAS to recruit researchers from universities or institutes that do not belong exclusively to the public sector, and the financial aspects of the institution, since funds can now be obtained from both the public and private sectors. At the same time, the strict evaluations by the Evaluation Committee may enhance the quality of the research programs and lead to a more efficient utilization of financial resources, ultimately furthering collaborative activities compatible with the needs of developing regions.

Research Planning and Coordination Division

■ Director Akinori Noguchi

The Research Planning and Coordination Division in itself does not act as a research division but rather serves to oversee and support the activities of the Research Divisions and Okinawa Subtropical Station. The Division consists of four sections which are the Research Planning Section, the Research Coordination Section, the International Relations Section, and the Publication and Documentation Section. In addition, a International Research Coordinator and a Public Information Officer are assigned to the Division.

In order to promote the implementation of research programs both overseas and in Japan, the first 3 sections are responsible for the overall planning of JIRCAS research projects, dispatching of researchers on long-term or short term bases, implementing programs for the invitation of researchers and administrators, and coordinating with international and domestic institutions and agencies. The Publication and Documentation section is responsible for the collection, classification, and supply of bibliographic materials from both overseas and domestic sources, as well as the release of public relation materials. The International Research Coordinator manages the comprehensive projects. The Public Information Officer is responsible for the publications of JIRCAS.

▶ [Continue to Administration Division](#)

Administration Division

■ Director Katsuyuki Kiryu

The Administration Division consists of three sections: the General Affairs Section, the Accounting Section, and the Overseas Support Section. The General Affairs Section is responsible for the management of official documents, personnel-related matters, and social affairs pertaining to JIRCAS staff. The Accounting Section handles overall accounting, all budgeting, settlements, and wage distribution. Lastly, the Overseas Support Section is in charge of all matters pertaining to JIRCAS overseas operations, which includes general international affairs, overseas expenditures, and overseas shipments of equipment and materials.

▶ [Continue to Development Research Division](#)

Development Research Division

■ Director Kazuyuki Tsurumi

This division gathers and analyses information and data on the natural and social environments, the macro economies, and the agriculture, forestry and fisheries sectors of developing regions throughout the world. Using these data, it carries out research aimed at developing a global food security data collection system and a world food supply forecasting model.

Another activity of this division is the assessment of current farming systems and development of improved systems in representative priority regions.

The division also carries out research to identify the directions of technology development most likely to meet future needs, and contributes to the establishment of a comprehensive research strategy for JIRCAS.

▶ [Continue to Biological Resources Division](#)

Biological Resources Division

Director Masaru Iwanaga

The division masters the latest research techniques of the biotechnology and develops breeding materials and breeding methodology in order to ensure the effective utilization of genetic resources of the plants that play important roles in food production and environmental problems in the developing regions.

 [Continue to Crop Production and Environment Division](#)

Crop Production and Environment Division

Director Osamu Ito

The division carries out research to develop the sustainable agricultural technologies in consideration of harmony with the natural ecosystem and environmental conservation on global scale through effective utilization of diversified functions of crops and microbes, and appropriate utilization of natural resources.

 [Continue to Animal Production and Grasslands Division](#)

Animal Production and Grasslands Division

Director Toshiaki Taniguchi

The division aims to develop sustainable animal husbandry technologies in harmony with the natural, social and economical conditions of the developing regions. In order to achieve these, the division is carrying out researches for the development of feed resources, improvement of pasture management and livestock feeding, and control of important diseases of animals.

 [Continue to Food Science and Technology Divison](#)

Food Production and Technology Division

■ Director Toru Hayashi

The division evaluates the safety and nutritional characteristics of food resources, and acts to minimize the qualitative and quantitative losses through development of techniques in the conformity to the actual circumstances of developing countries.

In addition it develops techniques to evaluate food qualities and technologies concerning with the distribution and processing for the purpose of improving the incomes of the farmers.

▶ [Continue to Forestry Divison](#)

Forestry Division

■ Director Kiyoshi Nakashima

The division carries out research on the technologies for the sustainable forest management, proper utilization and processing of the forest resources in the developing regions.

▶ [Continue to Fishery Division](#)

Fisheries Division

Director Masachika Maeda

The division carries out research to develop the techniques for the management and sustainable utilization of marine fisheries resources, and to promote the aquaculture utilizing the new varieties of fishes.

In addition, it conducts experiments on the utilization, processing and transportation of marine and fresh water fishes, and the preservation and restoration of the coastal environment.

 [Continue to Okinawa Subtropical Station](#)

Okinawa Subtropical Station

Director Masaaki Suzuki

The substation carries out researches on the heat tolerance and breeding of tropical and subtropical crops, farming, utilization and diseases resistance of tropical fruits, and environmental management techniques for intensive agriculture by taking advantage of the special subtropical climatic conditions due to its geographical location.

GENES ESSENTIAL FOR MOLECULAR BREEDING OF DROUGHT TOLERANT PLANTS WERE ISOLATED.

Plant genes for transcription factors were isolated that control expression of genes involved in drought tolerance. Regulatory elements in promoters were also identified that control drought responsive gene expression. These transcription factors and promoters are expected to be useful for molecular breeding of drought tolerant plants by regulating number of genes involved in drought tolerance.

Strategies to develop crops that are tolerant to drought stress

Novel promoters control drought-responsive expression of GUS reporter gene

Offshore Environmental Research

Masachika Maeda
Director, Fisheries Division, JIRCAS

The argument for protecting the environment is based on the fear that the biotopes will be unable to withstand the disturbances caused by human activities, along with a deep concern for the future generations, in particular the under-privileged groups in the society.

Despite the development and use of modern measurements and technologies, far too little is actually being done for the promotion of sustainable development. There is not even a clear agreement as to what sustainable development is. Under these conditions, to enable the development of common standards for sustainable production in the field of agriculture, forestry and fisheries, scientific research will play a crucial role.

Coastal zones sharply illustrate the problems and policy challenges faced locally as well as on a global scale. These zones are under increasing environmental pressure and are showing an unacceptable level of environmental degradation as a result of population growth, urbanization, reckless adoption of aquaculture and other multiple and often conflicting changes in resource utilization. The alleviation of these problems and the adoption of practical and sustainable economic development policy objectives will require innovative policy responses. Integrated coastal zone management (ICZM) is one of such comprehensive policy/management options. ICZM requires the formulation of a wide range of general principles, as well as the combination of economically efficient and sustainable resource utilization with prevention strategies.

In many coastal areas, maintenance or expansion of the regional economy is a major, often the primary, objective. However, the benefits associated with the development in coastal economies, such as tax revenues, tourist expenditures, and employment may be reduced as a result of the deterioration of water quality.

In the context of regional and area economic development, the objectives of ICZM can be expressed in two forms: the negative and positive aspects. On the negative side, people will have to bear the costs of normal production, net coastal management, discharge reduction, mangrove or beach restoration, coastal protection, cost for repair of existing damage and the administrative cost of management. The positive factors include improved income from increased gross regional product combined with benefits from improved environmental quality processes which are an international focus of interest. For example, by using natural microbial foods and taking advantage of the capacity of highly productive mangrove ecosystems to absorb effluents, aquaculture can become an eco-friendly process (Fig. 1), that will provide the fishermen with a higher income in the long term.

In addition, we should remember the words of the famous novelist Ryotaro Shiba: "People of the late 20th century, having gained the knowledge that they are merely one part of Nature, have again begun to fear Nature in the way people feared the gods in ancient times. The period in which man regards himself as master of Nature will come to an end as we draw increasingly close to the 21st century. Human beings do not live on their own, but are kept alive by a great presence."

Collaborative Research Projects between ICIPE and JIRCAS

Satoshi Nakamura

Crop Production and Postharvest Technology Division, JIRCAS

The International Centre of Insect Physiology and Ecology (ICIPE), based in Nairobi, Kenya, was established in 1970 as an advanced research institute amidst growing global concern about the misuse and overuse of synthetic pesticides. ICIPE was registered as an intergovernmental organization in 1986, with governance through a 16-member international Governing Council. Due to its broader mandate encompassing health and environment as well as agriculture, ICIPE has remained outside the CGIAR system, whose work is primarily commodity-oriented. Interested donors judiciously established a Sponsoring Group (SGI) in 1980 to help guarantee scientific excellence and funding.

Building of ICIPE

Sign at the entrance of ICIPE

Today, ICIPE continues to follow its original mandate of developing technologies to alleviate world poverty and to ensure food security and good health for the peoples of the tropics through management and control of both harmful and useful arthropods. The Centre's current objectives aim at improving and promoting the activities of the "4H's" (human, animal, plant and environmental health) interdisciplinary teams of scientists engaged in research related to ecosystems science, behavioral biology and chemical ecology, molecular biology and biotechnology and social sciences. Research support is provided by biomathematics, animal breeding and quarantine and biosystematics units, and computer and information services. The 360-strong staff members originate from 19 countries, primarily in developing regions. Programs are mainly focused on plant pest management, disease vector management, insect biodiversity conservation and utilization, and capacity building from post-doctoral to farmer level.

Collaboration is a by-word at ICIPE, with partners from 45 universities throughout the world, including 30 African universities in ARPPIS (The African Regional Postgraduate Programme in Insect Science), other IARCs and CGIAR centres, more than 20 advanced research institutions, NARS in Africa and beyond, and NGOs.

JIRCAS is one of these partners and JIRCAS-ICIPE collaborative research started from 1994 and then the project: "Biorational Approaches to Long-term and Sustainable Management of Desert Locusts in East and North Africa" was conducted during the period 1995-1999, which produced fruitful results on the mechanism of change from the "solitary" to harmful "gregarious" phase of desert locusts, based mainly on physiological and endocrinological studies. Presently these studies are being taken over to the new five-year project: "Physiological and Ecological Studies for the Development of IPM for Economically Important Pests in Africa" funded by the Ministry of Agriculture, Forestry and Fisheries of Japan.

Besides locusts, another objective of the new project is to focus on the biological control of stemborers of staple cereals in East Africa. The spotted stemborer, *Chilo partellus*, an exotic cereal pest that was accidentally introduced into Africa from Asia in the 1930s, has been responsible for crop losses of up to 80%. A natural enemy of the stemborer, a parasitic wasp *Cotesia flavipes*, was imported by ICIPE from Pakistan in 1991 and has been found to be one of the most effective biological control agents for this destructive pest. However, for further suppression of stemborer densities, other promising natural enemies will be studied and introduced in the near future.

Utilization of Oil Palm Residues as a Raw Material for Pulp and Paper

Ryohei Tanaka
Forestry Division, JIRCAS

African oil palm, *Elaeis guineensis*, is one of the most important plants in Malaysia. It produces palm oil and palm kernel oil, which are widely used in food and other industries such as detergents and cosmetics. Malaysia is the world's largest producer and exporter of the oil, accounting for approximately 10% of the world's oil and fat production (1998). The total area of oil palm plantations is close to 3.2 million hectares, which account for almost 50% of the land under cultivation in Malaysia.

Although oil from the palm tree is an excellent product for the country, residues from oil palm have not been used sufficiently. One of the abundant lignocellulosic residues consists of empty fruit bunches (EFB), which are left behind after removal of oil palm fruits for the oil refining process at palm oil refineries. Tons of EFB are discharged from each refinery regularly, amounting to 16 million tons per annum in the year 2000. Some of them are used as fuel at the factories, but most of them are left unused.

Converting this lignocellulosic waste to paper-making pulp is a promising way of utilization, as the consumption of paper is increasing dramatically in the Southeast Asian countries including Malaysia. Several investigations have been carried out on EFB pulping, whereas studies on bleaching of EFB pulp have been very limited so far. Collaboration work between JIRCAS and Universiti Sains Malaysia (USM) has, therefore, focused on the bleaching of chemical pulp from EFB, especially using total chlorine-free (TCF) methods.

TCF bleaching was examined for EFB chemical pulps such as kraft, soda and soda-anthraquinone pulps. TCF processes include oxygen (O_2) delignification, ozone (O_3) bleaching, acid treatment, hydrogen peroxide (H_2O_2) bleaching and alkali extraction. It was found that a pulp brightness of 75% can be obtained for EFB kraft pulp by a bleaching sequence of O_2 -acid- O_3 - H_2O_2 . The brightness is required to be above 80% for commercial bleached kraft pulp based on JIS Standard. Mechanical properties such as tensile and tear strength of handsheets produced from this pulp were found to be comparable to those of hardwood pulps. Furthermore, since the TCF bleaching method removes most of the coloring compounds, that is lignin, in EFB, the bleaching ability is assumed to be similar to that of bleaching methods using chlorine. Soda pulp and soda-anthraquinone pulp of EFB, which contain less lignin than EFB kraft pulp, have also reached a brightness level of 70-75% with a single bleaching stage using O_2 or O_3 . This also indicates that the coloring materials in EFB can be easily removed without using any chlorine compounds.

Based on this study, we observed that the total chlorine-free bleaching method can be applied to EFB chemical pulps and that EFB is suitable as a raw material of chemical pulp. Although the bleaching and even pulping methods for producing EFB pulp for paper-making have not been optimized yet, there is a great potential for the utilization of this oil palm lignocellulosic residue in pulp and paper industries. Currently, the world trend in pulp bleaching is toward the application of non-chlorine processes because of environmental concern. Once the oil palm by-product becomes a raw material for pulp production, it will be essential to develop TCF bleaching processes in future.

Oil palm is one of important plant in Malaysia and some other tropical countries in South-East Asia

Simple and Rapid Technique for the Identification of an Aromatic Thai Rice Variety (Khao Dawk Mali 105)

Tadashi Yoshihashi

Crop Production and Postharvest Technology Division, JIRCAS

In order to meet consumers' demand for food, a large quantity of rice (*Oryza sativa* L.) is produced in many parts of the world. Aromatic rice types, i.e. rice varieties having a stronger aroma than ordinary rice, have become increasingly popular in Southeast Asian countries, Europe and the U.S.A.

An aromatic variety, Khao Dawk Mali 105 (KDML105), is mainly produced in Northeast Thailand. Being recognized for its better quality, market demand for this variety has increased both in Thailand and overseas. Although increase of production is urgently needed, the cultivation is limited due to infertile and drought-stricken sandy soils. Moreover, erratic rainfall at the beginning of the rainy season and labor shortage for transplanting are other constraints on the production of KDML 105. As a matter of fact, no objective method for the identification of such an aromatic variety has been developed. As a result, varieties different from KDML 105 are often marketed under the name of KDML 105.

In Japan, since rice is distributed as brown rice which can germinate, information about varieties can be obtained. In contrast, in Southeast Asia, rice is mainly marketed as milled rice unable to germinate. To identify varieties of milled rice in a mixture with varieties of similar appearance, conventional methods such as determination of the length-width ratio are not suitable.

Molecular marker techniques based on the polymerase chain reaction (PCR), have provided more objective methods for the identification of grain varieties. These techniques (i.e., microsatellite analysis, randomly amplified polymorphic DNA (RAPD) and amplified fragment length polymorphism (AFLP)) could be very useful for plant-based identification; microsatellite analysis is particularly useful for simple and rapid analysis. To apply this technique to milled rice, however, high quality DNA must be extracted from a single grain of milled rice. It is difficult to extract DNA, because the main components (starch and proteins) of milled rice show the same solubility as that of DNA. It should be emphasized that enzyme-inhibiting polysaccharides often contaminate the "purified" DNA.

Extracting procedures for simple and rapid identification of grain varieties require breakage of the cell wall, disruption of the cell membrane, protection of DNA from endogenous nucleases and finally removal of polysaccharides.

In our laboratory, we developed a DNA extraction method based on a freeze-and-thaw cycle for extracting purified, high molecular weight DNA from grains. The developed technique does not require expensive equipment and materials, and is not a time-consuming procedure.

Microsatellite analytical method for cultivar identification was used for extracting DNA. We analyzed rice samples obtained from Bangkok, Suwannaphum (Northeast Thailand) and Kuala Lumpur markets as well as selected varieties different from KDML 105 (Bangkok and Kuala Lumpur market rice samples). Fig. 1 shows the results of microsatellite analysis of market samples on agarose gel. Some of the rice samples originating from Kuala Lumpur and Bangkok markets did not match the KDML 105 variety.

[Fig. 1. Agarose gel electrophoresis of DNA fragments amplified from rice market samples by PCR using primer set RM17. Arrowheads indicate the position of the amplified fragments of authentic KDML105.](#)

A simple and rapid method for cultivar identification of milled rice is illustrated in Fig. 2. By applying the improved method, we were able to obtain DNA for microsatellite analysis within 2 h and the whole process of identification required 6 h. Time saving and the possibility to avoid the use of expensive instruments or toxic chemicals in the present method are an attractive alternative to existing methods of identification. The results obtained showed that DNA extracted from tested samples was of high quality and hence could be used in PCR-based techniques for cultivar identification even in laboratories with a moderate level of technology. Another feature of this developed technique was the saving in time and cost as well as the safety of the procedure.

[Fig. 2. Scheme of rapid DNA extraction and cultivar identification of milled rice.](#)

Genetic Variation in Amylose Content and Lipoxygenase-3 Activity of Seeds from Rice Genetic Resources in Yunnan, China

Kazuo Ise*, Sun Youquan*² and Dai Luyuan*²

*Biological Resources Division, JIRCAS, *²Yunnan Academy of Agricultural Sciences (YAAS), China

Yunnan province in China is a center for genetic diversity in Asian cultivated rice (*Oryza sativa* L.). We studied the biochemical properties of rice grains using a wide variety of genetic resources from Yunnan and Japan.

The amylose content in endosperm starch is a major determinant of eating, cooking, and processing of rice grains. Starch in nonglutinous endosperm contains both amylose and amylopectin, whereas starch in glutinous endosperm contains only amylopectin and lacks amylose, or contains a small amount of amylose. The eating quality of cooked rice is negatively correlated with the amylose content in nonglutinous rice. Cooler temperature during grain filling considerably affects the increase of the amylose content of rice plants cultivated in paddy fields at an altitude of 1500 - 2100 m above sea level in Yunnan province. To improve the eating quality, YAAS breeders are implementing a breeding program to develop new rice varieties with a low content of amylose.

We screened 581 varieties from Yunnan (n=376) and Japan (n=205) for the endosperm amylose content (Fig. 1). Yunnan rice showed a 1.7 times larger variation than Japanese rice based on the Shannon-Wiener index (H'). Upland rice exhibited the largest variation in the amylose content among the varietal groups from Yunnan: Indica paddy rice ($H'=0.734$), Japonica paddy rice ($H'=0.844$), and upland rice ($H'=0.909$). Upland rice varieties with a low amylose content (5-11%) are expected to be useful for the breeding of new varieties with improved eating quality in highland areas.

Rice grain deterioration and the development of staleness during storage are serious problems that reduce quality. It is difficult for developing countries to construct temperature-controlled warehouses that would help ensure proper treatment of harvested rice. Lipid degradation is considered to be responsible for the deterioration during rice storage. Lipoxygenase enzyme catalyzes the oxidation of polyunsaturated fatty acids containing a 1,4-pentadiene moiety into conjugated hydroperoxy fatty acids. The lack of lipoxygenase in rice grains may contribute to the reduction of oxidative deterioration during storage.

We screened the germplasm collection from Yunnan for the lipoxygenase-3 (LOX-3) content in embryos, by using monoclonal antibodies against LOX-3, in collaboration with Dr. Y. Suzuki, National Agriculture Research Center, Japan. We detected 22 varieties that lacked LOX-3, the major component among isozymes in rice seeds, after screening 108 varieties from Yunnan rice genetic resources. Most of the varieties that lacked LOX-3 belonged to upland rice, and to Groups 4 and 6 based on the esterase isozyme genotype of *Est1*, *Est2*, and *Est3* (Fig. 2).

Major agronomic features of the varieties lacking LOX-3 include early heading, red and round grains, long culms, and glabrous leaves and hulls. These varieties showed a poor agronomic performance in the paddy fields because of severe lodging before harvest. The lack of LOX-3 was inherited as a single recessive trait in a cross between CI-115 lacking LOX-3 and Norin 20 having LOX-3. CI-115 is a pure line selected from the indigenous upland variety Chongtui. No tight linkage was observed between the lack of LOX-3 and the red pericarp derived from CI-115.

Varieties lacking LOX-3 could help reduce off-flavor formation in rice stored in warehouses that are not temperature-controlled. We are currently developing breeding lines lacking LOX-3 by crossing CI-115 with improved varieties that are agronomically superior.

Fig. 1. Frequency distribution of varieties differing in the endosperm amylose content in Japanese rice and three groups of Yunnan indigenous rice. Varieties with less than 3% belong to glutinous rice.

Fig. 2. Relationship between lipoxygenase-3 (LOX-3) activity in seeds and rice varietal groups based on genotypes of esterase isozymes (*Est1*, *Est2*, and *Est3*) in leaves.

JIRCAS International Workshop:

"Brackish Water Mangrove Ecosystems - Productivity and Sustainable Utilization"

February 29 - March 1, 2000, Tsukuba, Japan

Twenty-one technical papers and 3 panel papers were presented at this workshop, which was attended by 114 participants. The workshop focused on the socio-ecological conditions in the Matang, Merbok and Lumut mangrove ecosystems in Malaysia, the main sites of the collaborative study entitled "Productivity and Sustainable Utilization of Brackish Water Mangrove Ecosystems," which was carried out in Malaysia from April 1995 to March 2000 by JIRCAS, Fisheries and Forestry Agencies in Japan, and the Fisheries Research Institute (FRI), the University of Malaya (UM) and the Forest Research Institute (FRIM) in Malaysia. The workshop consisted of 5 sessions: (1) Structure, management and reforestation of mangrove areas; (2) Nutrients, plankton and fish species in brackish water mangrove areas; (3) The ecological significance of benthic animals in the mangrove forest biotope; (4) Aquaculture in mangrove estuary areas; and (5) General Discussion on collaborative work on ecosystem research in brackish water mangrove areas.

This international workshop was held in the final year of the JIRCAS comprehensive project mentioned above, for which two rivers in Matang (the Selinsing and Sangga), one river each in Merbok (the Merbok) and in Lumut (the Dinding) were selected as the research sites in Malaysia. The characteristic differences between the three mangrove areas are that the ratios of mangrove forest area to river area are 4.7 in Matang, 2.1 in Merbok and 1.1 in Lumut. During this workshop, a wide range of results were reported, including the following: (1) the brackish water area of the River Selinsing in Matang was found to be important as a breeding ground for penaeid shrimp, (2) the freshwater areas of the River Sangga in Matang act as a feeding site for *Arridae* spp., (3) areas of the River Merbok are feeding sites for *Scianidae* spp. and (4) the freshwater areas of the River Dinding in Lumut act as a migration site for marine fish species, including *Leiognathidae* spp. The range of species and the ecological features of prawns and benthic animals were also elucidated in the three mangrove areas. Concerning the diversity of fish, in the Matang mangrove estuary area, the volume of fish catches was greater than that in the Merbok and Lumut ones. The diversity index of fish, however, showed a higher value in the Merbok than in the other two mangrove areas. In the Lumut area, the volume of fish catches and diversity index were the lowest of the three areas.

Socio-economic studies in these mangrove areas have additionally revealed that in well-managed areas, such as the Matang Mangrove Forest Reserve, mangrove forests generate significant social and economic advantages. On the other hand, inappropriate management of mangrove areas causes socio-economic losses due to the exhaustion of available resources.

(Masachika Maeda)

JIRCAS International Workshop

Brackish Water Mangrove Ecosystems -Productivity and Sustainable Utilization-

Feb. 29 ~ Mar. 1, 2000
International Congress Center
"Epochal Tsukuba"

Organized by

Japan International Research Center for Agricultural Sciences

Supported by

Agriculture, Forestry and Fisheries Research Council
Fisheries Agency, Forestry Agency, Japan
Fisheries Research Institute, Forest Research Institute
University of Malaya, Malaysia
Research Institute for Coastal Fisheries, Indonesia
Kasetsart University, Thailand
Kantho University, Vietnam
Southeast Asian Fisheries Development Center

JIRCAS International Symposium

The 7th JIRCAS International Symposium on "Agricultural Technology Research for Sustainable Development in Developing Regions" will be held on November 1-2 at Epochal-Tsukuba in conjunction with the 30th anniversary of TARC-JIRCAS. This is an opportune time to re-assess the progress of agricultural development in developing countries and to re-examine the roles and contributions of the different actors involved in development, from farmers to national research and extension organizations, non-governmental organizations, the private sector, as well as government and international research institutes including JIRCAS.

For further information, please contact:

Dr. M. Yajima

People

Dr. Masa IWANAGA, a plant geneticist, became Director of JIRCAS's Biological Resources Division on April 1, succeeding Dr. Tsuguhiro Hoshino who was appointed Director of the Department of Crop Physiology and Quality, National Agriculture Research Center. Dr. Iwanaga worked as Deputy Director General (Programmes) at the International Plant Genetic Resources Institute (IPGRI), Rome, Italy, for more than seven years. Before IPGRI, he worked for CIAT and CIP for three and ten years, respectively. Dr. Iwanaga holds a MS degree from Kyoto University and Ph. D. from the University of Wisconsin-Madison.

Dr. Osamu ITO, a plant physiologist, became Director of JIRCAS's Environmental Resources Division on April 1, succeeding Dr. Tadao Hamasaki who became Director of the Department of Natural Resources, National Institute of Agro-Environmental Sciences. Dr. Ito worked as International Research Coordinator for Thailand at JIRCAS's Research Information Division for six months after spending three years at the International Rice Research Institute as Director of the Agronomy, Plant Physiology and Agro-Ecology Division.

Dr. Makie KOKUBUN left JIRCAS on April 1, to take up his appointment as Professor of the Graduate School of Agriculture, Tohoku University. Dr. Kokubun served as International Research Coordinator for South America at JIRCAS's Research Information Division for four years.

Development of Agroforestry Technology for the Rehabilitation of Tropical Forests

- JIRCAS New Agroforestry Project -

Terunobu Suzuki
Director, Forestry Division, JIRCAS

With excessive logging and indiscriminate cutting of trees for fuel as well as with the increasing exploitation of arable land associated with the high demand for food, the deterioration and clearing of natural forest areas have been rapidly progressing, particularly in developing regions. This is bringing about serious economic and environmental problems not only at the local level but also on a global scale. Therefore, the rehabilitation and sustainable management of these forests are urgent issues. Development of forest production systems and postharvest technologies for local communities can be considered to be essential means for the reduction of forest degradation.

Forest rehabilitation and enrichment of denuded and degraded areas are the first steps in developing sustainable management of forest areas. JIRCAS has played a significant role in alleviating forest degradation by focusing its efforts on methods of reforestation and ways to motivate local inhabitants to participate in reforestation activities.

Research on methods for the establishment of fast-growing species as shelter wood for the promotion of growth of valuable indigenous trees such as Dipterocarps in logged-over tropical forests is being conducted in collaboration with the researchers of the College of Forestry, University of the Philippines at Los Banos (Philippines). Studies on the regeneration and growth of *Shorea* species seedlings on logging roads in Malaysia are conducted in collaboration with the researchers of the Forest Institute of Malaysia (FRIM), where joint investigations on the improvement of logging techniques for the selective management system applied in Malaysia, including the improvement of harvesting methods using a mobile tower yarder, are also in progress.

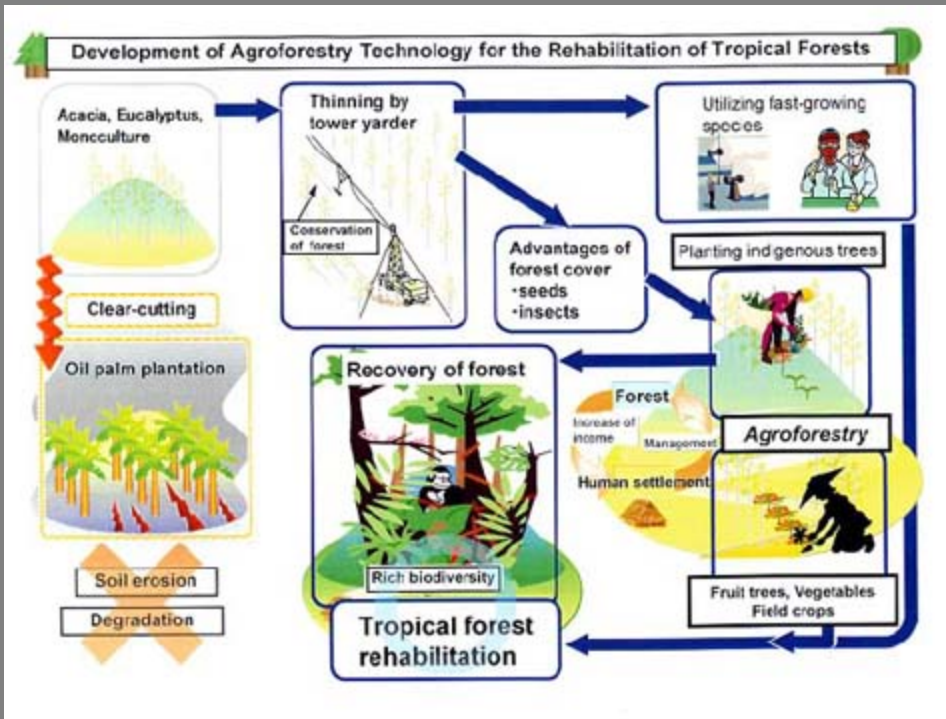

Malaysia is one example of several countries with which JIRCAS has been working closely on deforestation issues. In Malaysia, forests are logged on a large scale and the enrichment of remaining secondary forests is a major task for the government. Compared to other Southeast Asian nations, Malaysia's standard of living is higher and its forest management programs have been more effectively carried out, particularly in the state of Sabah. Nevertheless, in Sabah alone, several hundred thousand local inhabitants, over 10% of the state's population, still practice shifting cultivation. Their activities, which include unsustainable forest harvesting, slash and burn agriculture, repeated cultivation and wildfires have had a considerable impact on the forest ecosystems and resulted in losses of flora and fauna, erosion, flooding, decrease of forest resources and general soil degradation.

However, this situation may be improved by introducing agroforestry systems which encourage people to settle in a certain residential area, cultivate cash crops and participate in intercropping, afforestation and reforestation activities. Along with initiating the development of cultivation and farming technology, local authorities and scientists have been engaged in the assessment and analysis of social and economic factors in order to develop sustainable management systems for forest resources. In the 1970s, for example, agroforestry was first introduced to Sabah with a certain amount of success through the intercropping of cacao. On the whole, however, agroforestry techniques are essentially site-specific and for any given program to be successful, acceptance by the local community is indispensable. Given these conditions, we therefore proposed a more flexible research project titled: "Development of agroforestry technology for the rehabilitation of tropical forests." This program which will be implemented mainly in collaboration with the Forest Research Centre, Forestry Department, Sabah, Malaysia, aims at balancing out the effects of secondary forests, burnt forests, monoculture plantations and grasslands by introducing a cropping system consisting of cash crops including vegetables, fruit trees as well as indigenous trees. Our final objective is to establish a technological base for the ongoing development of biodiversity-rich forests, high-value timber forests, forests that perform critical environmental functions and fruit tree orchards where soil fertility has been improved or is well maintained. These studies will contribute to the mitigation of agriculture-forestry conflicts while promoting environmental conservation and sustainable forest resource management.

Over the seven-year (2000-2006) duration of the project, specific objectives will include a socio-economic evaluation of agroforestry, the re-establishment of a productive environment for agroforestry and the development of agroforestry techniques with the utilization of shade trees. Individual targets for the program include the development of technology for the re-establishment of a productive environment for agroforestry and development of techniques for growing non-arboreal crops under shade trees.

Finally, it is indispensable to promote close relations between forestry researchers and agriculture researchers in order to promote the project

and obtain good results.

Kenichi Kanda

Environmental Resources Division, JIRCAS

In Brazil, grasslands have been developed over large areas originally covered by savannas (Cerrados). However, problems of declining productivity have arisen in recent years because of the low soil fertility. Agro-pastoral systems that combine soybeans and grasses in rotation have been proposed for sustaining grassland productivity. One of the primary advantages of these systems is that lime and P fertilizer are used for crop cultivation and that the succeeding grasses can benefit from the remaining P. Since N is added to the system through the N₂ fixation of soybeans, the grasses grow well. On the other hand, the organic matter content of the soil decreases steadily under soybean cultivation. To evaluate the agro-pastoral systems in terms of N budget, N flow into the systems, N₂ fixation by soybean, input from rain, removal associated with harvest of soybean grains, gaseous losses from animal excreta and denitrification* as well as leaching were studied.

A long-term field experiment has been carried out at the National Beef Cattle Research Center (CNPGC), National Corporation of Agricultural Research (EMBRAPA), Campo Grande, MS, Brazil. The soil is classified as Purple Red Latosol. In a grassland with grazing beef cattle, NPK fertilizer (14 kg N/ha, 70 kg P₂O₅/ha and 70 kg K₂O/ha) was applied and *Brachiaria decumbens* cv. Basilisk was sown in November 1993. Soybeans were sown in November and harvested in April of the next year. PK fertilizer (80 kg P₂O₅/ha and 80 kg K₂O/ha) was applied at the time of seeding.

The rate of N₂ fixation of soybeans was determined using a non-nodulating isolate, T201, as a control. The rate ranged from 23 to 51% of the total plant N. Most of the plant N was removed after harvest of the grains, resulting in a negative N balance in the field. It was shown that the amount of N entering the system through rainwater was small. Nitrate accumulation from the surface to a depth of 100 cm in soil under soybeans indicated the potential leaching of nitrate (Fig. 1). The estimated amount of leaching from the soybean field was large compared with that from the grassland. A large negative N balance was observed in the soybean field, whereas there was a small negative N balance in the grassland (Fig. 2).

The nitrate that accumulated in the subsoil can be absorbed by grasses grown subsequently. Thus, rotational grassland may be more sustainable. On the other hand, both soybean field and grassland showed a negative N balance. It is concluded that in order to sustain N fertility in agro-pastoral systems, some application of N fertilizer may be necessary over time.

*Data relating to gaseous losses from animal excreta (ammonia volatilization and denitrification) were cited from Cadisch, G. *et al.*, Tropical Grasslands (1994), 28, 43-52.

Evaluation of Heat Tolerance of Snap Bean Based on Pollen Stainability

Katsumi Suzuki, Tadashi Tsukaguchi, Hiroyuki Takeda and Yoshinobu Egawa
Okinawa Subtropical Station, JIRCAS

Yield of temperate vegetables decreases at high temperatures in tropical and subtropical areas. Heat tolerance is one of the most important characters for the promotion and increase of vegetable production in these areas. It remained to be determined why heat-tolerant varieties show a superior yield under high temperature conditions. Simple methods of evaluation of heat tolerance are necessary for developing heat-tolerant varieties efficiently and introducing new crops suitable for high temperature conditions. JIRCAS Okinawa Subtropical Station is located on Ishigaki Island (lat. 24-20°N) under subtropical conditions in Japan. At this station, a heat-tolerant variety of snap bean (*Phaseolus vulgaris*), 'Haibushi', was developed from an accession collected in Southeast Asia by screening about 350 breeding lines and varieties. However, the mechanism controlling heat tolerance in 'Haibushi' compared with other varieties has not been elucidated. We investigated the pollen stainability of 'Haibushi' during cultivation in summer and compared it with that of other varieties under high temperature conditions.

The young pod yield, mean temperature and pollen stainability changed during the cultivation of snap bean as shown in Table 1. Mean air temperature during the harvest period of the first, second and third croppings was 25.7, 27.9 and 29.8, respectively. Young pod yield of all the varieties decreased when the mean temperature rose. As the mean air temperature during the flowering period in each cropping rose, pollen stainability decreased. In the first cropping, each variety showed a pollen stainability above 80%. While the pollen stainability of 'Okinawa Local' and 'Kentucky Wonder' decreased to 55 and to 65% in the second cropping, respectively, that of 'Haibushi' was still higher than 75%. In the third cropping, though the pollen stainability of the three cultivars decreased to less than 20%, that of 'Haibushi' was higher than 60%.

Fig. 1. Sterile pollen grains (a) of heat-sensitive variety 'Kentucky Wonder' (A) and normal pollen grains (b) of heat-tolerant variety 'Haibushi' (B) cultivated under high temperature conditions.

When the plants were exposed to a high temperature (32/28, day/night) for 24 hours and then returned back to optimum conditions (25/25) in a greenhouse, the pollen stainability of the flowers which opened 8 to 11 days after the treatment decreased. Pollen stainability thus decreased by exposure to high air temperature 8 to 11 days before flowering. Pollen stainability also decreased when the mean air temperature during this period exceeded 28 under field conditions. The heat-tolerant variety 'Haibushi', however, showed a higher pollen stainability than the heat-sensitive variety 'Kentucky Wonder' under high temperature conditions.

Reduction of young pod yield was ascribed to the decrease in pollen stainability, since a high correlation was observed between the pollen stainability and pod set. We concluded that the decrease of pollen stainability by high temperature led to a failure of fertilization and abscission of flowers, resulting in yield reduction in snap bean.

As mentioned above, yield reduction was accompanied by a lower pollen stainability. A heat-tolerant variety 'Haibushi' showed a high young pod yield and high pollen stainability under high temperature conditions. We suggest that examination of pollen stainability is one of the effective methods for evaluating heat tolerance.

Digestion Characteristics and Energy Requirements for Maintenance of Native Ruminants in Northeast Thailand

Tomoyuki Kawashima
National Institute of Animal Industry

Animal production in Northeast Thailand plays an important role in nutrient cycling for the development of sustainable agricultural systems. While exotic breeds have been introduced in the region to increase the production of meat and milk, the number of native ruminants, such as swamp buffalo and Thai native cattle, has been decreasing. Consequently, low quality roughages such as rice straw are not well utilized and some are burnt in the fields while the consumption of concentrate feed has been increasing. Although it is generally recognized that native ruminants have an inherent ability to digest low quality diet better than exotic breeds, the mode of digestion and nutrient requirements of native breeds developed in the tropics have not yet been fully elucidated.

Metabolism trials were conducted in sheep, Brahman cattle, swamp buffalo and Thai native cattle given Ruzi grass hay with different levels of soybean meal in order to examine the effect of protein levels on fiber digestion. The quality of hay used in each trial was slightly different and the crude protein (CP) contents in four dietary treatments ranged from about 3, 6.5, 10 and 13.5%. The outline of the results is shown in Fig. 1. In sheep, fiber digestibility was improved by the supplementation of soybean meal until the dietary CP content reached 10%. Beyond this level, the positive effect of supplements was not observed. In Brahman cattle, the fiber digestibility without protein supplements was lower than that with supplements (CP 6.5%). But there was no improvement by additional protein supplements to a level above 6.5%. On the other hand, in swamp buffalo and Thai native cattle, fiber digestibility without supplements was not different from that with supplements. And the fiber digestibility in Thai native cattle was generally higher than in the other animals. It was considered, therefore, that these native ruminants, especially Thai native cattle, have a superior ability to digest fiber without protein supplements.

Fig. 1. Changes in crude fiber digestibility depending on the supplementation of soybean meal.

A total of 44, 27 and 20 metabolism-trial data, in Brahman cattle, swamp buffalo and Thai native cattle, respectively, were examined in order to compare metabolizable energy (ME) requirements for maintenance. The ME requirements for maintenance were obtained by regression analysis of energy retention against ME intake based on the metabolic body size. The values were 377, 334 and 245 KJ/BWkg^{0.75} in Brahman cattle, swamp buffalo and Thai native cattle, respectively, which corresponded to 86, 76 and 56% of the value of Japanese Black Cattle. These findings clearly showed that native ruminants, such as Thai native cattle and swamp buffalo, require less energy to maintain their body weight compared with high performance breeds.

The ability to efficiently utilize low quality roughage and the lower energy requirements in native ruminants enable them to survive under a severe feeding environment. It was considered that such animals have been selected for their characteristics by farmers, which led to the development of a breed or a group adapted to the local conditions. The soil in Northeast Thailand, where the largest population of these native ruminants can be found, is characterized by low organic matter and nutrient contents. Re-construction of a system utilizing native ruminants in order to exploit available low quality feed may contribute to the sustainable development of agriculture and animal production in Thailand.

Development of Sustainable Agricultural Systems in Northeast Thailand

- Toward the end of the project -

Osamu Ito

Director, Environmental Resources Division, JIRCAS

The northeastern part of Thailand is a region with an unfavorable production environment characterized by infertile sandy soils and a long dry season. About half of the total land area in the region used to be covered with tropical rainforest which drastically decreased to 14% by deforestation. Intensive upland farming that reduces soil fertility and expansion of the arid land area have further accelerated the deterioration of croplands. Under such unfavorable conditions, rice, cassava, sugarcane and legumes are cultivated as cash crops, but they bring an insufficient income to the farmers (family income being only 40% of the national average). Regional development through agricultural technology improvement has become the highest priority in the Northeast.

In order to further develop agriculture in the region, it is necessary to shift the agricultural systems from those that depend heavily on a few cash crops to more sustainable systems in which diverse cropping options are combined with more efficient utilization of local resources. The project titled: "Comprehensive studies on sustainable agricultural systems in Northeast Thailand" was initiated in 1995 for a seven-year period in order to promote the technological development of rice, upland crops, vegetables, livestock and the sericulture industry, as well as to develop sustainable agricultural systems combining various types of farming and animal husbandry. The project has been implemented in close collaboration with Thai partners, including researchers from the Department of Agriculture (DOA), Department of Livestock Development (DLD), Land Development Department (LDD), International Training Center for Agricultural Development (ITCAD) and Khon Kaen University (KKU).

The project is composed of five main themes (Table 1). Until half of the project period, much focus had been placed on rather fundamental aspects within each research theme. Some of the outputs from fundamental research (Table 1) are now being integrated to develop sustainable agricultural systems suitable for the biophysical and socio-economic environment in the region. Main targets in the latter half of the project are as follows: (1) development of a rainfed lowland rice production system with more profitable farming operations and (2) crop-livestock integration in upland cropping systems with year-round feed supply and more efficient nutrient cycling. Farm mechanization for rice production in the transition from transplanting to direct seeding and utilization of locally available organic materials to sustain the soil fertility in upland fields are the central issues toward the end of the project.

In future, it may become important to maximize the use of water resources through the establishment of irrigation facilities compatible with the local hydrogeological characteristics, in order to further enhance the sustainability of agriculture in the region along with improving the socio-economic conditions of the rural communities.

Table 1. Main research themes and activities/outputs of the project

Research themes	Activities/outputs
I. Evaluation and effective utilization of environmental and biological resources in the region	<ul style="list-style-type: none"> ûEffective recycling systems of organic materials were proposed through the analysis of nutrient cycling of organic and inorganic components in present farmlands. ûThe salt-affected area was characterized using GIS and remote sensing. ûFor the development of water resources, the construction of sub-surface dams was proposed based on hydrogeological studies. ûSugarcane and pineapple were found to fix atmospheric nitrogen, indicating future possibility to cultivate these crops by reduced N application.
II. Development of sustainable crop production systems	<ul style="list-style-type: none"> ûThe proper planting interval of leguminous trees for alley cropping was determined in order to develop an integrated system of trees and crops. ûThe agronomical factors for the introduction of direct seeding on dried paddy fields were thoroughly examined, particularly in relation to non-tillage operations and farm mechanization.
III. Improvement of feeding management using local feed resources	<ul style="list-style-type: none"> ûFor feed supply during the dry season, leguminous pasture, fodder trees and sugarcane were examined for their growth under limited moisture conditions. ûFor the nutritional characterization of grass pastures, their nutritive value and digestion physiology were analyzed. ûMetabolizable energy and protein requirements for the maintenance of local ruminants were clarified.

The northeast part of Thailand is the region with unfavorable production environment characterized by unfertile sandy soils an

IV. Development of postharvest technologies for local agricultural products	ûThe main flavor component of Khao Dawk Mali 105 was identified as 2-acetyl-1-pyrroline. The analytical method for its quantification was established. A technique to identify the rice variety using DNA was developed, which makes it possible to detect mixing of non-Khao Dawk Mali 105 varieties. ûHigh-quality silk could be obtained through the use of cocoons after crossbreeding of polyvoltine and bivoltine silkworm strains.
V. Economic evaluation of multiple cropping and livestock farming systems	ûThe economic and managerial evaluation of the current agricultural systems shows that (1) mechanization of rice production could improve farmer's income under certain conditions and (2) profitability of dairy farming is relatively high, but further technological improvement is still required.

Workshop on Weather-Based Information Systems for Risk Reduction in West African Cropping Systems

On July 18, 2000, JIRCAS held an introductory workshop to start a new three-year project titled: "Development of Risk-Reducing Technologies for West African Cereal-Based Cropping Systems Based on Advanced Weather Modeling." This project seeks to respond to the global call made recently by the CGIAR to apply advanced technology to address the need to reduce poverty among those parts of the developing world that have benefited least from previous agricultural research. The objective of this project is to provide farmers with information that will enable them to make better choices among crops, production practices, and land use based on the analysis of farmer behavior and crop performance in response to weather variability. By combining results of advanced weather analysis, crop response, and understanding of farmer behavior, the project seeks to establish the criteria for more accurate and productive production choices in the face of rainfall variability. Information technology will enable to gather information on land use and farmer behavior at precise locations in small areas, as well as to develop a system in which it can be shared visually with farmers in a participatory way.

Twenty scientists from seven institutes and organizations representing a diversity of disciplines participated in the workshop. The workshop was organized around six topic areas: West African agriculture; soil and crop conditions; weather analysis and water use; information processing; risk management; and linkages to research in related on-going projects. After opening remarks by T. Ishitani and K. Tsurumi, Division Directors, JIRCAS, the workshop started with the first topic area, with two presentations on West African agriculture. J. Caldwell, JIRCAS, presented slides and data on rainfed cereal production in Mali, and T. Sakurai, JIRCAS, presented slides and data on rice production in several West African countries. The second topic area included presentations by K. Okada, JIRCAS, on soil fertility and its improvement in West Africa, and H. Hasegawa, Tohoku National Agricultural Experiment Station, on quantitative modeling of crop growth parameters. In the third topic area, H. Kanno, Tohoku National Agricultural Experiment Station, provided an introduction to weather analysis used in the Tohoku region of Japan, and possibilities for application of analysis methods in West Africa. K. Ozawa, JIRCAS Okinawa Subtropical Station, followed with a presentation on water use-efficient technologies for semi-arid regions. This was followed by two presentations in the fourth topic area. K. Takezawa, Hokuriku National Agricultural Experiment Station, presented information on decision support systems using pattern recognition. T. Hayashi, JIRCAS, described new portable information loggers appropriate for land use surveys. Next, in the fifth topic area, T. Nanseki, National Agriculture Research Center, provided an introduction to risk modeling. T. Sakurai presented results of research on household budgets and risk in semi-arid West Africa. In the last topic area, S. Asanuma, JIRCAS, described the studies carried out within the framework of the anti-desertification project, and H. Takagi, JIRCAS, explained the research being conducted within the framework of the West Africa rice improvement project. The workshop closed with a general discussion on how to implement the project plan, with a focus on the linkages among the project components of farmer production decision-making criteria, weather modeling, and risk management.

7th JIRCAS International Symposium

"Agricultural Technology Research for Sustainable Development in Developing Regions"

Date: 1 and 2 November 2000

Venue: Epochal Tsukuba

At the dawn of the new millennium, the Japan International Research Center for Agricultural Sciences (JIRCAS, formerly TARC, Tropical Agriculture Research Center), celebrates its 30th anniversary. TARC was established in 1970, just as the Green Revolution was reaching its peak. The major impetus to the Green Revolution at that time was the need to address the chronic food shortages in developing countries, especially Southeast and South Asia. These efforts enabled most countries to become self-sufficient in basic foods.

Today, at the start of a new century, agricultural research faces many more challenges. Increased food production continues to be a high priority in the face of continued world population increase. This needs to be achieved through the development of production systems in better harmony with the environment. Technology development targeted towards environments with marginal soil and water resources, where still over half of the farmers of developing countries make a living from agriculture characterized by unstable production, is a critical need. Advances in research and application of biotechnology, information technology, and other new technologies are needed to help solve these problems. In addition to such discipline-based research, strengthening farmer participation and linkages with other stakeholders in research and extension is essential to achieve new production and resource management systems with high sustainability.

This symposium will address four themes, with the objective of assessing future directions for sustainable agricultural development in developing regions, drawing from the experience of all symposium participants, including public institutions, non-governmental organizations and the private sector in each country, and international research institutions, with a focus on JIRCAS:

1. Accomplishments, needs, and potential for technology development for increased production
2. Concepts and approaches for agro-ecological sustainability
3. Farmer-researcher-extension-private sector partnerships for technology development and dissemination
4. Past achievements and future orientation of JIRCAS and partners in the development of sustainable agriculture, forestry and fisheries

Program

Day 1

Keynote addresses

- (1) An assessment of technology development from the Green Revolution to today

Dr. William D. Dar, Director General, ICRISAT

- (2) Key characteristics of agricultural sustainability

Dr. Pedro A. Sanchez, Director General, ICRAF

- (3) Evolution and new directions using information systems for enhanced farmer partnership in NARS agricultural research

Dr. Stein W. Bie, Director General, ISNAR

Session 1 Technology development for increased production: accomplishments, needs, and potential

(1) Developing new crop varieties for stress and low-input conditions

Prof. Kazuyoshi Takeda, Okayama University

(2) Contribution of molecular biology to breeding and issues associated with its application in developing countries

Dr. Ronald P. Cantrell, Director General, IRRI

(3) Distribution and processing systems for stable supply of products from agriculture, forestry and fisheries

Dr. Greg Johnson, Program Manager, Postharvest Technology, ACIAR

Session 2 Concepts, needs, and approaches for agro-ecological sustainability

(1) Sustainable land management for crop production

Dr. Eric T. Craswell, Director General, IBSRAM

(2) Sustainable water management for crop production

Dr. S. A. Prathapar, Director, IWMI Pakistan

(3) Sustainable aquaculture production and fisheries management

Dr. Meryl J. Williams, Director General, ICLARM

Day 2

Session 3 Evolution of farmer-researcher-extension-private sector partnerships for technology development and dissemination

(1) Evolution of concepts and approaches of systems-oriented, farmer participatory agricultural research

Dr. John S. Caldwell, International Research Coordinator, JIRCAS

(2) Contributions of farmer knowledge to agricultural technology development

Prof. Harold J. McArthur, University of Hawaii

(3) Institutionalization of technology development

Prof. David W. Norman, Kansas State University

(4) Developing sustainable agricultural systems: case study examples, determinants, future approaches, and roles of different partners, as viewed from the cooperation agency

Mr. Nobuyuki Samejima, Managing Director, JICA

(5) Developing sustainable agricultural systems: case study examples, determinants, future approaches, and roles of different partners, as viewed from the national agricultural research system

Dr. Ananta Dalodom, Director General, DOA, Thailand

Poster session

Session 4 Discussion and Synthesis of Symposium Themes: Past achievements and future orientation of JIRCAS and partners in the development of sustainable agriculture, forestry and fisheries

(1) Research output and future direction of JIRCAS

Dr. Takasuke Ishitani, Director, Research Planning and Coordination Division, JIRCAS

(2) Questions, comments, and discussion

(3) Synthesis and conclusions

For Sustainable Livestock Production in Farming Systems

Toshiaki Taniguchi

Director, Animal Production and Grassland Division, JIRCAS

The Animal Production and Grassland Division is currently implementing research projects on 1) Improvement of livestock production using locally available feed resources in Northeast Thailand in collaboration with Khon Kaen Animal Nutrition Center, Thailand, 2) Improvement of swine production in farming systems in the Mekong Delta in collaboration with Cantho University, Vietnam, and 3) Development of grassland management technologies for sustainable agro-pastoral systems in the subtropical zone of Brazil in collaboration with Empresa Brasileira de Pesquisa Agropecuaria (EMBRAPA), Brazil.

Two of the three projects mentioned above are focused on sustainable development of small-scale farming systems in Southeast Asia. The latter is focused on a sustainable crop and forage rotation system in large-scale livestock and crop production systems in South America. Livestock production remains at low levels throughout the developing world due to constraints such as low genetic potential, poor quality feeds, disease prevalence, harsh climatic conditions, and low management level. In Southeast Asia, the number of native animals, such as swamp buffalo, native cattle and swine (Photo) has been decreasing along with the introduction of exotic breeds for increasing the production of meat and/or milk. However, the introduction of exotic breeds may be frequently faced with low productivity due to malnutrition in the dry season, inadequate feeding management and endemic diseases. On the other hand, livestock play an important role in matter cycling in farming systems, namely the wastes from cattle and swine are used as fertilizer for the cultivation of crops, fruits and vegetables and as fuel in Northeast Thailand and the Mekong Delta. Therefore, removal of constraints in developing areas and maximization of the advantages of livestock are important for increasing the sustainability of livestock production in farming systems and animal industry in these areas.

Another aspect is to consider the efficient utilization of available native animals raised in various areas, because the native ruminants have a superior ability to digest fiber without protein supplements and require less energy to maintain their body weight compared with high performance breeds, as mentioned by Dr. T. Kawashima in a previous Newsletter (No. 24, Sept. 2000). Therefore, the development of a system utilizing native ruminants in order to exploit available low quality feed should contribute to

sustainable development of animal husbandry in these areas.

The next problem is how to obtain feed quality all the year round. Production of natural grasses and pastures decreases remarkably in the dry season in tropical areas. This is a key constraint on further development of livestock production. In the Mekong Delta, local by-products such as rice bran and meal leavings are used as swine feed. Local by-products such as rice straw and sugarcane stalks are used as good roughages for cattle feeding in the dry season in Northeast Thailand. Especially, wild relatives of sugarcane, such as *Saccharum spontaneum* and *Erianthus* spp. and inter-specific crosses between sugarcane varieties could be used as forage crops due to the high biomass production with a lower sugar content and attenuated leafy character in the near future under the collaborative research project between Khon Kaen Field Crops Research Center and JIRCAS. Use of available local feed resources is needed for developing a feeding system which is compatible with the local socio-economic and environmental conditions.

In the Brazilian savannas, decreasing grain yields have recently been observed in the region, as a result of continuous mono-cropping. In conventional mono-cropping systems, the intensive use of disk plows has resulted in the rapid loss of organic matter in most soils. Therefore, agro-pastoral systems (sustainable crop-pasture rotation) are considered to be an effective method of ensuring adequate physical, chemical, and biological soil conditions. It was demonstrated that the introduction of *B. brizantha* into agro-pastoral systems was the optimum solution to improve the quantity and depth distribution of soil organic matter due to the high biomass production of roots. Development of agro-pastoral systems compatible with individual farming systems may contribute to sustainable production of crops and livestock.

Maize stalks and leaves after harvest of maize cobs are also used as roughage for beef and dairy cattle. However, the nutrient level of maize stover is not always sufficient for animal feeding. Therefore, attempts were made to utilize agricultural commodities based mainly on maize and its residues for animal feed as silage in collaboration with the China Agricultural University and Jilin Academy of Agricultural Sciences.

It is also necessary to pay attention to the quality of the feed, including feed safety as roughage for livestock feeding, because, roughage contaminated with pathogens could become a source of infectious diseases and toxicosis in domestic animals.

The value of local feed resources and native animals should be more emphasized for future development of animal husbandry compatible with environmental and socio-economic characteristics in the respective regions.

Comprehensive Project in China Faces Mid-Term Evaluation

Osamu Koyama

Research Planning and Coordination Division, JIRCAS

Three years have already passed, since the new comprehensive collaborative research project conducted in China and titled "Development of sustainable production and utilization of major food resources" started in 1997. In the project, attempts were made to integrate several research activities, which had been separately carried out with Chinese research institutes engaged in different scientific fields, and aimed at solving the food problems in China from comprehensive viewpoints. The research project which was undertaken after the signature of a Memorandum of Understanding by both parties consists of the following five components.

1. Socio-economic research component, including research on food policies, impact of new technologies and regional food balance.
2. Environmental research component, including studies on material cycling and farming systems aimed at environmental conservation.
3. Rice research component, including studies on indigenous genetic resources, new breeding materials and insect pest management.
4. Soybean and maize research component, including studies on genetic resources in Northeast China and utilization of maize residues.
5. Food processing and distribution research component, including studies on starch and protein food from plants and freshwater fish meat.

Meeting at Beijing, China

For each component, detailed research subjects were drafted, and counterpart institutes were assigned, including ten institutes such as five research institutes under the Chinese Academy of Agricultural Sciences, China Agricultural University, and Shanghai Fishery University. From the Japanese side too, many research institutes affiliated to the Ministry of Agriculture, Forestry and Fisheries participated in the project in addition to JIRCAS. The project places emphasis on activities in Japan through the invitation of Chinese researchers, in addition to the conventional collaborative work conducted in China by the Japanese researchers dispatched. During FY 1999 (ended in March 2000), 35 researchers including 6 researchers on long-term assignments were sent to China, and 20 Chinese researchers including 11 research managers were invited to Japan.

The results of the studies have been reported gradually and increasingly, particularly in areas where the research activities had started without any constraint. For example, the socio-economic analysis based on field surveys, the study on soil nutrition balance focused on nitrogen dynamics, and the studies on processing technologies using materials from fresh-water fish, rice and soybeans for such food products as fish meat surimi, rice noodles, tofu, etc. are highly appreciated also in China. Many workshops have been held both in China and Japan for the dissemination of the results and exchanges of views among the wide range of researchers. General audience was also invited to some workshops.

However, the priorities of the project are changing rapidly. Recently China has enjoyed continuous high yields and excess stock has been reported for some commodities such as low-quality cereals. National research institutes are trying to define the future orientation of their activities within the context of economic and organizational reforms. The gap appears between what we expected at the planning stage of the project and what we are currently facing regarding the research organization and the recognition of the problems. On the other hand, however, various attempts are being made to develop sustainable production technologies based on the increasing awareness about environmental degradation, and the need for practical research such as food processing and distribution technologies is rapidly increasing in China. At the end of the fiscal year 2000, halfway in the course of the whole project, mid-term evaluation will be made and the above issues will be discussed.

In addition, cooperation between the project and a new program of technology transfer sponsored by Japan International Cooperation Agency (JICA) is being pursued. It is essential that both projects be effectively conducted through joint ownership of the results, joint utilization of the facilities and exchanges of views among researchers, when grant-aid is allocated and technical cooperation programs in agricultural research are implemented. JIRCAS is participating in the planning of these programs through the exchange of experience and expertise.

An Osmosensor as a Molecular Tool for the Genetic Improvement of Drought-Tolerant Crops

Takeshi Urao and Kazuko Yamaguchi-Shinozaki
Biological Resources Division, JIRCAS

As the world population rapidly increases, we are now faced with the need to increase and stabilize food production. In marginal or arid lands in developing countries, environmental factors such as drought, high salinity, high temperature, and flooding are serious problems that lead to instability of crop production. To address these problems, development of stress-tolerant plants had so far been conducted by transfer of a gene encoding protective proteins or enzymes involved in stress tolerance from various organisms. However, past efforts yielded limited success due to the genetic complexity of stress responses and adaptation. This indicated that the introduction of a large number of genes into a plant is necessary to confer fully improved stress tolerance. To overcome this limitation, our approach currently being studied is to manipulate a regulatory gene that controls the amounts and timing of numerous effector molecules described above. Under drought conditions, a change in cellular osmotic pressure caused by water loss triggers various intracellular responses, including activation of signal transduction pathways followed by gene expression of osmoprotectants. The first step in this event is the perception of osmotic changes by a sensor or receptor protein(s) at the plasma membrane. Therefore, we aimed at developing an osmosensor as a regulatory gene.

Based on an analogy in bacteria and yeast, histidine kinase(s) was expected to function as an osmosensor in plants, leading us to clone a cDNA encoding a histidine kinase ATHK1 from *Arabidopsis*. RFLP mapping showed that the ATHK1 gene is located on chromosome 2. The ATHK1 mRNA was more abundant in roots than in other tissues and accumulated under high salinity and low temperature conditions. Histochemical analysis of GUS activities driven by the ATHK1 promoter further indicated that the ATHK1 gene is transcriptionally up-regulated in response to changes in external osmolarity. These results suggest that ATHK1 is necessary for efficient sensing of environmental signals such as high salinity and drought stresses. ATHK1 contains two hydrophobic transmembrane regions adjacent to a putative extracellular domain in the N-terminal half, suggesting the presence of a functional similarity to the yeast osmosensor SLN1. Overexpression of the ATHK1 cDNA suppressed the lethality of a yeast *sln1* mutant. By contrast, the substitution of either putative phosphorylation site, His or Asp, failed to complement the *sln1* mutant, indicating that ATHK1 acts as a histidine kinase and that ATHK1 is in an active form in the absence of external signals (e.g. high osmolarity). Moreover, the introduction of the ATHK1 cDNA into a yeast mutant lacking both osmosensors, SLN1 and SHO1, allowed normal growth and activation of the HOG1 MAPK cascade under the high osmolarity conditions, suggesting that the ATHK1 activity changed from the active state to the inactive state in response to increases in external osmolarity. Thus, we demonstrated, by analyzing both sensing (input) and catalytic (output) activities of ATHK1 *in vivo* using the yeast osmosensing-defective mutants, that ATHK1 is able to sense and transduce a signal of external osmolarity to the downstream targets. This is the first evidence that a plant histidine kinase acts as an osmosensor. The ATHK1 gene could be one of useful molecular tools or biological resources for the genetic improvement of drought-tolerant crops. We are currently generating

transgenic *Arabidopsis* and rice plants to examine the ability to improve stress tolerance.

Possible function of an osmosensor in intracellular signaling under drought conditions

Changes in Soymilk Properties after Two-Stage Ohmic Heating

Eizo Tatsumi and Liu Zhishong*²*

**Crop Production and Postharvest Technology Division, JIRCAS, *²China Agricultural University, China*

Thermal processing is a traditional method in the food processing industry. Currently, most of the thermal processing techniques employ indirect heating by thermal conduction and thermal convection. However, these techniques limit the processing of the food material by several-stage heating because of the difficulty in controlling the temperature in a short time. For instance, the external part of a food material needs to be held at a processing temperature for several minutes before the center of the material reaches the required temperature; at that time the rest of the food will have been significantly overprocessed. An alternative technique is direct heating, in which heat is generated within the food material itself. Ohmic heating, which uses the inherent electrical resistance of a material to generate heat, is a relatively new process in food engineering, and has already attracted the attention of some companies. It is important to mention that both the outer and inner parts of a food material can reach a required temperature in a short time.

Soymilk is used to make tofu, which is one of the most popular foods in the world. Usually, soymilk is heated at more than 95°C for several minutes before the addition of a coagulant to make tofu. Almost all the tofu factories and researchers have paid attention to the temperature and time by using one-stage heating because of the technical limitation in the traditional heating procedure. Soymilk was heated under several conditions using a simple ohmic heating system. The rate of increase of the temperature was 40°C/min. Fig. 1 shows that heated soymilk by the standard method (at 95°C for 5 min) had essentially the same viscosity as raw soymilk. However, the viscosity of soymilk heated by the two-stage procedure (at 75°C for 15 min, and then at 95°C for 5 min) was 6 times higher.

Fig. 1. Viscosity of soymilk after ohmic heating under different conditions.

During the heat treatment, proteins in soymilk are transformed into a partially denatured conformation. Under the denatured state, some non-covalent bonds of protein molecules are destroyed and hydrophobicity in the surface area of the molecules increases. In consequence, protein molecules are dissociated and/or associated. We found that many small particles were produced in soymilk after two-stage heating. These observations suggest that the degree of aggregation in protein molecules was quite different between different heating conditions. The denaturation temperatures for 7S and 11S globulin, which are major protein components in soybean milk, are around 75°C and around 85°C, respectively. The dissociation/association of 7S and 11S globulin occurred at the same time under one-stage heating. In the case of two-stage heating, 7S globulin sub-units were dissociated/associated selectively at the first heating stage. During the second stage, 7S sub-units and/or newly dissociated 11S sub-units were associated cooperatively. Consequently, large aggregated molecules, which affected the increase in the viscosity, were produced in heated soymilk.

Partially denatured states of several food proteins are closely related to their functionality, including gelling and emulsifying properties. The tofu gel properties under the different heating conditions were evaluated in terms of consistency, elasticity, and water loss (Fig. 2). We found that the tofu prepared from two-stage heated soymilk was firmer and more elastic although the first step temperature and

heating time were slightly lower than those obtained from viscosity analysis. The tofu displayed a lower water loss. That is, moderately associated protein molecules enabled tofu to form a tight gel after the addition of a coagulant.

Ohmic heating in high temperature short time processing has been developed to produce high quality sterile food. From the above observations, we concluded that, unlike traditional thermal processing techniques, several-stage ohmic heating enables us to obtain a more suitable texture for a food material, which contains multiple lipids, carbohydrates, and proteins.

Studies on Treatment System for Wastewater from Prawn Aquaculture Pond Using Natural Purification Ability of Mangrove Stand

Toru Shimoda and Taufic Ahmad*²*

**Fisheries Division, JIRCAS, ²Research Institute for Coastal Fisheries, Indonesia*

In the Southeast Asian countries including Indonesia, prawn aquaculture is actively carried out to acquire foreign currency. Coastal areas, including areas of mangrove forest, have been destroyed to develop aquaculture ponds for this purpose. Moreover, wastewater containing large quantities of nutrient materials is discharged from the aquaculture ponds, causing environmental deterioration in coastal waters.

The present studies were conducted to analyze the effectiveness of improving the water quality of wastewater using mangrove stands and the mangrove ecological system prior to the discharge of wastewater into the environment.

The investigation site is shown in Fig. 1. Wastewater from the prawn aquaculture pond was introduced into a mangrove reforestation area. The mangrove stand consisted of saplings aged 0 to 2 years planted in a pond at intervals of 40 cm. Water that had passed through the mangrove pond was recirculated to the prawn aquaculture pond via an oyster pond and an seaweed pond. Thirty percent of the water in the prawn pond was exchanged once every 3 days. Water evaporation and seepage into the soil were compensated for by supplying river or well water depending on the degree of salinity. Investigations were conducted at the site once every 15 days. Water temperature, salinity, dissolved oxygen, pH, turbidity, and the concentrations of nutrients (ammonia, nitrate, nitrite, phosphate, and silicate) and chlorophyll *a* were measured.

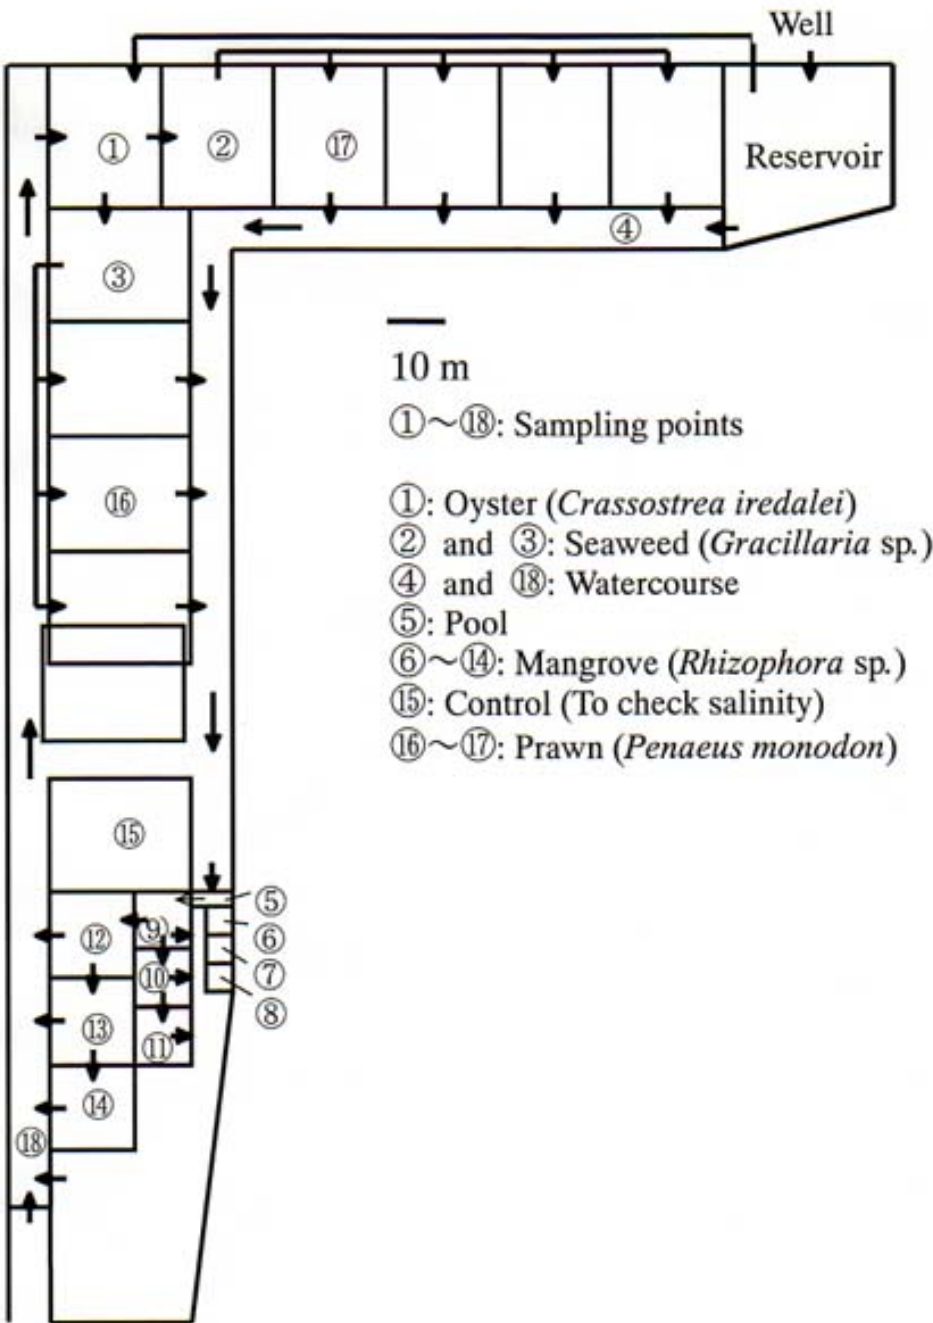

Fig. 1. Investigation site in Maranak, South Sulawesi, Indonesia.

The water temperature ranged from 25 to 30. Salinity exceeded 40(psu) in the dry season and fell below 30(psu) in the rainy season. From the beginning of the experiment, ammonia (NH_3) (Fig. 2) and nitrate (NO_3) concentrations were always high and increased in the oyster pond and the algae pond. The phosphate (PO_4) concentration was initially high because that of the supplied river water was high. Subsequently, it decreased once, then slightly increased in all the ponds. The silicate (SiO_2) concentration increased in the oyster pond, the seaweed pond, and the mangrove pond due to the well water supplied. In the prawn pond, on the other hand,

after increasing once, it decreased due to the increase in the population of diatoms, which have a silicious skeleton. Chlorophyll *a* (Fig. 2) concentration increased gradually in the prawn pond, and exceeded 160 μ g/l at the end of the experiment.

Fig. 2. Changes in ammonia and Chl. *a* concentration in mangrove, oyster seaweed and shrimp aquaculture ponds.

In this experiment, the pond in which wastewater was most effectively disposed of was the oyster pond. Since the oysters fed on phytoplankton while excreting ammonia, the phytoplankton concentration was very low after 30 days while the ammonia concentration was high. Therefore, the amount of phytoplankton, an organic material, markedly decreased. The ammonia and phosphate concentrations in the seaweed pond adjacent to the oyster pond were lower than those in the oyster pond, indicating that the algae took up nutrients. The ammonia concentration in the mangrove pond was always higher than that in the prawn pond and continued to gradually increase. It is considered that the amounts of nutrients generated from the feed and excreta were greater than those taken up by the mangrove stand, presumably because the area of the mangrove pond was too small compared with that of the aquaculture pond. We will attempt to obtain an afforestation area that corresponds to the area of the aquaculture pond by analyzing the material balance in the mangrove stand and the amount of nutrients taken up per unit area of the mangrove stand.

JIRCAS 7th International Symposium

On November 1-2, 2000, JIRCAS held its 7th International Symposium, with 300 participants. To mark the 30th anniversary of JIRCAS and its predecessor, the Tropical Agriculture Research Center (TARC), and to define the future direction of the activities of JIRCAS and its partners in the new century, a broad theme was selected, "*Agricultural Technology Research for Sustainable Development in Developing Regions.*"

Session 2: Nov. 1

**Opening address:
Dr. Maeno, Director General, JIRCAS**

The symposium addressed this overall theme in five parts. There were three keynote addresses. Dr. Dar, ICRISAT, reviewed the accomplishments of agricultural technology research from the Green Revolution until today, and presented needs and directions for the future including applications of biotechnology and information technology. Dr. Sanchez, ICRAF, centered his presentation on the key characteristics of agricultural sustainability in the tropics, emphasizing the need to adopt a new approach to find solutions to low productivity and poverty in marginal areas. Dr. Bie, ISNAR, suggested that information technology could contribute to the design of agricultural programs more directly relevant to the needs of farmers. This was followed by three sessions focused on specific areas of research. Session I assessed the development of crop varieties with tolerance to stress and low-input conditions (Prof. Takeda, Okayama Univ.), contributions of molecular biology (Dr. Cantrell, IRRI) and the importance of postharvest technology, with emphasis placed on distribution and processing systems (Dr. Johnson, ACIAR). Session II examined agro-ecological sustainability, considering land (Dr. Craswell, IBSRAM) and water management (Dr. Prathapar, IWMI) for crop production, as well as fisheries management and aquaculture production (Dr. Williams, ICLARM). Session III considered partnerships for technology development, including farmer participatory research (Dr. Caldwell, JIRCAS), contributions of farmer knowledge (Prof. McArthur, Univ. of Hawaii) and changes in institutional structures (Prof. Norman, Kansas State Univ.). The strategy adopted by the Japan International Cooperation Agency (JICA) for the transfer of technology (Mr. Samejima) and the policies of national agricultural research systems (Dr. Fagi, Indonesia; Dr. Carrao-Panizzi, Brazil) were also presented. In the closing session, Dr. Maeno, Director General of JIRCAS, reviewed JIRCAS' contributions to date and offered four research strategies for the coming years: strategic basic research, comprehensive research, postharvest technology research, and strengthening of the collaborative approach. A large part of the general discussion that followed was devoted to the potential contributions and limitations of farmer participation in research. Comments on other topics included the importance of 1) developing human resources, 2) emphasizing the content of information in the field of information technology, 3) emphasizing value-adding in postharvest technology and 4) the importance of animals in agriculture. As for the future orientation of JIRCAS activities, several suggestions were made including: the need to 1) strike a balance between strategic basic research and adaptive research and 2) control of preharvest losses in addition to postharvest losses. It was also suggested that since farmer participation in research is being promoted in many international research centers, JIRCAS could benefit from the experience gained by these organizations for the implementation of some of its programs, while building on its strength in basic strategic and comprehensive research. (John S. Caldwell)

Topic

Mr. Motai, Chairman of AFFRC and Mr. Tsuchiya, Director of International Research Division of AFFRC Visited China

Mr. Shigeru Motai, Chairman of the Agriculture, Forestry and Fisheries Research Council, AFFRC, Ministry of Agriculture, Forestry and Fisheries, MAFF, Mr. Tadashi Tsuchiya, Director of the International Research Division, AFFRC/MAFF and Mr. Kazuyuki Tsurumi, Director of the Research Information Division of JIRCAS visited China in September 2000. Their main purpose was to hold discussions with key persons who are concerned with the collaborative research project titled: "Development of sustainable production and utilization of major food resources," on the research direction in the second half of the project, and to visit the research laboratories and fields.

In Beijing, they had the opportunity of meeting with Mr. Liu Jian, Vice-Minister, Ministry of Agriculture, People's Republic of China and Mr. Tang Zhengping, Director General, Department of International Cooperation, Ministry of Agriculture. They also met with Dr. Wang Hongyi, Vice-President of the Chinese Academy of Agricultural Sciences and they exchanged views on the research results so far obtained and future activities relating to the collaborative research project. At the China Agricultural University, they attended the opening ceremony of the Japan-China Food Research Center. Mr. Motai gave an address for the celebration and cut the ribbon to open the center together with Dr. Li Lite, Vice President of China Agricultural University, Dr. Liu Xing Xin, Vice-President of the China Food Oil Society, and Mr. Tsuchiya. About hundred people, including members of the Ministry of Agriculture, Ministry of Education, food oil societies and oil industry associations in Beijing, attended the ceremony. Dr. Li Lite is convinced that this new center will enable to promote research activities in food processing, one of the key sectors in agriculture in China presently.

Cutting the ribbon during the opening ceremony for Japan-China Food Research Center

(from left, Dr. Liu, Dr. Li, Mr. Motai and Mr. Tsuchiya)

In Jilin, they visited the Jilin Academy of Agricultural Sciences (JAAS) and discussed with Dr. Feng Wei, President of JAAS and Dr. Liu Kai, Director of Soybean Institute of JAAS, various aspects relating to the soybean research activities. The JAAS members explained that they had developed a soybean variety with high fat and protein contents which is now being disseminated in Jilin.

In ZheJiang, they visited the China National Rice Research Institute (CNRRI) and held discussions with Dr. Cai Hong-Fa, Director General of CNRRI and Dr. Zhang Zhi Tao, Vice-Director General of CNRRI on the rice situation in China. CNRRI explained that rice double-cropping cultivation has been decreasing mainly due to the low quality of the first crop and that hybrid varieties account for half of the planted area in China. In Shanghai, they visited Shanghai Fisheries University (SFU) and discussed with Dr. Zhou Ying Qi, President of SFU, and Dr. Hung Shuolin, Vice-President of SFU various aspects relating to fish research activities, particularly the processing sector.

On these occasions, they visited farmers in Jilin and ZheJiang, and noticed that agricultural activities had changed during the last decade. In Jilin, cultivated commodities have been diversified from maize to vegetables and fruits, such as strawberry, watermelon and grape, which are more profitable. In ZheJiang, some farmers have entrusted other farmers with tilling and harvesting activities, particularly in the rural areas where employment opportunities are available in other industries than agriculture. *(Kazuyuki Tsurumi)*

People

Mr. Akira Mizushima became Director of JIRCAS's Administration Division on September 1, 2000. He was until recently Director of Computer Division of Tsukuba Office, Agriculture, Forestry and Fisheries Research Council Secretariat of MAFF.

Animal Production in Developing Regions: Importance of the Conservation of Genetic Resources

Mitsugu Shimizu

Director, Animal Production and Grassland Division, JIRCAS

Farm animals contribute to more than 30% of agricultural products and supply food rich in protein, hide, fiber, fertilizer for crops, and draught power. In the developing regions, animal production may enable smallholders to upgrade their living conditions through the improvement of their diet and health conditions and the increase of farm household income, alleviation of poverty, and diversification of resources to reduce risks. In addition, animal production is an important component of sustainable agricultural systems in these areas, because animals can use agricultural by-products and residues as feed resources, animal excreta and wastes can be utilized as a source of household energy and fertilizer for crops, while draught power is used for plowing land and for transportation. However, animal productivity is reduced by many constraints in developing regions. The major factors involved in the low animal productivity are the deficiency in feed in terms of quantity and quality and low nutrition level, inappropriate management practices, and the depletion of grassland resources, which result in poor growth of the animals. The other serious problem is related to animal health. Farm animals in developing regions, especially in tropical and subtropical countries are often reared in unsanitary and stressful environments, and are frequently exposed to various pathogens, including viruses, bacteria, and parasites and to harsh climatic conditions that cause considerable damage to the animals. Economic losses of animal production due to sanitary problems in the developing regions have been estimated at more than 40% of total production.

Therefore, the Animal Production and Grassland Division (APGD), Japan International Research Center for Agricultural Sciences (JIRCAS), has promoted collaborative research with various countries, placing emphasis on securing feed resources by either identifying new feedstuffs or utilizing agricultural by-products and residues along with the improvement of grassland and animal management, and implementation of measures for disease control. For instance, oil-palm fronds and sugarcane stalks have been successfully used as ruminant feeds through collaborative research with Malaysian and Thai scientists, respectively, and the project entitled "Development of Agro-pastoral Systems in the Subtropical Area of Brazil" is being carried out to develop a sustainable technology for grass production in Brazil. APGD, JIRCAS intends to continue these research activities in order to achieve a sustainable increase of animal production compatible with the preservation of natural resources and environmental conditions in the respective regions.

To increase livestock production in developing regions, research on genetic characterization and conservation of indigenous breeds of farm animals, and their effective utilization for animal raising is important. In the past 12,000 years, human beings developed about 4,500 breeds of domestic animals from approximately 40 animal species, and most countries, depending on the geographic and climatic conditions, have their own unique animal breeds with various traits. Only a few breeds of important domestic animals have been successfully developed to improve some traits in relation to production in developed regions, mostly in northern countries. These breeds consume nutritious feeds and live in favorable environments. As a result, they produce more meat, milk, eggs, etc, when they are fed with sufficient quantities of high quality feeds, and reared under well controlled environments. However, they may not be adapted to the conditions prevailing in the developing regions where animals are usually reared with poor quality feeds, and always exposed to harsh climatic conditions, various pathogens, diseases, insect bites, and other environmental stresses. On the other hand, many indigenous breeds that are well adapted to the harsh conditions of the respective regions are distributed in the developing regions. Although these locally adapted breeds harbor valuable traits for adaptation to harsh climatic conditions, low quality feeds and various diseases, many of them are now becoming endangered species. These indigenous breeds appear to be valuable, and essential for further enhancement of sustainable animal production that does not depend upon high inputs and skillful management in the developing regions. The genetic characterization of indigenous breeds, and the conservation and utilization of useful genetic resources, particularly genes controlling heat and drought tolerance, adaptability to low quality feeds, disease resistance, and so on, should be promoted to improve animal production in the developing regions.

Although JIRCAS is not currently involved in such activities, in future, research along these lines should be considered.

Suppression of Nitrification in Soil by a Tropical Grass

Takayuki Ishikawa

Environmental Resources Division, JIRCAS

Nitrogen in fertilizers and organic components is transformed into ammonium-N in soil by microorganisms. In the nitrification process, ammonium-N is converted into nitrite-N by ammonium-oxidizing bacteria and nitrite-N is converted into nitrate-N by nitrite-oxidizing bacteria. Since plants can absorb only ammonium-N and nitrate-N, nitrification markedly influences the nitrogen absorption efficiency by plants. Nitrate-N that is not absorbed by plants easily leaches down from the rhizosphere to the deeper layers of soil and pollutes the underground water. During the process of nitrification, nitrous oxide, one of the greenhouse gases, is emitted from the soil to the atmosphere. By controlling nitrification, it is possible not only to increase the nitrogen absorption efficiency by plants but also to minimize the nitrogen loss by leaching and volatilization. In order to decrease the nitrogen loss, chemical fertilizers with nitrification inhibitors have been developed but their application is very limited in developing countries because of their high cost. If plants could inhibit the nitrification process, their nitrogen absorption efficiency would be considerably enhanced. It was reported that the amount of nitrate-N accumulated in the soil where a tropical grass grew seemed to be smaller than that in the soil where other tropical grasses grew. The objective of this study was to demonstrate the ability of this tropical grass to suppress nitrification and to identify the relation between nitrification suppression and nitrous oxide emission to the atmosphere.

Three tropical grasses (*Brachiaria decumbens* (Bd), *B. humidicola* (Bh), *Melinis minutiflora* (Mm)) supplied by CIAT were grown for 6 weeks in Wagner pots and soils were sampled. Ammonium-N was applied to the sampled soils and the nitrification process was observed. In soils with Bd and Mm, the content of ammonium-N decreased 4 days after ammonium-N application and nitrification started rapidly (Fig. 1). However, the content of ammonium-N in the soil with Bh did not change until the 8th day and there was a lag period before the onset of nitrification. The results indicate that only *B. humidicola* suppressed nitrification in soil.

[Fig. 1. Content of ammonium-N in soil](#)

In order to study the effect of nitrification suppression on nitrous oxide emission, Bd, Bh and Mm were grown for 4 weeks in Wagner pots and ammonium-N was applied to the soil. From soils without plants (No Plants), and with Bd and Mm treatments, nitrous oxide was emitted at a rate of $3 \frac{1}{4}$ g-N/m²hr one day after ammonium application (Fig. 2). From the No Plants soil, nitrous oxide emission increased from the twelfth day. In the case of the Bd and Mm treatments, nitrous oxide emission continued for more than 4 days and then began to decrease because nitrogen in soils was absorbed by the plants. However, nitrous oxide emission from the soil with the Bh treatment was low throughout the experimental period. The amount of nitrous oxide emitted from the soil with the Bh treatment was 1/4 smaller than that from the Bd and Mm treatments.

[Fig. 2. Nitrous oxide emission from soil](#)

In another experiment, it appeared that *Brachiaria humidicola* suppressed the multiplication of ammonium-oxidizing bacteria specifically but had no effect on the nitrite-oxidizing bacteria. Of the two nitrification processes, it is assumed that the process in which ammonium-N is changed into nitrite-N is a rate-determining process. By the suppression of multiplication of ammonium-oxidizing bacteria, *Brachiaria humidicola* suppresses nitrification in soil and nitrous oxide emission to the atmosphere. Generally it is considered that tropical grasses preferentially use nitrate-N compared to ammonium-N. Among the *Brachiaria* species, it is assumed that only *B. humidicola* can utilize both forms of nitrate-N and ammonium-N and that this function of *B. humidicola* may lead to an efficient use of nitrogen in soil.

Native pastures are widely distributed in various countries of the tropical zone but their productivity is very low. In order to increase livestock production, if *Brachiaria humidicola* could be introduced, it would be possible to decrease the nitrogen input for agriculture in addition to preserving the environment and ecosystems.

Compound Resistance Mechanisms to the Whitebacked Planthopper in Chinese Japonica Rice Variety "Chenjiang 06"

Kazushige Sogawa

Crop Production and Postharvest Technology Division, JIRCAS

Rice agriculture in China is characterized by the wide adoption of high-yielding F1 hybrid rice. Since its introduction in 1976, the cultivation of hybrid rice has expanded rapidly and hybrid rice was planted to about half of the total rice area in China in the 1990s. The remarkable increase in rice production in the 1980s was largely dependent on hybrid rice. However, Chinese hybrid rice has caused a new pest problem, namely outbreaks of the whitebacked planthopper, *Sogatella furcifera*, because of its high susceptibility to the pest. Subsequent increase of insecticide applications has resulted in the development of resistance of insect pests to pesticides in paddy fields, and increased the risk of pest resurgence due to the destruction of natural enemies in the paddy ecosystem. Growing pest and pesticide problems in rice agriculture in China drew our attention to varietal resistance to insect pests in Chinese rice as an effective component of the ecologically based pest management (EBPM) system. In the course of the JIRCAS-CNRRRI Collaborative Research Project on EBPM for rice planthoppers in China, we demonstrated the mechanism of varietal resistance to *S. furcifera* in Chinese japonica rice "Chenjiang 06 (CJ-06)".

S. furcifera resistance of CJ-06 was investigated in comparison with that of a susceptible indica hybrid rice cultivar "Shanyou 63 (SY-63)." Field experiments revealed the high field resistance of CJ-06 to *S. furcifera*. The *S. furcifera* immigrants did not land and failed to establish populations on CJ-06. They preferred to settle on SY-63 on which they could well reproduce. Under a free choice condition, significantly fewer *S. furcifera* individuals alighted on CJ-06 than on SY-63. The significantly smaller amount of honeydew excreted by *S. furcifera* females on CJ-06 than on SY-63 indicated a low sucking activity on CJ-06. Both fecundity and egg hatchability were markedly reduced on CJ-06, when newly emerged *S. furcifera* females continuously fed and were allowed to oviposit on it. Consequently, the number of nymphs hatched on CJ-06 amounted to only about one-tenth of that on SY-63. *S. furcifera* eggs showed a high mortality in watery lesions at oviposition sites of CJ-06. The watery lesions rapidly led to the formation of conspicuous necrotic symptoms before the eggs hatched. The egg mortality in the watery lesions occurred within 1-2 days after oviposition (Fig. 1). Such watery lesions seldom occurred in SY-63, where the eggs hatched normally.

[Fig. 1. Embryonic development of *S. furcifera* eggs in resistant CJ-06 and susceptible SY-63.](#)

Based on the above findings, we concluded that sucking suppression and ovicidal reaction were critical factors for the *S. furcifera* resistance in CJ-06. These functions are associated with the antixenosis mechanism against *S. furcifera* immigrants, as well as the antibiosis mechanism whereby fecundity and egg hatchability of inhabitants are reduced, respectively. Such dual mechanisms of varietal resistance may result in a stable and durable field resistance to *S. furcifera* in Chinese japonica rice CJ-06 (Fig. 2). It would be important to identify the chemical components responsible for the sucking inhibition and ovicidal reaction associated with the resistance of CJ-06 to *S. furcifera*, compared to the susceptibility of SY-63 and to analyse the genetic basis of the resistance for subsequent breeding work.

[Fig. 2. Antixenotic and antibiotics resistance to *S. furcifera* in Chinese japonica rice, CJ-06.](#)

Analysis of Chitinolytic Enzyme Genes of a Mycoparasitic Bacterium *Flexibacter* sp. FL824A

Yasuo Ando

Animal Production and Grassland Division, JIRCAS

The purpose of this study is to develop disease control utilizing lytic microorganisms. We detected a lytic activity in a mycoparasite *Flexibacter* sp. FL824A toward several plant pathogenic fungi, consisting of the secretion of lytic enzymes, chitinolytic enzymes (chitinases and *N*-acetylglucosaminidases), β -1,3-glucanases and proteases. Chitinolytic enzymes are considered to play an important role in the mycoparasitic process, because chitin, poly- β -1,4-*N*-acetylglucosamine [(GlcNAc)_n], is a major structural component of cell walls of fungi. In the first step of our study, we analyzed the genes of chitinolytic enzymes from *Flexibacter* sp. FL824A.

A genomic library of *Flexibacter* sp. FL824A using pUC19 and *Escherichia coli* was constructed. Hydrolysis activity of the crude protein of the transformants was determined by using analogs of chitin derivatives, 4-methylumbelliferyl- β -D-*N*, *N'*-diacetylchitobioside [4-MU-(GlcNAc)₂] or 4-methylumbelliferyl- β -D-*N*,*N'*,*N''*-triacetylchitotriose [4-MU-(GlcNAc)₃] as substrates. Among 6,000 transformants tested, four clones showed a positive activity. They fell into two groups according to their specificity to the substrates (Table 1). We selected two clones CHF1149 and CHF1351, based on the activity level, specificity to the substrates, size of DNA-inserted fragment, and digestion pattern of the insert with restriction endonucleases.

Table 1. Enzymatic activity of positive clone using 4-MU-*N*-acetylchitooligoside as substrate

Clone	Enzymatic activity $\frac{1}{4}$ Unit/ml ¹⁾		Ratio of activity (dimer/trimer)
	dimer ²⁾	trimer	
Group A			
CHF2778	7.63	10.36	0.74
CHF2601	15.81	26.16	0.60
CHF1149	232.19	446.39	0.52
Group B			
CHF1351	768.50	40.33	19.06

1) 1Unit of enzymatic activity was defined as 1mmol of 4-MU/min at 37°C.
2) dimer, 4-MU-(GlcNAc)₂; trimer, 4-MU-(GlcNAc)₃.

An open reading frame (ORF) of 4236 bp was found to code for a chitinase with 1412 amino acids based on the nucleotide sequence and deduced amino acid sequencing of an 8.7-kbp insert of pCHF1149. Homology analysis of the deduced amino acid sequence of this protein revealed that the enzyme has a multiple domain structure consisting of at least seven domains (Fig. 1). The most interesting property is that the enzyme has two catalytic domains, one homologous to the catalytic domain of chitinase A1 of *Bacillus circulans* WL-12 on the N-terminal side of the protein and the other homologous to that of chitinase D of the same bacterium on the C-terminal side.

Fig. 1. Schematic representation of the domain structures of chitinases from several bacteria

The DNA sequence of 5.0 kbp of the DNA-inserted fragment of pCHF1351 was determined after subcloning. An open reading frame (ORF)

of 1962 bp was found to code for a putative protein with 654 amino acids. The protein shared a 25% homology with endo- β -*N*-acetylglucosaminidase of *Clostridium perfringens*.

Strong lytic activity of *Flexibacter* sp. FL824A may be due to the presence of a unique chitinase with two catalytic domains. Further studies on the chitinase should be carried out to analyse the chitin degradation of this mycoparasitic bacterium.

Seminar on "High Value Timber Species for Plantation Establishment - Teak and Mahogany Species -"

Disappearance of the natural forests has prompted the Southeast Asian nations to establish and develop artificial forest plantations. The trees selected for this purpose have been mostly fast-growing species for pulp and/or light use timber. Recently, however, in Malaysia, including Sabah State, there has been a growing interest in planting high value timber species with longer rotation periods. Not only the foresters, from either governmental organizations or the private sector, but also estate plantation holders and farmers are interested in planting teak (*Tectona grandis*) in their plantation or farm areas, and more recently some of them have also started to plant mahogany species (American mahogany, *Swietenia macrophylla*, and African mahogany, *Khaya ivorensis*). Malaysian experience with these species is, however, rather limited.

To fill this gap, JIRCAS, INNOPRISE (Sabah Foundation) and Sabah Forestry Department decided to jointly organize a "Seminar on High Value Timber Species for Plantation Establishment" with emphasis placed on teak and mahogany species. The seminar was held at the Auditorium of Sabah State Library, Tawau, Sabah on December 1, 1998. Following the opening addresses by Datuk Musa Haji Aman (Chief Executive of INNOPRISE), Dr. Kiyoshi Tanaka (Director of Forestry Division, JIRCAS) and Mr. Herman Anjin (Deputy Forestry Director of Sabah Forestry Department), Dato' Dr. Salleh Mohd. Nor (Executive Director of TROPBIO Research) gave a keynote address and 14 experts from five countries presented nine papers related to silviculture, propagation, protection, wood utilization and marketing in three sessions. More than 130 participants, including forestry scientists, foresters and many plantation holders from Sabah, Sarawak and Peninsular Malaysia, held animated discussions and exchanged information. More than 50 participants also joined a field trip to the Luasong Forestry Centre, about 100 km from Tawau to observe demonstration/experimental stands of teak and mahogany on the next day. This seminar was very timely and successfully promoted the establishment of plantations of teak and mahogany species in Malaysia, especially in Sabah.

4th Seminar on "Brackish Water Project" Held in Malaysia

On December 8-9, 1998, the 4th "Brackish Water Project" seminar was held in the Conference Room of the Hotel Equatorial Penang, in Penang Island, Malaysia. This project on "Productivity and Sustainable Utilization of Tropical and Subtropical Brackish Water Mangrove Ecosystems" aims to evaluate the productivity of the above areas and identify the criteria for sustainable utilization of resources. The West coast of peninsular Malaysia has been selected as the study area due to the presence of various types of mangrove forests differing in the level of management and exploitation. The counterpart organizations include the Fisheries Research Institute (FRI), the University of Malaya (UM) and the Forest Research Institute of Malaysia (FRIM).

Subjects addressed in the seminar were as follows:

1) Forest and litter fall, 2) Benthic communities, 3) Aquatic organisms, 4) Socio-economic aspects, 5) Environmental aspects. About 40 scientists and government officials from Japan, Malaysia, and Australia participated in the seminar, and fourteen papers were presented.

During the 4th seminar, Mr. Hashim Ahmad, Deputy Director General of the Department of Fisheries Malaysia gave an opening address, and Dr. Shiro Uno of JIRCAS presented closing remarks.

During the two days' seminar, it was concluded that the surveys conducted in 1997-1998 in the mangrove forest and waters had been completed. At that stage, it is necessary to analyse the structure of the mangrove ecosystems and to ensure that economic activities in these areas are sustainable.

Current Status of Collaborative Research Activities between IWMI and JIRCAS

The International Irrigation Management Institute (IIMI), one of the sixteen organizations supported by the CGIAR, was established by an Act of Parliament in Sri Lanka. The Act is currently under amendment to rename the Institute as International Water Management Institute (IWMI).

IWMI implements four global research programs to improve water resources and irrigation management as follows: 1) Performance and Impact Assessment, 2) Design and Operation of Irrigation Systems, 3) Policy, Institutions and Management, and 4) Health and Environment. Collaborative research activities between IWMI and JIRCAS cover the Design and Operation of Irrigation Systems Program.

Two studies are being carried out as follows: "Optimal Water Management under Water Deficit Conditions" and "Soil Salinity Problems."

The site for the "Optimal Water Management" study is located in the North-Central province of Sri Lanka. Irrigation water is used not only for agriculture but also for bathing, washing, as drinking water, etc. Although rainfall is usually abundant in this area, due to the lack of effective water management, the amount of water available for agriculture and daily life is sometimes insufficient. Many small tanks (ponds) are connected to one another (tank cascade system) in the area and they comprise the main water reservoirs. At first, it is necessary to analyse the water balance in these systems for identifying optimum cropping patterns based on traditional systems and more advanced technology in order to improve water management. As a result, crop productivity could be enhanced and maintained during the dry season, also. These practices could be adopted in other areas in Sri Lanka and in other countries.

Soil salinity is one of the most severe problems in arid and semiarid environments. Sometimes, it is caused by inadequate water management practices such as waterlogging, which is associated with excessive irrigation and which induces soil salinity. Soil salinity is a complex phenomenon which is region-specific. Productivity can be improved in the affected areas and it is important to determine the main causes of salinity so as to reduce it. The main factors can be determined by statistical methods, and one prediction model could be constructed with these parameters to predict the areas that may experience soil salinity.

"Soil slotting" is considered to be a useful technique to improve salinized (sodic) land. In this technique, some slots are cut and filled with soil and chemical substances or organic matter. It is important to analyse the soil-water and solute movement in this technique to identify suitable specifications (slot width, depth, space, etc.). These parameters can be simulated using a solute movement model under different water management conditions. Such a technology may enable to promote sustainable agriculture and raise the productivity of crops. The results could be applied to other salinized areas.

<The 6th JIRCAS International Symposium>

GIS Applications for Agro-environmental Issues in Developing Regions

The symposium on "GIS Applications for Agro-environmental Issues in Developing Regions" will be held in Tsukuba, Japan during the period of September 7 – 9, 1999.

The greatest challenge for mankind today is to develop agricultural systems that would enable to utilize biological and natural resources adequately to feed the global human population and preserve the resources simultaneously. To meet this objective, quantitative and temporal evaluation of the resources in a given environment is required. However, geographic information to be used for this purpose has been lacking in many developing regions, which has hindered the precise evaluation. Geographic Information Systems (GIS) are now expected to become an effective tool to produce various kinds of evaluation maps on the environment by overlaying multiple geographic data. These data include not only drawn map sheets and written statistics but also digital remote sensing data, which have been accumulated for a quarter of a century and should be effective for quantitative and temporal analyses of various agro-environmental issues, including deforestation, desertification, soil erosion and salinity, etc.

JIRCAS is actively implementing GIS-related research in collaboration with various countries in different geographic environments. This symposium offers a unique opportunity to review the studies carried out in this field by JIRCAS and other institutes, evaluate the current status of research and plan for the future. About 200 participants will attend the symposium and JIRCAS welcomes their active participation.

The symposium consists of two keynote speeches and three sessions as follows:

Keynote Speech: Application of GIS and remote sensing technology for agro-environmental issues in developing regions

Dr. Andrew K. Skidmore, ITC, Netherlands

Dr. Tsuyoshi Akiyama, Gifu University, Japan

Session 1	Development of global dataset and models for agro-environmental sciences Six presentations from representative institutes of USA and Japan
Session 2	Applications of GIS for agro-environmental issues in various developing regions Nine presentations covering different geographic environments (Nepal, Indonesia, China, Pakistan, Colombia, Thailand and Japan)
Session 3	Education and training in the field of GIS Presentations from AIT (Thailand), PUSDATA (Indonesia) and JIRCAS (Japan)

President of Tanzania Visited JIRCAS

The President of the United Republic of Tanzania, Benjamin William Mkapa visited Japan in December, 1998. It was the first visit by an African head of state since the Second Tokyo International Conference on African Development (ITCADA) held in Tokyo in October. Since gaining its independence, Tanzania has maintained close ties with Japan and Japan continues to extend technical and economic assistance for development in many areas such as agriculture, health, telecommunications and human resources development.

During his stay in Japan, President Mkapa visited JIRCAS on December 15. After the welcome-ceremony and the briefing of the center's activities by Dr. Nobuyoshi Maeno, Director General of JIRCAS, (Photo, left) President Mkapa (Photo, center) and his group observed the Biotechnology Laboratory where research on "Improving Plant Tolerance to Environmental Stress by Gene Transfer" is being carried out.

PEOPLE

Masachika MAEDA, a microbiologist (and protozoologist), became Director of the Fisheries Division on January 1, succeeding Dr. Shiro Uno who was transferred to the National Research Institute of Fisheries Sciences (NRIFS). Before joining JIRCAS, Dr. Maeda was Director, Physiology and Molecular Biology Section, NRIFS. Dr. Maeda was a visiting research fellow at the Royal Society and British Museum, England from 1980 to 1983.

Animal Production in Developing Regions: Importance of the Conservation of Genetic Resources

Mitsugu Shimizu

Director, Animal Production and Grassland Division, JIRCAS

Farm animals contribute to more than 30% of agricultural products and supply food rich in protein, hide, fiber, fertilizer for crops, and draught power. In the developing regions, animal production may enable smallholders to upgrade their living conditions through the improvement of their diet and health conditions and the increase of farm household income, alleviation of poverty, and diversification of resources to reduce risks. In addition, animal production is an important component of sustainable agricultural systems in these areas, because animals can use agricultural by-products and residues as feed resources, animal excreta and wastes can be utilized as a source of household energy and fertilizer for crops, while draught power is used for plowing land and for transportation. However, animal productivity is reduced by many constraints in developing regions. The major factors involved in the low animal productivity are the deficiency in feed in terms of quantity and quality and low nutrition level, inappropriate management practices, and the depletion of grassland resources, which result in poor growth of the animals. The other serious problem is related to animal health. Farm animals in developing regions, especially in tropical and subtropical countries are often reared in unsanitary and stressful environments, and are frequently exposed to various pathogens, including viruses, bacteria, and parasites and to harsh climatic conditions that cause considerable damage to the animals. Economic losses of animal production due to sanitary problems in the developing regions have been estimated at more than 40% of total production.

Therefore, the Animal Production and Grassland Division (APGD), Japan International Research Center for Agricultural Sciences (JIRCAS), has promoted collaborative research with various countries, placing emphasis on securing feed resources by either identifying new feedstuffs or utilizing agricultural by-products and residues along with the improvement of grassland and animal management, and implementation of measures for disease control. For instance, oil-palm fronds and sugarcane stalks have been successfully used as ruminant feeds through collaborative research with Malaysian and Thai scientists, respectively, and the project entitled “Development of Agro-pastoral Systems in the Subtropical Area of Brazil” is being carried out to develop a sustainable technology for grass production in Brazil. APGD, JIRCAS intends to con-

tinue these research activities in order to achieve a sustainable increase of animal production compatible with the preservation of natural resources and environmental conditions in the respective regions.

To increase livestock production in developing regions, research on genetic characterization and conservation of indigenous breeds of farm animals, and their effective utilization for animal raising is important. In the past 12,000 years, human beings developed about 4,500 breeds of domestic animals from approximately 40 animal species, and most countries, depending on the geographic and climatic conditions, have their own unique animal breeds with various traits. Only a few breeds of important domestic animals have been successfully developed to improve some traits in relation to production in developed regions, mostly in northern countries. These breeds consume nutritious feeds and live in favorable environments. As a result, they produce more meat, milk, eggs, etc, when they are fed with sufficient quantities of high quality feeds, and reared under well controlled environments. However, they may not be adapted to the conditions prevailing in the developing regions where animals are usually reared with poor quality feeds, and always exposed to harsh climatic conditions, various pathogens, diseases, insect bites, and other environmental stresses. On the other hand, many indigenous breeds that are well adapted to the harsh conditions of the respective regions are distributed in the developing regions. Although these locally adapted breeds harbor valuable traits for adaptation to harsh climatic conditions, low quality feeds and various diseases, many of them are now becoming endangered species. These indigenous breeds appear to be valuable, and essential for further enhancement of sustainable animal production that does not depend upon high inputs and skillful management in the developing regions. The genetic characterization of indigenous breeds, and the conservation and utilization of useful genetic resources, particularly genes controlling heat and drought tolerance, adaptability to low quality feeds, disease resistance, and so on, should be promoted to improve animal production in the developing regions.

Although JIRCAS is not currently involved in such activities, in future, research along these lines should be considered.

Suppression of Nitrification in Soil by a Tropical Grass

Takayuki Ishikawa
Environmental Resources Division, JIRCAS

Nitrogen in fertilizers and organic components is transformed into ammonium-N in soil by microorganisms. In the nitrification process, ammonium-N is converted into nitrite-N by ammonium-oxidizing bacteria and nitrite-N is converted into nitrate-N by nitrite-oxidizing bacteria. Since plants can absorb only ammonium-N and nitrate-N, nitrification markedly influences the nitrogen absorption efficiency by plants. Nitrate-N that is not absorbed by plants easily leaches down from the rhizosphere to the deeper layers of soil and pollutes the underground water. During the process of nitrification, nitrous oxide, one of the greenhouse gases, is emitted from the soil to the atmosphere. By controlling nitrification, it is possible not only to increase the nitrogen absorption efficiency by plants but also to minimize the nitrogen loss by leaching and volatilization. In order to decrease the nitrogen loss, chemical fertilizers with nitrification inhibitors have been developed but their application is very limited in developing countries because of their high cost. If plants could inhibit the nitrification process, their nitrogen absorption efficiency would be considerably enhanced. It was reported that the amount of nitrate-N accumulated in the soil where a tropical grass grew seemed to be smaller than that in the soil where other tropical grasses grew. The objective of this study was to demonstrate the ability of this tropical grass to suppress nitrification and to identify the relation between nitrification suppression and nitrous oxide emission to the atmosphere.

Three tropical grasses (*Brachiaria decumbens* (Bd), *B. humidicola* (Bh), *Melinis minutiflora* (Mm)) supplied by CIAT were grown for 6 weeks in Wagner pots and soils were sampled. Ammonium-N was applied to the sampled soils and the nitrification process was observed. In soils with Bd and Mm, the content of ammonium-N decreased 4 days after ammonium-N application and nitrification started rapidly (Fig. 1). However, the content of ammonium-N in the soil with Bh did not change until the 8th day and there was a lag period before the onset of nitrification. The results indicate that only *B. humidicola* suppressed nitrifi-

cation in soil.

In order to study the effect of nitrification suppression on nitrous oxide emission, Bd, Bh and Mm were grown for 4 weeks in Wagner pots and ammonium-N was applied to the soil. From soils without plants (No Plants), and with Bd and Mm treatments, nitrous oxide was emitted at a rate of 3 μ g-N/m²hr one day after ammonium application (Fig. 2). From the No Plants soil, nitrous oxide emission increased from the twelfth day. In the case of the Bd and Mm treatments, nitrous oxide emission continued for more than 4 days and then began to decrease because nitrogen in soils was absorbed by the plants. However, nitrous oxide emission from the soil with the Bh treatment was low throughout the experimental period. The amount of nitrous oxide emitted from the soil with the Bh treatment was 1/4 smaller than that from the Bd and Mm treatments.

In another experiment, it appeared that *Brachiaria humidicola* suppressed the multiplication of ammonium-oxidizing bacteria specifically but had no effect on the nitrite-oxidizing bacteria. Of the two nitrification processes, it is assumed that the process in which ammonium-N is changed into nitrite-N is a rate-determining process. By the suppression of multiplication of ammonium-oxidizing bacteria, *Brachiaria humidicola* suppresses nitrification in soil and nitrous oxide emission to the atmosphere. Generally it is considered that tropical grasses preferentially use nitrate-N compared to ammonium-N. Among the *Brachiaria* species, it is assumed that only *B. humidicola* can utilize both forms of nitrate-N and ammonium-N and that this function of *B. humidicola* may lead to an efficient use of nitrogen in soil.

Native pastures are widely distributed in various countries of the tropical zone but their productivity is very low. In order to increase livestock production, if *Brachiaria humidicola* could be introduced, it would be possible to decrease the nitrogen input for agriculture in addition to preserving the environment and ecosystems.

Ammonium-N in soil was taken as 100% at 0 days.

Compound Resistance Mechanisms to the Whitebacked Planthopper in Chinese Japonica Rice Variety “Chenjiang 06”

Kazushige Sogawa

Crop Production and Postharvest Technology Division, JIRCAS

Rice agriculture in China is characterized by the wide adoption of high-yielding F1 hybrid rice. Since its introduction in 1976, the cultivation of hybrid rice has expanded rapidly and hybrid rice was planted to about half of the total rice area in China in the 1990s. The remarkable increase in rice production in the 1980s was largely dependent on hybrid rice. However, Chinese hybrid rice has caused a new pest problem, namely outbreaks of the whitebacked planthopper, *Sogatella furcifera*, because of its high susceptibility to the pest. Subsequent increase of insecticide applications has resulted in the development of resistance of insect pests to pesticides in paddy fields, and increased the risk of pest resurgence due to the destruction of natural enemies in the paddy ecosystem. Growing pest and pesticide problems in rice agriculture in China drew our attention to varietal resistance to insect pests in Chinese rice as an effective component of the ecologically based pest management (EBPM) system. In the course of the JIRCAS-CNRI Collaborative Research Project on EBPM for rice planthoppers in China, we demonstrated the mechanism of varietal resistance to *S. furcifera* in Chinese japonica rice “Chenjiang 06 (CJ-06)”.

S. furcifera resistance of CJ-06 was investigated in comparison with that of a susceptible indica hybrid rice cultivar “Shanyou 63 (SY-63.” Field experiments revealed the high field resistance of CJ-06 to *S. furcifera*. The *S. furcifera*

immigrants did not land and failed to establish populations on CJ-06. They preferred to settle on SY-63 on which they could well reproduce. Under a free choice condition, significantly fewer *S. furcifera* individuals alighted on CJ-06 than on SY-63. The significantly smaller amount of honeydew excreted by *S. furcifera* females on CJ-06 than on SY-63 indicated a low sucking activity on CJ-06. Both fecundity and egg hatchability were markedly reduced on CJ-06, when newly emerged *S. furcifera* females continuously fed and were allowed to oviposit on it. Consequently, the number of nymphs hatched on CJ-06 amounted to only about one-tenth of that on SY-63. *S. furcifera* eggs showed a high mortality in watery lesions at oviposition sites of CJ-06. The watery lesions rapidly led to the formation of conspicuous necrotic symptoms before the eggs hatched. The egg mortality in the watery lesions occurred within 1-2 days after oviposition (Fig. 1). Such watery lesions seldom occurred in SY-63, where the eggs hatched normally.

Based on the above findings, we concluded that sucking suppression and ovicidal reaction were critical factors for the *S. furcifera* resistance in CJ-06. These functions are associated with the antixenosis mechanism against *S. furcifera* immigrants, as well as the antibiotics mechanism whereby fecundity and egg hatchability of inhabitants are reduced, respectively. Such dual mechanisms of varietal resistance may result in a stable and durable field resistance to *S. furcifera* in Chinese japonica rice CJ-06 (Fig. 2). It would be important to identify the chemical components responsible for the sucking inhibition and ovicidal reaction associated with the resistance of CJ-06 to *S. furcifera*, compared to the susceptibility of SY-63 and to analyse the genetic basis of the resistance for subsequent breeding work.

Analysis of Chitinolytic Enzyme Genes of a Mycoparasitic Bacterium *Flexibacter* sp. FL824A

Yasuo Ando

Animal Production and Grassland Division, JIRCAS

The purpose of this study is to develop disease control utilizing lytic microorganisms. We detected a lytic activity in a mycoparasite *Flexibacter* sp. FL824A toward several plant pathogenic fungi, consisting of the secretion of lytic enzymes, chitinolytic enzymes (chitinases and *N*-acetylglucosaminidases), α -1,3-glucanases and proteases. Chitinolytic enzymes are considered to play an important role in the mycoparasitic process, because chitin, poly- α -1,4-*N*-acetylglucosamine [(GlcNAc)_n] is a major structural component of cell walls of fungi. In the first step of our study, we analyzed the genes of chitinolytic enzymes from *Flexibacter* sp. FL824A.

A genomic library of *Flexibacter* sp. FL824A using pUC19 and *Escherichia coli* was constructed. Hydrolysis activity of the crude protein of the transformants was determined by using analogs of chitin derivatives, 4-methylumbelliferyl- α -D-*N*, *N'*-diacetylchitobioside [4-MU-(GlcNAc)₂] or 4-methylumbelliferyl- α -D-*N*,*N'*,*N''*-tri-

acetylchitotriose [4-MU-(GlcNAc)₃] as substrates. Among 6,000 transformants tested, four clones showed a positive activity. They fell into two groups according to their specificity to the substrates (Table 1). We selected two clones CHF1149 and CHF1351, based on the activity level, specificity to the substrates, size of DNA-inserted fragment, and digestion pattern of the insert with restriction endonucleases.

An open reading frame (ORF) of 4236 bp was found to code for a chitinase with 1412 amino acids based on the nucleotide sequence and deduced amino acid sequencing of an 8.7-kbp insert of pCHF1149. Homology analysis of the deduced amino acid sequence of this protein revealed that the enzyme has a multiple domain structure consisting of at least seven domains (Fig. 1). The most interesting property is that the enzyme has two catalytic domains, one homologous to the catalytic domain of chitinase A1 of *Bacillus circulans* WL-12 on the N-terminal side of the protein and the other homologous to that of chitinase D of the same bacterium on the C-terminal side.

The DNA sequence of 5.0 kbp of the DNA-inserted fragment of pCHF1351 was determined after subcloning. An open reading frame (ORF) of 1962 bp was found to code for a putative protein with 654 amino acids. The protein shared a 25% homology with endo- α -*N*-acetylglucosaminidase of *Clostridium perfringens*.

Strong lytic activity of *Flexibacter* sp. FL824A may be due to the presence of a unique chitinase with two catalytic domains. Further studies on the chitinase should be carried out to analyse the chitin degradation of this mycoparasitic bacterium.

Table 1. Enzymatic activity of positive clone using 4-MU-*N*-acetylchitooligoside as substrate

Clone	Enzymatic activity (μUnit/ml) ¹⁾		Ratio of activity (dimer/trimer)
	dimer ²⁾	trimer	
Group A

which induces soil salinity. Soil salinity is a complex phenomenon which is region-specific. Productivity can be improved in the affected areas and it is important to determine the main causes of salinity so as to reduce it. The main factors can be determined by statistical methods, and one prediction model could be constructed with these parameters to predict the areas that may experience soil salinity.

"Soil slotting" is considered to be a useful technique to improve salinized (sodic) land. In this technique, some slots are cut and filled with soil and chemical substances or organic matter. It is important to analyse the soil-water and solute movement in this technique to identify suitable specifications (slot width, depth, space, etc.). These parameters can be simulated using a solute movement model under different water management conditions. Such a technology may enable to promote sustainable agriculture and raise the productivity of crops. The results could be applied to other salinized areas.

(Yoshiyuki Shinogi)

JIRCAS Symposium

The 6th JIRCAS International Symposium GIS Applications for Agro-environmental Issues in Developing Regions

The symposium on "GIS Applications for Agro-environmental Issues in Developing Regions" will be held in Tsukuba, Japan during the period of September 7 – 9, 1999.

The greatest challenge for mankind today is to develop agricultural systems that would enable to utilize biological and natural resources adequately to feed the global human population and preserve the resources simultaneously. To meet this objective, quantitative and temporal evaluation of the resources in a given environment is required. However, geographic information to be used for this purpose has been

lacking in many developing regions, which has hindered the precise evaluation. Geographic Information Systems (GIS) are now expected to become an effective tool to produce various kinds of evaluation maps on the environment by overlaying multiple geographic data. These data include not only drawn map sheets and written statistics but also digital remote sensing data, which have been accumulated for a quarter of a century and should be effective for quantitative and temporal analyses of various agro-environmental issues, including deforestation, desertification, soil

erosion and salinity, etc.

JIRCAS is actively implementing GIS-related research in collaboration with various countries in different geographic environments. This symposium offers a unique opportunity to review the studies carried out in this field by JIRCAS and other institutes, evaluate the current status of research and plan for the future. About 200 participants will attend the symposium and JIRCAS welcomes their active participation.

The symposium consists of two keynote speeches and three sessions as follows:

Keynote Speech: Application of GIS and remote sensing technology for agro-environmental issues in developing regions

Dr. Andrew K. Skidmore, ITC, Netherlands

Dr. Tsuyoshi Akiyama, Gifu University, Japan

Session 1: Development of global dataset and models for agro-environmental sciences

Six presentations from representative institutes of USA and Japan

Session 2: Applications of GIS for agro-environmental issues in various developing regions

Nine presentations covering different geographic environments (Nepal, Indonesia, China, Pakistan, Colombia, Thailand and Japan)

Session 3: Education and training in the field of GIS

Presentations from AIT (Thailand), PUSDATA (Indonesia) and JIRCAS (Japan)

Visitor

President of Tanzania Visited JIRCAS

The President of the United Republic of Tanzania, Benjamin William Mkapa visited Japan in December, 1998. It was the first visit by an African head of state since the Second Tokyo International Conference on African Development (ITCAD II) held in Tokyo in October. Since gaining its independence, Tanzania has maintained close ties with Japan and Japan continues to extend technical and economic assistance for development in many areas such as agriculture, health, telecommunications and human resources development.

During his stay in Japan, President Mkapa visited JIRCAS on December 15. After the welcome-ceremony and the briefing of the center's activities by Dr. Nobuyoshi Maeno, Director General of JIRCAS, (Photo, left) President Mkapa (Photo, center) and his group observed the Biotechnology Laboratory where research on "Improving Plant Tolerance to Environmental Stress by Gene Transfer" is being carried out.

PEOPLE

Masachika MAEDA, a microbiologist (and protozoologist), became Director of the Fisheries Division on January 1, succeeding Dr. Shiro Uno who was transferred to the National Research Institute of Fisheries Sciences (NRIFS). Before joining JIRCAS, Dr. Maeda was Director, Physiology and Molecular Biology Section, NRIFS. Dr. Maeda was a visiting research fellow at the Royal Society and British Museum, England from 1980 to 1983.

Contribution of Biological Resources Research to the Stabilization and Increase of Production of Main Crops

Tsuguhiro Hoshino

Director, Biological Resources Division, JIRCAS

1. Background and importance of biological resources research

Human beings had succeeded in producing enough food by using natural resources hitherto. However, due to the rapid growth of the population, many developing regions in the world are now faced with the need to utilize land with major constraints on crop cultivation as well as to increase and stabilize agricultural production through methods compatible with the preservation of the environment. Agricultural technologies that optimize the use of biological resources will play an important role in determining whether these objectives can be achieved. In response to these concerns, the Biological Resources Division is placing considerable emphasis on collaborative on-site breeding research in foreign countries and on biotechnology in Tsukuba.

2. Current activities

JIRCAS is currently engaged in collaborative projects with 3 international centers supported by the CGIAR. At the International Maize and Wheat Improvement Center (CIMMYT) in Mexico, doubled haploid breeding method has been applied for enhancing breeding efficiency. This is because the artificial production of haploid plants followed by chromosome doubling is the quickest method for developing homozygous breeding lines from heterozygous parental genotypes in a single generation. Different sources of resistance genes to fusarium head blight are being mapped using RFLP and SSR markers. In cooperation with the International Rice Research Institute (IRRI) in the Philippines, studies on rice blast resistance have enabled to identify rice blast resistance genes in IR varieties (see related article on page 7). The collaborative research on interspecific hybridization between the African and Asian rice species (*Oryza glaberrima* and *O. sativa*) has been initiated at the West Africa Rice Development Association (WARDA). Studies on the genetic and eco-physiological characterization of the interspecific progenies are being carried out with emphasis placed on tolerance to drought and acid soil conditions in West Africa.

In China, breeding research projects have started for the evaluation of genetic resources and development of novel breeding materials of rice and soybean. Through the projects, elite germplasm will be selected from the abundant indigenous germplasm for the development of disease and insect pest resistance. In soybean production in tropical and subtropical areas, one of the major problems is the damage caused by insects, especially *Spodoptera litura* Fabricius. Since highly resistant germplasm to *S. litura* has not been identified yet, soybean lines with a higher resistance will be obtained through back-crossing by pyramiding of moderate resistance genes. Moreover, breeding research for improving nutrient quality and disease resistance was initiated in Brazil. New rice and soybean cultivars with superior characteristics will be developed by the utilization of indigenous genetic resources.

Basic research for the application of advanced technology is being promoted in Tsukuba to support overseas research activities and to develop new technologies for the future. Molecular biotechnological methods have been recently utilized to study the tolerance to environmental stresses such as drought, salinity and freezing in higher plants. In particular, the researchers are determining how to use genes and regulatory factors for the production of transgenic crops tolerant to environmental stresses. A number of genes involved in stress tolerance were isolated using *Arabidopsis thaliana* and cowpea plants, and regulatory factors for the expression of these genes were analyzed for stress response. Many genes for transcription factors, controlling the expression of the stress tolerance genes, have been also isolated. Regulatory elements in promoters were identified that control stress-responsive gene expression. Using the genes for transcription factors and the stress-responsive promoters, multi-stress tolerance to freezing, drought and salinity was improved in transgenic *Arabidopsis* as a model. The existence of similar regulatory systems has been reported in other crop plants such as rice, tobacco and cowpea.

Such studies may lead to the development of commercial crops capable of withstanding potentially damaging environmental stresses, thereby contributing to mitigating problems relating to the food crisis and environmental degradation in developing countries.

3. Orientation of activities in the future

In developing countries, cooperation for biological resources research should be further promoted through consortia and networks with advanced research units worldwide. Therefore, JIRCAS plans to strengthen its activities in close collaboration with CGIAR centers for the evaluation of genetic resources and breeding methodologies. Through the use of genetic resources and application of biotechnological procedures, collaborative breeding projects should be implemented in various countries in order to develop new varieties of rice, soybean and wheat characterized by high yield potential and resistance to various diseases and environmental stresses. These new varieties should contribute to the increase and stabilization of agricultural production with lower inputs in the developing countries.

Detection of Bruchid-Resistant Strains in Wild Adzuki Bean Germplasm

Yoshinobu Egawa, Katsuyuki Kohno, Keiichi Takahashi, Norihiko Tomooka*,
Somsong Chotechuen*², Ithnin Bujang*³ and Yoichi Tateishi*⁴

Okinawa Subtropical Station, JIRCAS, *National Institute of Agrobiological Resources, *²Chai Nat Field Crops Research Center, Thailand,
*³Universiti Malaysia Sabah, Malaysia, *⁴University of the Ryukyus

Adzuki bean, *Vigna angularis* var. *angularis* (2n=22, 2x) considered to have originated in East Asia is one of the most familiar legumes for Japanese people. This bean is cultivated for the preparation of various forms of foods including "anko" (sweet bean jelly), "seki-han" (steamed rice with red adzuki bean), etc. Adzuki bean belongs to the subgenus *Ceratotropis* of the genus *Vigna*. This subgenus is divided into two groups morphologically and phylogenetically, adzuki bean group and mungbean group. It is known that several wild relatives (germplasm) belonging to the adzuki bean group occur in Asia. Wild germplasm should be considered to be primary and secondary gene pools for the breeding of cultigens. Wild germplasm, however, is now confronted with gradual extinction due to the disturbance of the natural habitat by recent widespread land clearance for the construction of roads and buildings. Against this background, we collected wild adzuki bean germplasm in Southeast Asian countries (**Photo 1**).

Photo: 1 Collection of wild adzuki bean germplasm in Peninsular Malaysia

Adzuki bean weevil (*Callosobruchus chinensis*) causes serious damage to adzuki bean, mungbean and cowpea seeds during storage (**Photo 2**). One accession of wild progenitor species of mungbean (*V. radiata* var. *sublobata*), TC1966, is known to exhibit a complete resistance against *C. chinensis*. However, since there is a reproductive isolation between adzuki bean and mungbean, it was impossible to incorporate the resistance from TC1966 to adzuki bean through conventional crossing procedures. Therefore, we examined the accessions of wild adzuki bean germplasm including *V. angularis* var. *nipponensis* (wild progenitor of adzuki bean), *V. nakashimae*, *V. nepalensis*, *V. minima* var. *minor*, *V. hirtella*, *V. umbellata* and *V. trinervia*, etc. to detect the occurrence of bruchid-resistant strains within them.

Photo 2: Infestation with adzuki bean weevil (*Callosobruchus chinensis*)

Based on feeding tests by adzuki bean weevil, *V. hirtella*, *V. umbellata* and *V. trinervia* exhibited a resistance against the infestation with *C. chinensis* although other species were highly susceptible. It was reported that the resistance exhibited by TC1966 was controlled by a single dominant gene. We plan to examine this aspect for these three wild species. *V. hirtella* is distributed in India (Assam, Bengal), Myanmar, Thailand, Indo-China, South China and Malaysia and the strains examined by us were collected in the northern part of Thailand under a JIRCAS project. Cross-compatibility of *V. hirtella* with adzuki bean was high and we have successfully obtained fertile F₁ hybrids between them (**Photo 3**). We are now backcrossing the F₁ hybrids with adzuki bean to develop bruchid-resistant lines with a combination of feeding test by adzuki bean weevil. Wild form of *V. umbellata* is distributed widely in northern Thailand and several accessions have been collected under the JIRCAS project. Hybridization between adzuki bean and *V. umbellata* was impossible. *V. minima* var. *minor* was, however, cross-compatible with both adzuki bean and *V. umbellata*, and could be used as a bridging species for gene flow between them. To develop

resistant lines of adzuki bean, we plan to transfer the resistance gene(s) of *V. umbellata* first to *V. minima* var. *minor* by backcrossing this species recurrently to the hybrid between *V. minima* var. *minor* x *V. umbellata*, and then incorporate the resistance to adzuki bean by crossing with *V. minima* var. *minor* (which has become resistant). Geographical distribution of *V. trinervia* ranges from Madagascar, through South India, Sri Lanka, Myanmar and Indonesia, to Papua New Guinea and we have successfully collected a large number of accessions from Peninsular Malaysia. Cross-compatibility of *V. trinervia* with adzuki bean has not yet been analyzed.

Photo 3: Hybrid plant between *V. hirtella* and adzuki bean, showing that the F₁ fertility is high

Generally, exploration and collection of wild germplasm are a time-consuming and difficult task, and there is little or no information available about potentially useful characteristics which it harbors. Considering the genetic erosion that occurs rapidly on a worldwide scale, it is important to collect wild *Ceratotropis* species from the areas covering their wide range of geographical distribution and evaluate and preserve them as genetic resources.

Surface Analysis of Starch Granules

*Tamao Hatta, Seiko Nemoto and Keiji Kainuma**

Environmental Resources Division, JIRCAS

**Bio-oriented Technology Research Advancement Institution (BRAIN)*

Surface-sensitive analytical techniques, AFM (Atomic Force Microscopy) and XPS (referred to as either X-ray Photoelectron Spectroscopy or ESCA: Electron Spectroscopy for Chemical Analysis) have been developed in many fields. With AFM, imaging of nearly any surface can be achieved by atomic force under vacuum, air and solution conditions and surfaces can be observed during reactions. XPS is used for the characterization of electron structure, chemical binding state, and alteration process of the area near surface (less than 5 nm in thickness) of solid. A large number of recent studies on the mechanisms of rock weathering, mineral dissolution, soil genesis and desertification have been reported using AFM (SPI3800+SPA300, Seiko Instruments Inc.) and High-Resolution XPS (ESCA300, Gammadata-Scienta AB) in our laboratory. Recently, AFM and XPS have been applied to a wide variety of materials.

The results of application of AFM and XPS for the characterization of the surface structure of starch granules is presented in this paper. Data on AFM imaging and detailed XPS spectra of starch had not been reported hitherto. The detailed structure of the starch surface observed by AFM is shown in **Fig.1a**. This is the first time that the rough surface structure of a potato starch granule was studied by AFM. We observed a cavity, presumably hilum, less than 1 μm in diameter. After embedding potato starch in paraffin, sample specimens were prepared by cutting with a microtome and the linear structure of the inner part of the granule was observed at the molecular level(**Fig.1b**).

[•@Fig. 1. AFM images of a potato starch.](#)

[\(a\) A granule of potato starch. 10 \$\mu\text{m}\$.](#)

[\(b\) Inner part of potato starch granule. 80 nm.](#)

Considering the electron shell in relation to the molecular structure, we analysed the electronic state of the starch granule using XPS as chemical structural probe. The narrow spectra of $C1s$ orbital of potato starch and waxy corn starch were measured compared with those of several saccharides (**Fig. 2**). The $C1s$ photopeak of starch is characterized by the presence of a chemical shift with a small peak at the low binding energy site. To examine this peak, the amorphous precipitate was prepared by gelatinization of native crystalline starch. The peak at the low energy site disappeared in the $C1s$ spectrum of the amorphous product as anticipated. Consequently, it was revealed that the specific photopeak of starch corresponds to the three-dimensional structure of the crystal in reference to the double helix structure of starch. Investigations of the atomic structure and binding state of crystals of starch and saccharides using AFM and XPS have just been initiated.

Assessing Nitrogen Pollution in Chinese Agriculture

Kazuyuki Yagi

Environmental Resources Division, JIRCAS

China is the largest producer, as well as the largest consumer, of food in the world. The introduction of new technologies and reform policies has substantially improved food supply conditions to meet the large demand for grain in this country. On the other hand, adverse effects of modern intensive agriculture on the environment have recently become apparent and the sustainability of land resources and environment has become a cause for concern. Environmental problems due to intensive agriculture, such as land degradation, shortage of irrigation water, and pollution of air and water, have become serious in various parts of China. Many of these problems have resulted from the use of agricultural land in a manner that overloads nutrients, in particular nitrogen. Indeed, consumption of nitrogen fertilizer in China has increased by about 60% during the last decade and accounted for 23.6 M ton nitrogen in 1995. Chinese agriculture must now address serious issues: How large is the environmental impact of intensive cropping systems? How is the impact changing? What will happen in future? How can we mitigate the impact?

To answer these questions, JIRCAS launched a 7-years' collaborative research project entitled "Evaluation and Development of Methods for Sustainable Agriculture and Environmental Conservation" with two Chinese research institutes: the Institute of Soils and Fertilizers, Chinese Academy of Agricultural Sciences and the Institute of Soil Sciences, Chinese Academy of Sciences since 1997. The project is conducted as one of the components under the comprehensive collaborative research project between JIRCAS and research institutes and universities in China and aims to develop technologies that minimize the adverse impact associated with nitrogen fertilization and, at the same time, secure sustainable food production.

The project covers four major and remarkable agricultural regions in China (**Fig. 1**): 1) Huang-Huai-Hai plain which is one of the main maize-wheat production areas distributed in alluvial lands of three large rivers. 2) Jing-Jin-Tang region where highly intensive farming of upland crops and vegetables is performed in the suburbs of big cities. 3) Tai-hu region where highly intensive rice-wheat cropping is performed in the lower reaches of Changjiang River. 4) Red soil region where double cropping of rice is widely adopted in hilly lands located in the subtropical zone. Both field experiments and regional analyses are conducted at typical sites of each study area. The field experiments determine the plant uptake efficiency and environmental impact of different types and management practices of nitrogen fertilizers. The regional analyses evaluate the nitrogen balance and its losses to the environment in the region by the application of a nitrogen flow model. Combining the results of the field experiments and the regional survey, the status of nitrogen pollution in each region will be evaluated and alternative management strategies to minimize the impact on the environment will be proposed.

[Fig. 1. Map showing the study area of the project.](#)

The project is proceeding and is entering the third year as planned. Field experiments at Lingxian, Xishan, and Qiyang are currently being conducted. Attempts to analyse regional nitrogen flows are also being made at the corresponding sites. For instance, based on a preliminary analysis of the nitrogen flow in Lingxian County, Shandong Province, it was estimated that the input of nitrogen to cultivated land was, on the average, 594 kgN ha⁻¹ year⁻¹, while the output was 265 kgN ha⁻¹ year⁻¹ (**Fig. 2**). These findings indicate that cultivated land in this region receives a balance of 329 kgN ha⁻¹, annually. A part of the excess nitrogen flows out to groundwater through leaching, to surface water through runoff, and to the atmosphere through volatilization in various forms of gaseous nitrogen. The remaining part accumulates in the soil layers. The results for Lingxian in this analysis suggested the potential risk of substantial pollution in the near future.

[Fig. 2. Estimated nitrogen flow in agro-ecosystems of Lingxian, 1997. The value for the flow from accumulation in cultivated land to the environment will be determined from the results of ongoing field experiments.](#)

Although increased use of nutrients is essential for meeting the growing demand of food, it is a double-edged sword. Unless nutrient supply is managed properly, the contribution to agricultural productivity could be offset by the adverse impact on the environment. This collaborative project may enable to develop environmental conservative agricultural technologies in order to contribute to sustainable development of agriculture in China.

International workshop on "Learning from the Farming Systems Research Experiences in Indonesia"

The International Workshop on "Learning from the Farming Systems Research Experiences in Indonesia" jointly organized by JIRCAS and the Center for Agro-Socioeconomic Research (CASER), the Agency for Agricultural Research and Development (AARD), Ministry of Agriculture, Republic of Indonesia, was held in Bogor, Indonesia during the period 3-4 March, 1999.

Farming Systems Research (FSR) is a highly controversial subject. Some critics pretend that it has been proved to be ineffective, while some others tend to criticize the excess expectation from donors and policy-makers and lack of consensus among the different actors involved in the FSR activities during the boom period of the 1970s and early 1980s. Indonesia was not an exception and hosted a myriad of internationally funded farming systems projects. Compared to these, FSR activities in Indonesia in recent years did not attract the attention of international observers. However, with the establishment of the Assessment Institutes for Agricultural Technology throughout the country in 1995, it appears that Indonesia has entered another stage of FSR.

By combining both historical and up-to-date information regarding FSR experiences within the AARD organizations, this workshop contributed to the reconciliation of views between the two extremes, negative or positive, regarding the benefit of FSR. The participants in the workshop tried to address the following key issues from various angles and with diverse personal experiences.

- How can we interpret the past 25-year history of FSR in Indonesia?
- What are the roles and relationships of researchers and extension specialists in FSR?
- What are the roles of the social and natural sciences in the FS approach?
- How adequate or inadequate is the institutional framework?
- Foreign assistance in and commitment to FSR: How can Indonesia use these most effectively?
- Technology in FS approach: assessment of technology vs. technology for assessment

Approximately fifty people from Indonesia, Japan, Australia, and the U.S.A. participated in the workshop. The workshop was successful due to the strong commitment of the experienced staff of CASER. All the participants realized that the system of FSR still needs improvement and stressed the importance of mutual exchange of information. The Proceedings of the Workshop will be published by JIRCAS in 1999/2000.

"JIRCAS Seminar in Bangkok"

JIRCAS Thailand Office held a seminar entitled "JIRCAS Seminar in Bangkok 1999" on March 3, 1999 at Maruay Garden Hotel in Bangkok. The main purpose of the seminar was to introduce our collaborative research activities to the people who had been concerned about or interested in the activities of JIRCAS in Thailand. This type of seminar was held in 1994 at the time of the 25th anniversary of the collaboration between the research organizations in Thailand and TARC (Tropical Agriculture Research Center)/JIRCAS. Therefore, this seminar covered JIRCAS activities in Thailand during the past 4 years.

To better understand and overcome agricultural problems in Northeast Thailand, JIRCAS initiated a research project entitled "Comprehensive Studies on Sustainable Agricultural Systems in Northeast Thailand." Therefore, most of the scientists who have been dispatched to Thailand by JIRCAS at present are more or less related to the Northeast Thailand project except for the collaborative project in the field of fisheries entitled "Studies on the Development of Sustainable Aquaculture Technology in Southeast Asia."

There were 150 participants from the Department of Agriculture (DOA), Department of Livestock Development (DLD), Land Development Department (LDD), Kasetsart University (KU), Khon Kaen University (KKU), Asian Institute of Technology (AIT), National Research Council of Thailand (NRCT) and International Board for Soil Science Research and Management (IBSRAM).

After the Inaugural Address delivered by Dr. Ananta Dalodom, Director General of DOA, 19 reports were presented during 6 sessions. In Session 1, an outline of the project on "Sustainable Agricultural Systems in Northeast Thailand" was given by the project leader Dr. S. Matsui and 3 reports were presented. Technical reports on animal production and grassland were presented in Session 2. In Sessions 3 and 4, nine reports were presented on soils and plant nutrition. Three reports were presented in the field of fisheries in Session 5. In Session 6, 2 reports were presented on plant pathology and postharvest technology.

At the end of the seminar, special comments related to the activities of JIRCAS in Thailand were made by Prof. Karl E. Weber, Vice President of AIT, Mr. Chaiyasit Anecksamphant, Deputy Director-General of LDD, Associate Prof. Supot Faungfupong, Vice President of KU, Associate Prof. Anake Topakngam, Dean of KKU and Ms. Tuenchai Niyamangkoon, Chief of NRCT.

The proceedings entitled "Highlights of Collaborative Research Activities between Thai Research Organizations and JIRCAS" with 58 reports were published by JIRCAS Bangkok Office.

IRRI-JIRCAS Collaboration within the Framework of the Special Project Funded by the Japanese Government

Hiroshi Kato and Motohiko Kondo

IRRI, Los Banos, Laguna, Philippines

Background of the project

Japan International Research Center for Agricultural Sciences (JIRCAS) and International Rice Research Institute (IRRI) have been collaborating by assigning Japanese breeders, agronomists and physiologists to IRRI in the Philippines under a special project funded by the Japanese Government since 1984. The first phase of the project covering the period 1984 to 1989 dealt with the development of low nitrogen input technology and the identification of genes that conferred a resistance to various races of the pathogen of bacterial leaf blight disease. The second phase covering the period 1989 to 1994 dealt with the development of direct seeding technology and study of genetic aspects of rice tungro disease. The third phase of the project initiated since December 1994 will be terminated in November 1999. Studies on the genetic control of rice blast and nutrient-water interaction in upland rice are being currently carried out.

Rice blast

Rice blast is a major disease of rice worldwide. For improving the varietal resistance against rice blast, pyramiding of major genes, accumulation of minor genes, combination of major and minor genes, and development of multilines of major genes are considered to be effective methods. Information about the genetic constitution of major genes in rice cultivars and the pathogenicity of blast isolates is a prerequisite for all these strategies.

Resistance genes of various varieties were estimated based on their reactions to Philippine blast isolates whose pathotypes were confirmed by the use of Japanese differential varieties. Inheritance of blast resistance and allelism tests were also conducted by inoculating BC₁F₂ lines of crosses of IR varieties with CO39. Blast resistance genes, *Pi b*, *Pi k-s*, *Pi a*, and *Pi 20* were identified in IR24. *Pi 20* has been recently identified. The blast resistance gene constitution of IR34, IR36, IR46, IR56, IR60, IR64, and IR74 was determined and the resistance genes of other IR varieties were also estimated based on the reaction to Philippine blast isolates.

We are developing lines with a single additional resistance gene from crosses with four recurrent parents and over 40 donor parents with blast resistance genes. The lines possess the genetic background of Lijiangsintuanheigy (LTH), CO39, IR24, and IR49830-7-1-2-2. LTH is a *japonica* variety which does not harbor any known rice blast resistance genes. CO39 is an *indica* variety which is expected to harbor a *Pi a* gene for rice blast. These lines will be used as rice blast differential systems for the identification of the pathogenicity of blast isolates in each country. By using such isolates, the resistance genes of different varieties in the world will be identified. IR24 is a variety suitable for irrigated rice ecosystems and IR49830-7-1-2-2 is an elite line for rainfed lowland areas in Thailand. These lines will be used as rice blast-resistant multilines for the first time in tropical areas.

Nutrient-water interaction in upland rice

In the last few decades, a remarkable increase in rice yield was achieved in irrigated ecosystems in Asia. In contrast, the average yield in the upland areas remains at 1.2 t ha⁻¹, a value much lower than the average yield of 3.5 t ha⁻¹ in the irrigated systems. Major factors that limit the productivity of upland rice include unstable water-availability and low nutrient supply. The IRRI-JIRCAS Project seeks to analyse the role of the interaction of water and nutrients in determining yield and develop management options for overcoming these two constraints.

The study focuses on the effect of soil and crop management on the water-capturing capacity of rice roots and the improvement of N use efficiency under fluctuating water regime in upland areas. High sensitivity of rice to water stress can be primarily attributed to the low capacity of shallow roots to capture water. After water stress, corn could extract water from lower layers deeper than 60 cm, while rice could extract it only at a low rate below 40 cm so that the total water uptake declined rapidly (**Fig. 1**). It is important to improve the effective rooting zone for water capture by genotypic and environmental manipulation. Field experiments in major upland rice areas in the Philippines, Thailand, and India, revealed that the nutrient supply environment for N and P in the surface soil may have a significant effect on the water-capturing capacity from layers below the surface through its effect on root development and, consequently, on the performance of the rice plant under stress. This finding implies that the deficiency in nutrients is likely to enhance water stress. In the course of the project, a quantitative analysis of the compensating effect of nutrient input on yield loss due to drought in tropical Asia is being conducted presently.

[Fig. 1. Water extraction from soil profile by rice and maize under water stress.](#)

To alleviate the scarcity of water which is becoming a serious constraint on agriculture in the tropics with increasing population, efforts for the improvement of rice production under water-limited conditions are considered to be crucial for maintaining the food security.

The fourth phase

The fourth phase is under preparation, and it will start in October 1999 until September 2004. In that phase Japanese scientists will conduct "Physiological and genetic studies on yield determination and ecological adaptability for sustainable agriculture." The Japanese scientists are

expected to breed varieties that are resistant to multiple diseases and pests and are environment-friendly and to develop suitable agronomic practices for the new varieties by using DNA marker selection technology.

ICRISAT/JIRCAS International Workshop

The International Workshop:

Food Security in Nutrient-Stressed Environments: Exploiting Plant Genetic Capabilities

The workshop on "Food Security in Nutrient-Stressed Environments: Exploiting Plant Genetic Capabilities" will be held at ICRISAT-Patancheru, India during the period of September 27-30, 1999, organized by the International Crops Research Institute for the Semi Arid Tropics (ICRISAT) and Japan International Research Center for Agricultural Sciences (JIRCAS).

ICRISAT has been hosting a Special Project funded by the Government of Japan on "Sustainable Cultivation of Upland Crops in the Semi-Arid Tropics" since December 1984. During the first phase (1984-89), scientists found that pigeonpea can increase the available phosphorus (P) pool of cropping systems in which it is grown by accessing Fe-P via its unique root exudates. In the second phase (1989-94), root distribution in cropping systems was examined as a prerequisite to understanding N acquisition from the soil. The current phase III (1994-1999) is examining the physiological and genetic adaptation of crop plants to low-nutrient environments. This workshop is being organized to round off the activities of phase III of the project.

The objectives of the workshop are:

- To explore the scope for genetic manipulation of the ability of crop plants to gain access to and utilize nutrients (N, P)
- To prioritize candidate mechanisms for enhancing nutrient uptake and use in terms of suitability for genetic manipulation
- To examine appropriate methodologies for genetic enhancement of crop plant ability to absorb nutrients and use them efficiently
- To suggest how genetic options can best be combined with management options to improve nutrient uptake and use

The workshop consists of four sessions as follows:

Session 1: Breeding for low nutrient environments: is it sustainable?

Session 2: Candidate mechanisms

Session 3: Methodology for genetic manipulation of nutrient availability

Session 4: Combining genetic improvement with natural resource management

PEOPLE

Kazuyuki TSURUMI, an agricultural economist, became Director of JIRCAS's International Research Information Division, succeeding Mr. Kunio TSUBOTA who moved to Agricultural and Economic Development Analysis Division, Economic and Social Department, FAO. Mr. Tsurumi, until recently, was Managing Director, Agriculture Forestry and Fisheries Development Study Department, Japan International Cooperation Agency (JICA). He joined the Headquarters of the Ministry of Agriculture, Forestry and Fisheries (MAFF) in 1974 and mainly worked in the field of international affairs. During 1986-1991, he served as an agricultural economist at OECD, Paris.

Toshiaki TANIGUCHI, a veterinary pathologist, succeeded Dr. Mitsugu SHIMIZU as Director of JIRCAS's Animal Production and Grassland Division. Before joining JIRCAS, he was Associate Director for Research, Department of Pathology and Physiology, National Institute of Animal Health. Dr. Taniguchi was involved in several JICA's animal health projects in Indonesia, Malaysia and Thailand as a short-term expert.

Collaborative Research on Issues Relating to Environmental Resources

Tadao Hamazaki

Director, Environmental Resources Division, JIRCAS

In developing regions, increasing the supply of agricultural products and stabilizing agricultural productivity are matters of great urgency due to the rapid increase in human population and the improvement in the standard of living. In these regions, the greatest challenge for agriculture today is to sustain agricultural production under adverse soil and climatic conditions, because most of these regions are located in unfavorable agricultural environments such as low soil fertility and/or arid and semi-arid climate, and many farmers can not afford to use enough fertilizers and agricultural chemicals due to economic constraints. Therefore, it is necessary to develop agricultural technologies, which may enable to use more efficiently the local organic resources or to maximize useful functions of plants and microorganisms, based on the characteristics of soils, climate, and socioeconomic conditions.

Recently many attempts have been made to increase food production in these regions. However, these efforts have led to a deterioration of agricultural environments and global environmental problems such as pollution of rivers, lakes and inshore waters, soil degradation, and deforestation. These environmental problems have been caused by excessive application of fertilizers and agricultural chemicals, large-scale feeding of livestock, overgrazing, inappropriate irrigation, overcropping, and expansion of agricultural lands. Accordingly, sustainable agricultural technologies compatible with environmental preservation should be developed based on the analysis of the mechanisms of material cycling in the agro-ecosystems.

On the other hand, agriculture is practiced under various natural and social environments in these regions. Therefore, it is necessary to analyze the actual conditions and characteristics of the environmental resources to develop agriculture compatible with environmental conservation. However, geographic information on land and environmental resources is lacking in many of these regions. Geographic information systems (GIS), are now expected to become an effective tool for developing methods for the analysis and evaluation of the spatial and temporal changes of environmental resources and for producing various kinds of evaluation maps on environment by overlaying multiple geographic data including remote sensing data.

To address these problems, the Environmental Resources Division (ERD) is conducting research to develop technologies for the promotion of sustainable agriculture and environmental conservation. In the comprehensive research projects on sustainable agricultural technologies in Northeast Thailand and on agro-pastoral rotation systems in Brazil, EDR researchers are carrying out studies on the evaluation of sustainability of the agricultural systems from the viewpoint of material cycling and utilization of local organic resources and nitrogen-fixing plants. At the same time, in the comprehensive research projects on sustainable production and processing of major food resources in China and on the evaluation and improvement of farming systems in the Mekong Delta of Vietnam, other EDR researchers are performing studies on the evaluation and development of methods for the improvement of agricultural activities compatible with the preservation of the environment and the ecosystems.

The Division is also promoting research on GIS. Within the framework of the Northeast Thailand project and the comprehensive research project on the evaluation and improvement of regional farming systems in Indonesia, EDR researchers are analyzing the mechanisms of land use changes and physical factors for regional farming systems. Additionally, in the China project, GIS researchers are studying the spatial and temporal characteristics of environmental conditions of agricultural lands.

Furthermore, one researcher is developing monitoring systems of evapo-transpiration, depth of snow and soil moisture under the harsh climatic conditions in the Mongolian plateau.

The Division is also conducting two special projects in collaboration with the international agricultural centers. With the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India, the Division has been involved in studies on the physiological and genetic adaptation of sorghum and pigeonpea to low nutrient availability in the semi-arid tropical environment. Researchers dispatched by the Division to the International Rice Research Institute (IRRI) in the Philippines have been conducting studies on the stabilization of rice culture under water stress in the tropics utilizing a broader spectrum of genetic resources. These two projects will end in 1999, and the Division is planning to dispatch a researcher to initiate a new research project entitled "Physio-genetic studies on yield determination and ecological adaptability for sustainable rice culture" at IRRI scheduled to begin by the end of this fiscal year.

On the other hand, at WARDA (West Africa Rice Development Association), one researcher is carrying out studies on the genetic and eco-physiological characterization of indigenous rice varieties and interspecific progenies, with emphasis placed on tolerance to drought and

acid soil conditions in the West African region.

In addition, the EDR is actively engaged in research activities within the framework of the JIRCAS Fellowship Program in the field of material cycling, GIS, photoelectron spectroscopy, etc. and frequently invites to Tsukuba counterpart researchers from the organizations with which JIRCAS carries out collaborative studies.

Biological Control of Fish Diseases in Aquaculture

Masachika Maeda

Director, Fisheries Division, JIRCAS

The health of fish in aquaculture, as well as in nature, depends primarily upon their inherent resistance to microbial invasion, and the biological equilibrium between competing beneficial and detrimental microorganisms at the fish/water environment interface. In fact, useful and harmful microbes in the water environment directly affect the growth of fish (Maeda, 1999).

More than one million of microorganisms per milliliter inhabit the aquatic environment and affect each other, both through the substances they produce and emit, as well as through the various ways they come into contact with one another. Fertilization of aquaculture seawater, through the addition of low concentrations of organic materials, leads to an increase in the number of microorganisms which utilize the organic materials as nutrients to construct microbial assemblages which enhance the survival rates of fish larvae (Maeda, 1999). In aquaculture, where phytoalgae are used as the main live food, the survival rates of prawns, crabs and finfish are not considered to be sufficiently high. However, if certain species of bacteria are present with the algae, the survival rate increases significantly. It is therefore preferable to feed microbes to fish along with algae (Maeda, 1999), although the control of these microbial assemblages is essential to prevent the pathogens from dominating the microbial communities. Thus microorganisms play several useful roles which help to maintain suitable environmental conditions in aquaculture and promote fish growth, as well as functioning as live food.

The bacterial strain cultured in the ZoBell 2216E medium in seawater at 25°C for 4 days was added into seawater where the larvae of striped jack were reared

The methods of determining how to keep pathogenic microorganisms, mainly bacteria and viruses, away from fish rearing environments are one of the main concerns of the people engaged in aquaculture. To this end, the filtration of water, the addition of sodium chloride, ozonation, the use of ultraviolet light, and even the use of artificial compound food containing antibiotics for sterilization, are all commonly adopted techniques in aquaculture. People in aquaculture tend to consider that these procedures can eventually eliminate all the microbes in seawater, and produce and maintain a nearly pure water quality. However, with these treatments, pathogenic microorganisms which cause fish diseases cannot be permanently removed from the water. For example, if the antibiotic kanamycin is added to seawater, the bacterial numbers decrease for about two days, but eventually the numbers will recover to their original level. The same phenomena can be seen when seawater is sterilized by filtration, ozonation or ultraviolet light treatment. After such treatments, bacteria grow very quickly because antagonism among the bacterial populations is reduced. Furthermore, no one can anticipate what kind of bacterial species may grow in the vacant space generated by the above treatments. *Penaeus* prawn aquaculture in Asia and South America in part has not yet recovered from its collapse in the 1980s. In addition, many fish diseases are spreading through aquaculture facilities worldwide.

Although people who are engaged in aquaculture have started to realize that antibiotics are less effective, almost no alternative method of controlling diseases has been developed. It is therefore essential that new methods should be adopted wherein the antagonism of certain microorganisms is used to repress other pathogenic microbes, bacteria and viruses, in seawater.

The antagonism among microbes is a naturally occurring phenomenon through which pathogens can be killed or reduced in number in the aquaculture environment. This method, which is called biological control or biocontrol, has already been recognized in the field of agriculture. For example, the famous bacterium, *Bacillus thuringiensis*, which infects pathogenic insects orally and eventually kills them is now commercially available in Europe and North America where several thousands of tons are used. These positive results have led to further studies using viruses, fungi and protozoa as biocontrol agents to eliminate pathogenic organisms. This approach in aquaculture is described in detail herein.

Several viral diseases have seriously affected the fish rearing industry. *Penaeus* prawn, *P. monodon* and *P. japonicus*, have almost all been infected with Baculo-like viruses. In Taiwan, the production of *P. monodon* decreased from about 90,000 metric tons in 1987, to 30,000 in 1988, to 20,000 in 1989, and has still not recovered. In Japan since 1993, the prawn rearing industry of *P. japonicus* has been seriously

damaged by a virus infection, and many prawn nursery ponds in the western part of Japan stopped production because all the prawns died. There are also other viruses: Infectious Hematopoietic Necrosis Virus (IHNV) and Infectious Pancreatic Necrosis Virus (IPNV) which infect salmon, HIRRV which infects a flounder, the Yellowtail Ascites Virus (YAV) which infects yellowtail, Striped Jack (Sima-Aji) Nervous Necrosis Virus (SJNNV) which mainly infects striped jack, the Irido Virus which infects sea-bream, and many more, all of which cause serious damage in aquaculture.

Using the direct counting method combined with electron microscopy, virus counts were reported to range from 10^4 - 10^8 virus particles /ml, i.e. numbers which were 10^3 - 10^7 times higher than previous reports of virus particle numbers in natural aquatic environments, that in turn were based on counts of plaque-forming units using various host bacteria. Thus viral concentrations changed from 10^4 to 10^8 virus particles/ml, which indicates the possible effect of anti-viral microorganisms on the presence of virus particles in seawater. This phenomenon helps to explain why the concentration of viruses fluctuates so markedly in sea and fresh-water. In addition, viruses have the ability to be transferred from one infected organism to another through the water environment. If anti-virus bacteria dominate the water environment, virus transfer among fish communities may be repressed to a large extent. Based on this concept, anti-virus bacteria are used in rearing procedures of larvae in practical aquaculture applications.

According to one hypothesis, bacteria which are able to inhibit the growth of other bacteria, may also inhibit the growth of viruses. From this point of view, for the detection of anti-virus bacteria in seawater, the first step should be to determine the anti-bacterial activity. This procedure is easier than determining the anti-viral activity directly. The bacterial strain VKM-124, *Pseudoalteromonas undina*, which has a vibrio-static activity and is used in practical aquaculture, inhibited the appearance of the cytopathic effect (CPE) on the epithelioma papillosum cyprini (EPC) cells in which about a 2-day delay was observed in the *P. undina* experimental fraction, compared to the control fraction. Thus this strain, which shows a strong antibacterial activity, can inhibit the growth of the virus.

The bacterial strain VKM-124, *Pseudoalteromonas undina*, used in aquaculture processes, is able to prevent fish larvae from being infected with SJNNV, Baculo-like viruses and Irido virus. When this useful strain was added to water at a concentration of about 10^6 cells/ml in rearing containers of *Penaeus* prawn, Sima-aji and Sea-bream larvae, the survival rates of these larvae were much higher in the presence of the bacterium than without the bacterium. All the fish larvae died due to viral disease without the addition of the bacterium (**Fig. 1**) (Maeda, 1999).

Fig. 1. Survival of Sima-aji (Striped jack, *Caranx delicatissimus*) larvae with and without the bacterium VKM-124, *Pseudoalteromonas undina*. Larvae died due to infection with the virus, SJNNV, in the container without the addition of the bacterial strain.

Viruses in seawater spread from infected fish to others which are not yet suffering from disease. However, probiotic bacteria may inhibit the migration of viruses among fishes. In addition, if fish feed on such probiotic bacteria, the immune system of the fish may become stronger, as shown in the enhancement of immune activities of vertebrates with bacteria in many reports. With such useful effects and features, probiotic bacteria could certainly be extremely effective in protecting fish from the spread of viral diseases in aquaculture.

Note: Detailed information and references are available in the book of Maeda (1999); Microbial Processes in Aquaculture. Natl. Res. Inst. Aquaculture, 102 pp. The scientists who would like to read this book can obtain it by writing to JIRCAS.

Fig. 1. Survival of Sima-aji (Striped jack, *Caranx delicatissimus*) larvae with and without the bacterium VKM-124, *Pseudoalteromonas undina*. Larvae died due to infection with the virus, SJNNV, in the container without the addition of the bacterial strain.

Numbers of larvae used: 254, 000 Ind.

Water volume: 20 metric tonnages.

Bacterial numbers added every day for 17 days: about 1 million cells/ml.

Soybean Virus Diseases in Northeast China

Masaaki Nakano
Biological Resources Division, JIRCAS

Northeast China is the major soybean production area in China. More than 40% of soybean grains in China are produced in three provinces in the Northeast, i.e., Heilongjiang, Jilin, and Liaoning. JIRCAS has initiated a program of collaborative research on soybean breeding with The Soybean Institute of Jilin Academy of Agricultural Sciences. At first, we focused on soybean virus diseases that cause severe damage to soybean production.

In a soybean field, sometimes plants display symptoms such as curling of leaves, deep leaf color and pale green or yellow mosaic, brownish necrosis along the leaf veins, or dwarfing. These are the typical symptoms of soybean virus diseases and sometimes they lead to a severe yield reduction. Many viruses infect soybean in China. Since each virus shows a different mode of transmission, the kinds of viruses should be identified and characterized in Jilin province for control including breeding of resistant varieties.

We investigated soybean virus diseases all over the Jilin province by applying the Dot-ELISA method using virus-specific antisera and by electron microscopy. We could detect the soybean mosaic virus (SMV), cucumber mosaic virus-soybean stunt strain (CMV-SS), alfalfa mosaic virus (AMV), and bean common mosaic virus (BCMV) during the period 1996-1998 (**Table 1**).

Table 1. Detection of soybean viruses by Dot-ELISA in Jilin province (1996-1998)

Region	No. of tested materials	SMV	BCMV	CMV-SS	AMV
Baicheng	35	3	2	0	0
Qianguo	22	0	2	0	0
Siping	279	128	10	9	6
Changchun	21	5	0	0	0
Jilin	52	22	0	2	2
Yanbian	174	5	0	1	5
Tonghua	10	1	0	4	0
Baishan	11	0	0	2	0
Total	604	164	14	18	13

BCMV causes severe vein necrosis on some cultivars (Fig. 1). This virus infects other legume crops such as bean, mungbean, and adzuki bean and some of the plants may become a source of inoculum. Although severe yield reduction in individual soybean plants can be observed, the incidence is very low.

AMV causes distinct yellow mosaic symptoms on leaves (Fig. 2). Since alfalfa and some legume grasses for animal feeds are a source of inoculum, AMV could be detected on soybean plants cultivated next to alfalfa fields.

Mosaic disease caused by SMV was the major virus disease in this area (Fig. 3). As SMV can be detected in soybean seeds, SMV is disseminated by seeds over a soybean-growing area and the germinated plants become inoculum sources. Then SMV is rapidly transmitted to neighboring soybean plants by aphids.

Although CMV-SS is also a seed-transmissible virus, its incidence was lower than that of SMV.

The most effective method of control of SMV is the utilization of resistant cultivars. However, many SMV strains infect various resistant cultivars. Therefore, although resistant cultivars enable to control certain SMV strains, if another SMV strain infects the resistant cultivar, a severe epidemic may occur. We investigated the SMV strains in Jilin province to select cultivars suitable for the control of SMV. Our work revealed that almost all the isolates of SMV in this area belonged to the SMV-B strain in Japan. Besides, we observed that almost all the cultivars developed at Jilin Academy of Agricultural Sciences for the past years were resistant to SMV-B. If farmers replace the old cultivars with new cultivars, SMV could be eliminated in their fields. After the introduction of resistant cultivars, the occurrence of other virulent SMV strains should be carefully monitored and the agricultural institutes are responsible for providing pathogen-free seeds.

Recently, we have isolated an unidentified virus from SMV-resistant soybean plants. This virus is different from SMV and other known

viruses in this area, because it does not react with the antisera used and was not transmitted by aphids. This virus must show other ecological characters. Therefore another strategy for control should be developed. We will soon identify it and will show how we can control it in the near future.

Experimental Plantation of Dipterocarp Species in Luzon Island, Philippines

Shiro Okuda* and Antonio F. Gascon*²

*Forestry and Forest Products Research Institute,

²College of Forestry, University of the Philippines at Los Banos

Dipterocarp species are one of the main component trees of the tropical forest. Due to the high commercial value, Dipterocarp stands have been logged on a large scale, leading in some areas to a serious decline of forest resources. In the Philippines, lowland forests had been dominated by Dipterocarp species in the past, and recently logging has spread all over the country, resulting in a remarkable reduction of useful timber resources.

Reproduction of the forest generally has been achieved by natural regeneration which is too slow in some hardly disturbed cases. Planting of seedlings is more efficient to establish a targeted forest in a short period of time. In the case of Dipterocarp species, planting had been commonly carried out under canopy trees, to obtain a higher survival rate of planted seedlings. However, stagnation of growth was often observed. Light is efficient for the growth of seedlings and it is important to explore the possibility of plantation in an open environment with Dipterocarp species.

A joint experimental plantation site had been established at the campus of UPLB (University of the Philippines at Los Banos) in cooperation with the SFI Department. Seedlings of eight species belonging to the Dipterocarp family were planted. All the species were indigenous to the Philippines and seedlings from seeds collected from Mt. Makiling Forest Reserve and the surrounding area were maintained in a nursery for 6 months prior to planting. To analyze the growth response under different light conditions, the site was divided into two parts, one in a fully opened area and the other under the canopy of an *Acacia* stand (RLI about 30%).

The initial growth for two years after plantation differed depending on the species. In the fully opened part, *Anisoptera thurifera* ssp. *thurifera* (Palosapis) and *Shorea contorta* (White Lauan) grew better than the other species both in terms of height and diameter. On the other hand, in the case of *Dipterocarpus grandiflorus* (Apiton) the values for these parameters were the lowest. The other species showed an intermediate growth between the two groups. There was no appreciable difference in growth between seedlings in the fully opened part and the part under the canopy for *D. grandiflorus*. However, the species that became big in the fully opened part showed only less than half growth in the part under the canopy. The survival rate showed the same trend as that of *A. thurifera* ssp. *thurifera* and *S. contorta* i.e., around 90%. The rate was not significantly different between the two parts of the site. The other species showed a lower rate, and particularly *D. grandiflorus* reached a rate of about 50% after planting.

Weed and vine growth was luxuriant in the fully opened part. This vegetation competed with the planted seedlings. To maintain higher growth and survival rates, weeding was an efficient treatment when practiced at intervals of 2, 3 months. In the non-weeded site, the survival rate decreased for all the species that had been planted.

Thus the growth and survival varied with the species and site conditions in the opened area; microclimatic factors may vary not only in terms of light intensity compared to the area under canopy, but temperature and humidity of air and soil may also be different. Therefore, light is not the only factor that accelerates growth. Further studies focused on the response of growth to other factors should be carried out to analyze the species characteristics.

Farming Systems Research in Indonesia - Toward the Improvement of Household Economy in Rural Areas in West Java

Shuichi Asanuma
Research Information Division, JIRCAS

Natural and socio-economic conditions surrounding agriculture

Agricultural land area accounts for about 23% of the total land territory of Indonesia, while for 67% in Java Island. Agricultural production varies markedly from location to location, depending upon the natural environmental and socio-economic conditions in each region. For instance, rapid economic growth, industrialization, and urbanization on Java have widened the gap between cities and villages and altered fundamentally the social and economic conditions in rural areas. On the outer Islands, on the contrary, generally the low standard of living reflects the slow pace of economic development including agricultural production and the delay in the development of appropriate technologies to overcome the difficulties in resources exploitation.

Cabbage field in mixed cropping system on steep slope of Mt. Bromo, East Java

Beans planted in paddy fields in Pasuruan, East Java

Agricultural production and research

Most of the agricultural research in Indonesia has been focused on lowland farming systems based on the cultivation of rice. This focus, when combined with the effects of other governmental programs to help rice farmers, allowed Indonesia to achieve its national goal of self-sufficiency in rice by 1984. On the other hand, upland crop areas have not much benefited from the modern agricultural technologies although numerous research projects have targeted upland or rainfed lands. Consequently, upland agriculture remains much less developed than lowland agriculture throughout the country. Under these conditions, in addition to the shortage of rice production experienced during the past few years, increase of food crop production, particularly of rice, maize and soybean, both in the lowland and the upland, has become the most urgent target in agricultural research and development in Indonesia (Table 1).

Table 1. Production and import of main grain crop commodities in Indonesia

Implementation of farming systems research in Indonesia

The comprehensive research project entitled "Evaluation and Improvement of Regional Farming Systems in Indonesia" aims at examining, from farmers' standpoint, the socio-economic and technical achievements of the past and on-going practices relating to farming systems research and extension in Indonesia and at suggesting ways for improvement. A "farming systems research approach" is characterized by a bottom-up participatory process and an emphasis on a multi-disciplinary approach to problems in agriculture. The project started in April, 1998 based on the Memorandum of Understanding (MOU) between the Agency for Agricultural Research and Development (AARD) of Indonesia and the Japan International Research Center for Agricultural Sciences (JIRCAS), and is scheduled to last for five years. The research institutes of Indonesia with which JIRCAS is currently collaborating include the Center for Agro-Socio-Economic Research (CASER), the Research Institute for Legume and Tuber Crops (RILET) of the Central Research Institute for Food Crops (CRIFC), and the Center for Soil and Agroclimate Research (CSAR) and Lembang Assessment Institute for Agricultural Technology (AIAT-Lembang).

Research activities under progress and planning

The following research activities are in progress, 1) studies on the farmer-state linkages in upland farm development in Indonesia, 2) analysis of physical environmental resources using remotely sensed data and GIS for evaluation and improvement of regional farming systems in Indonesia, and 3) evaluation of Indonesian soybean varieties for the processing and improvement of traditional fermented foods. An additional activity consisting of the evaluation of vegetable-based farming systems and improvement of vegetable and fruit cultivation in highland regions in West Java is now under planning, the objectives of which are 1) to analyze geographic, climatic and socio-economic conditions, of temperate vegetable-producing areas in West Java, 2) to analyze the demand for temperate vegetable production in Indonesia, 3) to analyze and evaluate the distribution systems of temperate vegetables and fruits in West Java, 4) to analyze and evaluate the present cultivation and protection technology of temperate vegetables in West Java, and 5) to analyze and evaluate the characteristics of upland crops and fruit trees utilized in the mixed cropping systems of temperate vegetable cultivation in West Java and to suggest the incorporation of alternative varieties of upland crops and/or fruit trees into the systems.

We expect that the collaborative research between AARD and JIRCAS will contribute to the improvement of vegetable farmers' life in West Java through the increase of household income in the near future.

Mr. Matsumoto, Chairman of AFFRC, Mr. Tsuchiya, Director of International Research Division of AFFRC and Dr. Maeno, DG of JIRCAS Visited Brazil

Kiyomi Kosaka
Animal Production and Grassland Division, JIRCAS

Visit of a laboratory at CNPGC. From left: Dr. Maeno, Dr. Boock, Mr. Matsumoto and Dr. Miranda

Mr. Sakue Matsumoto, Chairman of the Agriculture, Forestry and Fisheries Research Council, AFFRC, Ministry of Agriculture, Forestry and Fisheries, MAFF, Mr. Tadashi Tsuchiya, Director, International Research Division, AFFRC/MAFF and Dr. Nobuyoshi Maeno, Director General of JIRCAS visited Brazil in August 1999. In Sao Paulo, they had the opportunity of meeting with Dr. Sugai, economist of the Brazilian Agricultural Research Corporation, EMBRAPA, and they discussed various aspects relating to the orientation of future collaborative research activities between Brazil and Japan, especially in the field of socio-economic studies.

Mr. Matsumoto, Mr. Tsuchiya and Dr. Maeno visited the National Center for Beef Cattle Research (CNPGC), EMBRAPA in Campo Grande and discussed with Dr. Arae Boock, Director General of CNPGC, and his staff, in greater detail various aspects relating to the on-going collaborative research project entitled "Comprehensive Studies on the Development of Sustainable Agro-Pastoral Systems in the Subtropical Area of Brazil." In Campo Grande, they also had the opportunity of meeting with Mr. Moacir Kohl, Director General of the State Department of Agriculture and Vice President of Mato Grosso do Sul and Mr. Paulo Shiguenori Kanazawa, Deputy Director of State Finance and Science Department, and learned more about recent agricultural developments in the Cerrados Area.

On these occasions, Mr. Matsumoto, Mr. Tsuchiya and Dr. Maeno also had the opportunity of meeting with many immigrant farmers who became the leaders of the Japanese communities of Brazil in Sao Paulo, Campo Grande, Mariria and Gutapara, in particular with Mr. Shunji Nishimura, owner of Pompeia Agriculture and Industry High School, who contributed significantly to forging close links between the Brazilian and Japanese agricultural organizations for many years.

Future Orientation of International Collaborative Research on Postharvest Technology for Developing Countries

Akinori Noguchi

Director, Crop Production and Postharvest Technology Division, JIRCAS

The Crop Production and Postharvest Technology Division implements research projects on topics ranging from production and storage to the processing and marketing of agricultural products. Our research activities encompass a variety of disciplines including agronomy, plant protection (pest, disease, and weed control), agricultural mechanization, irrigation, drainage, cropping systems, food storage, postharvest technology, farm management and agricultural economics.

Far too often the problem of feeding the world's hungry is conceived in terms of producing a sufficient amount of food. Equally pressing problems related to preservation and distribution issues that affect food products between harvest and consumption are frequently neglected. Postproduction operations in agriculture and horticulture include a wide range of functions necessary for supplying good quality food, reducing transaction costs, and raising domestic welfare. It is necessary to place emphasis on postharvest studies of agricultural products, such as quality improvement, safety, extension of shelf life, and control of insects and microorganisms in foodstuffs. These constitute important objectives of this Division.

Finally, sustainable production of agricultural commodities can only be supported by the development of sustainable markets. Technology for enhancing the value of agricultural products is being developed with a view to increasing incentives for farmers to promote sustainable production. Economic studies are essential for furthering the development of target countries.

It is only natural that food production covers wide fields as a chain from the cultivation to the final food market. Postharvest technology including selection, preservation, packaging and processing has contributed to the promotion of agricultural production through the improvement of farmer's income by raising the value of agricultural produce. Agriculture is very sensitive to the natural environment and there are many constraints on the rapid increase of production. Therefore, it is very important to develop techniques to reduce postharvest losses as well as to preserve or improve the quality, freshness and nutritional value of agricultural produce until the products reach the consumers.

The Division will concentrate its research activities on the prevention of postharvest losses, with emphasis placed on the improvement of methods of drying, transportation and storage of the products, quality preservation and evaluation and food processing. The constraints on the infrastructure and relevant technologies in developing regions, result in quality deterioration of agricultural produce and in compelling the farmers to sell their products at a low price in the market. Low-input preservation technology will be developed by identifying the factors controlling quality deterioration during collection, storage and distribution. On the other hand, since the price of agricultural products is determined based on their quality such as freshness, shape, size, color, flavor, texture, components, nutritional value, safety, damage caused by pests and functional properties for processing, technology for quality preservation and evaluation will play a very important role in the pricing of agricultural products. However, since most of these technologies have been designed in developed countries, they must be adapted to the needs of developing regions and more simple and low-cost technology for quality preservation and evaluation should be developed. As for processing, in general, traditional methods of food processing aim at meeting the requirements of the domestic market sometimes under unpredictable supply of raw materials and limited level of technology. The Division will attempt to analyze and improve the various steps involved in the traditional methods of food processing to meet the increasing demand of consumers for diversified foods, along with developing new technologies for food processing through technology transfer.

This approach was also emphasized during the 19th ASEAN and 1st APEC Seminar on Postharvest Technology (Ho Chi Minh City, Vietnam, 9-12 November 1999). This seminar covered a wide range of durable and perishable agricultural commodities and focused on issues relating to quality assurance, evaluation of quality, quality maintenance and contaminant reduction, cost efficiencies and systems approaches to postharvest research and development.

Natural Food Chain in Aquaculture

Masachika Maeda

Director, Fisheries Division, JIRCAS

For years the food chain in seawater has been misunderstood, and consequently aquaculturists have often followed the wrong direction. Until recently, scientists had considered that the food chain's primary producers (microalgae, which fix light energy and yield organic materials), were consumed by the zooplankton as soon as they were produced. However, recent studies have shown that several other food transfer pathways exist as well. For example, it was reported that the dominant species in zooplankton communities, which have been considered to be typical herbivores, feed on detritus and bacteria. Maeda (1999) also outlined the significant role of bacterial aggregates as food for the zooplankton.

In terrestrial ecosystems, few of the primary producers are directly utilized by predators as food. In the forest ecosystem, for example, only a small proportion of the leaves is eaten by animals, whereas a major proportion of the nutrients from fallen leaves is transferred through bacteria, fungi and protozoa, as well as through small plants and small to middle-sized animals.

Although this energy transfer is considered to represent the detritus food chain, a large number of microorganisms attached to the detritus are in fact the main nutrient source for the predators (**Fig. 1**).

Fig. 1. Microbial cell assemblages in detrital materials in seawater.

This food pathway could thus be designated as microbial food chain instead of detritus food chain (Maeda 1999). It is therefore more appropriate to define primary producers as builders of a dissolved organic matter (DOM) pool. Based on this DOM pool, which originates from exudates of microalgae, etc., "microbial food assemblages" are formed. These assemblages are the starting point of the energy flow in the lower trophic levels of the food chain in the aquatic environment as shown in **Fig. 2**, although the effect of viruses on these microorganisms has not been considered.

Fig. 2. Food chain in the lower trophic level of larval rearing water in aquaculture.

Since many protozoa feed on bacteria, the bacteria contribute to higher trophic levels. In fact, protozoa are considered to be a significant food source for fish and zooplankton. Furthermore, Robertson (1983) increased the feeding rate of *Acartia* by using tintinnids as food at a concentration of 10^3 cells/L. It is interesting to note that the copepod *Scottolana canadensis* was capable of producing eggs more frequently when ciliated protozoa were given as food than when only microalgae were available. Gall *et al.* (1997) also reported the significant role of protozoa as live feeds to oyster, *Crassostrea gigas*.

In aquaculture, the concept of the microbial food chain can be adopted. In fact, the addition of low concentrations of organic matter promotes the growth of fish. For example, in cases where the phytoplankton is used as the main live food, certain species of bacteria may be added with the algae. Under such treatment, survival rates of fish increase significantly. It is therefore considered preferable to feed microbes to fish along with algae. In conclusion, microbial food assemblages formed by the addition of microalgae and organic matter play a significant role as live food in aquaculture waters.

Note: Detailed information and references are available in the book of Maeda (1999). The scientists who would like to read this book can obtain it by writing to JIRCAS.

JIRCAS International Workshop

JIRCAS plans to organize an International Workshop on "Brackish Water Mangrove Ecosystems _ Productivity and Sustainable Utilization -" to be held in Tsukuba, Japan during the period February 29 _ March 1, 2000.

Four themes will be covered in four sessions as follows:

- 1) Production and decomposition processes in mangrove areas
- 2) Nutrient flux from rivers to coastal areas
- 3) Energy flow in brackish water of mangrove areas
- 4) Socio-economic evaluation of mangrove coastal areas.

A Fungus (*Ephelis* sp.) of Grasses on Ishigaki Island and Its Effect on the Feeding of Two Insect Pests

*Keiichi Takahashi**, *Michael J. Christensen*^{*2}, *Katsuyuki Kohno*^{*3}, *Takao Tsukiboshi*^{*4} and *Makoto Kobayashi*^{*5}

National Food Research Institute, ^{*2}*AgResearch, New Zealand*, ^{*3}*Okinawa Subtropical Station, JIRCAS*, ^{*4}*National Institute of Agro-Environmental Sciences* and ^{*5}*National Grassland Research Institute*

A number of alkaloids with insect deterrence or toxicity are present in grasses infected with fungi belonging to the tribe Balansiae, especially *Neotyphodium* species. However, no information is available for *Ephelis* species. We, therefore, studied *Ephelis*-infected grasses and their effect on the feeding of insect pests in Okinawa.

Ephelis sp., a fungus belonging to the family Clavicipitaceae (tribe Balansiae), was detected in fifteen species of grasses on Ishigaki island, Okinawa; *Brachiaria mutica* (Forsk.) Stapf, *Chloris barbata* Swartz, *C. divaricata* R. Br., *Chrysopogon aciculatus* (Retz.) Trin., *Cynodon dactylon* (L.) Pres., *C. pletostachyus* (K. Schem.) Pilger, *Digitaria decumbens* Stent., *D. violascens* Link, *Imperata cylindrica* (L.) Beauv. var. *koenigii* (Retz.) Durand et Schinz, *Leptochloa panicea* (Retz.) Ohwi, *Panicum crus-galli* Beauv. var. *praticola* Ohwi, *P. repens* L., *Paspalum scrobiculatum* L., *P. urvillei* Steud. and *Eriochloa procera* C. H. Hubb.

Sites with *Ephelis* infection were most commonly wet areas that had remained undisturbed for many years. The frequency of infection varied widely between grass species. In three of the fifteen grasses, *C. aciculatus*, *D. violascens* and *P. scrobiculatum*, infected plants were observed at many sites, while in other species, infected plants were present at only one or two sites. *Ephelis* infection of *C. dactylon*, *E. procera* and *P. urvillei* was found only in a single plant. The number of infected tillers at each site was typically low, and apparently showed a random distribution, with no evidence of spread from sites of infection. Infected plants were characterized by stromata that covered the inflorescence with dense mycelial growth (**Photo 1**). Numerous narrow, elongated conidia were present on the stromata (**Photo 2**). In most grasses, hyphae were observed on the surface of the leaf blades. Infected plants of 10 species revealed that the *Ephelis* fungus was essentially an epiphyte, with hyphae in vegetative tillers being located on the surface of the stem apex, including primordial leaves. Hyphae on leaf blades were also apparently confined to epiphytic growth.

Photo 1:
Inflorescence of *Digitaria decumbens* covered with stroma of the *Ephelis* fungus

Photo 2:
Elongated conidia of *Ephelis* on stroma in *Brachiaria mutica*

Insect feeding deterrence associated with the presence of the *Ephelis* sp. was detected in choice tests involving infected and uninfected leaves. Larvae of the armyworm, *Mythimna (Pseudaletia) separata*, preferred *Ephelis*-free grass to *Ephelis*-infected leaves of *D. decumbens* (**Fig. 1**), but feeding was unaffected on *Ephelis*-infected leaves of *C. pletostachyus*. Adults of the grasshopper, *Aiolopus thalassinus tamulus*, preferred *Ephelis*-free to *Ephelis*-infected leaves of *D. decumbens* and *C. pletostachyus* (**Fig. 1**). Adults of *A. thalassinus tamulus* fed on *Ephelis*-free *D. decumbens* leaves survived over a significantly longer period than those fed on *Ephelis*-infected leaves (**Table 1**). These studies indicate that the *Ephelis* fungus occurring on Ishigaki island produces at least one feeding deterrent in the host grasses examined.

Fig. 1. [Comparison between *Ephelis*-infected \(E+\) and *Ephelis*-free \(E-\) *Digitaria decumbens* leaves in relation to eating preference of the 6th instar larvae of *Mythimna \(Pseudaletia\) separata* and the adults of *Aiolopus thalassinus tamulus*. The numbers indicate the number of individuals.](#)

* : Significantly different based on Mann-Whitney test. $P < 0.05$

A number of alkaloids with insect deterrence or toxicity are present in grasses infected with fungi belonging to the tribe Balansiae. These have been extensively studied in grasses infected with *Neotyphodium* species, in particular those which form seed-borne endophytic associations with perennial ryegrass, *Lolium perenne* L. and tall fescue, *Festuca arundinacea* Scrb. The main alkaloids known to confer resistance are peramine, lolines and ergovaline. Peramine is a feeding deterrent that affects oviposition. Lolines are toxins that occur at high concentrations, up to 10,000 ppm. Ergovaline, found throughout the Balansiae, is mainly considered to be a mammalian toxin but is known to enhance protection against insect pests. The presence of ergovaline and other alkaloids in *Ephelis*-infected grasses in Japan, and the spectrum of alkaloids in different host species, remain to be determined.

Ascaris suum Infection in the Mekong Delta, Vietnam and Application of Anthelmintics

Shinobu Yoshihara
National Institute of Animal Health

It is well known that helminthic diseases are associated with the low productivity of pigs and cause economic losses in small-scale farms in the Mekong Delta. Therefore, an attempt was made to estimate the economic losses due to *A. suum* infection.

Six littermate pigs weighing approximately 40 kg from the Experimental Animal Farm of Can Tho University were used. *A. suum* eggs were detected. Group 1 consisted of 3 pigs treated with 1 mL per 15 kg of polystrongyle (injectable form of tetramizole hydrochloride, France). Group 2 consisted of 3 untreated control pigs. Their body weight was checked biweekly for 12 weeks. In 3 pigs of the treated group, adults of *A. suum* were eliminated within a few days after treatment. However, since *A. suum* eggs were found again 6 weeks later, the treatment was resumed. The growth period of the treated pigs which reached a weight of 80 kg was shortened at least by 2 weeks compared with the untreated pigs (**Table 1**). **Fig. 1** shows an emaciated pig in the untreated group. Based on data collected in Vietnam, it was estimated that the economic loss due to the infection amounted to about 25,000 Don Vietnam (about US\$ 2.0) per head in an experimental farm. Low nutrition level including deficiency in protein and vitamin A may exert more deleterious effects on the growth of infected pigs. Therefore, it is considered that the growth rate of untreated pigs in small-scale farms may be even lower.

As a result, it may be necessary that the farmers use anthelmintics to increase productivity.

Table 1. Body weight of treated and untreated pigs

Remarkable Antimutagenic Effect of a Thai Ginger, Fingerroot

Gassinee Trakoontivakorn^{*}, *Kazuhiko Nakahara*^{*2}, *Makiko Takenaka*^{*3}, *Mayumi Kameyama*^{*3},
Hiroshi Shinmoto^{*4}, *Tadahiro Nagata*^{*5} and *Tojiro Tsushida*^{*3}

**Institute of Food Research and Product Development Kasetsart University, Thailand, *2Crop Production and Postharvest Technology Division, JIRCAS, *3National Food Research Institute, *4Tohoku National Agricultural Experimental Station and *5National Institute of Animal Industry*

It has been suggested that antimutagenic phytochemicals, such as polyphenols, in some fruits or vegetables may play a role in the prevention of cancer based on epidemiological investigations as well as animal model experiments. Several edible plants, such as common ginger (*Zingiber officinale*) and turmeric (*Curcuma longa*), in the family of Zingiberaceae are reported to contain some phenolic compounds that exhibit strong antimutagenic effects. In Thailand, several members of the Zingiberaceae family besides common ginger and turmeric are available in food markets. One of them, fingerroot (*Boesenbergia pandurata* Schl. syn. *Kaempferia pandurata* Roxb.), known as "krachai" in Thailand, has a characteristic appearance with several slender, long tubers sprouting in the same direction from the central part of the rhizome (**Fig. 1**). Fingerroot is generally utilized as a folk medicine in Southeast Asia. Interestingly, fingerroot is used as an ingredient in some dishes in Thailand. Since it had been already reported that fingerroot contains a large amount of some polyphenols as major constituents, it was expected that the plant would display an antimutagenic effect. In the current studies, we examined the antimutagenic properties of fingerroot and determined the chemical structure of active constituents under the JIRCAS Visiting Research Fellowship Program at Tsukuba.

One kilogram of fresh fingerroot rhizomes, purchased in a local market in Bangkok, were homogenized and extracted in 80% methanol. Then, the filtrate was collected, concentrated under reduced pressure and used for an antimutagenic assay (Ames Test). In this study, the antimutagenic effect was manifested by the suppressive activity of the extract toward the mutagenicity of 3-amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (Trp-P-1) with *Salmonella typhimurium* TA98 in the presence of S-9 enzyme, that activates Trp-P-1, prepared from rat liver. The fingerroot extract showed a highly potent antimutagenic activity (**Fig. 2**). Only 0.15 mg of the fingerroot extract almost completely suppressed the mutagenesis, while a Thai spice galanga (*Languas galanga* syn. *Alpinia galanga*) showed about 80% of suppression at the same dose. The antimutagenic effect of both fingerroot and galanga was much more pronounced than that of lemon grass, another common spice in Thailand. It was reported that 10 mg of lemon grass extract suppressed 84% of mutagenesis.

Subsequently, active compounds in the extract were isolated to analyze the antimutagenic properties and chemical structure. Six antimutagenic compounds FR1, FR2, FR3, FR4, FR5 and FR6 were obtained. And, all six isolated compounds exhibited a potent antimutagenic activity in a suppressive range of 90% to 95% at a concentration of 25 μ g/plate. Effective dose of these compounds that can suppress 50% of mutation (ED₅₀) was estimated at 1.1, 0.9, 0.5, 1.0 μ g, for FR1, FR2, FR3 and FR4, respectively. Preparations of FR5 and FR6 could not be used for the experiments and structural determination due to the very small amount obtained. The chemical structure of FR1, FR2, FR3 and FR4 was determined by liquid chromatography mass spectrometry, UV-absorption spectrometry and nuclear magnetic resonance spectrometry. FR1 and FR3 were identified as two chalcone derivatives, 2', 4', 6'-trihydroxy chalcone and cardamonin. FR2 and FR4 were identified as two flavanone derivatives, pinocembrin and pinostrobin, respectively. All of these four identified compounds are not new ones. However, the antimutagenic activity of these compounds had not been reported except for pinocembrin. Edenharder reported that pinocembrin acted as an effective antimutagen against another mutagen, 2-amino-3-methylimidazo[4,5-f]-quinoline (IQ). This was not surprising because Trp-P-1 and IQ are metabolized by almost the same molecular species of cytochrome P450 in S-9.

When rhizomes of fingerroot are utilized as ingredient in Thai dishes, heating is involved in the preparation process. It was reported that antimutagens found in vegetables could be either heat-stable or heat-sensitive. Therefore, heat stability of antimutagens (FR1, FR2, FR3 and FR4) in fingerroot was determined by heating at 105° C for 15 min. No deterioration of the antimutagenic activity of any of the compounds was observed, which is an important information for food ingredients. The results suggested that fingerroot may play an important role in cancer chemoprevention, and, may have a potential as an effective functional food.

<SYMPOSIUM>

The 6th JIRCAS International Symposium: "GIS Applications for Agro-Environmental Issues in Developing Regions" Was Held in Tsukuba

The 6th JIRCAS International Symposium on "GIS Applications for Agro-Environmental Issues in Developing Regions" organized by Japan International Research Center for Agricultural Sciences (JIRCAS) in cooperation with International Center for Tropical Agriculture (CIAT), National Institute of Agro-Environmental Sciences (NIAES), Forestry and Forest Products Research Institute (FFPRI) and National Research Institute of Fisheries Science (NRIFS), was held in Tsukuba, Japan during the period of September 7 – 9, 1999.

GIS technology which involves complex computer-based processing of georeferenced and attribute data obtained from various sources, including remote sensing, provides integrated and updated spatial and temporal information for the inventory and monitoring of environmental resources which are closely related to agriculture, forestry and fisheries activities. JIRCAS is actively implementing GIS-related research in collaboration with various countries in different geographic environments. This symposium offered a unique opportunity to review the studies carried out in this field by JIRCAS and other institutes, evaluate the current status of research and plan for the future.

A total of 155 scientists and administrators including 26 participants from abroad representing 13 countries gathered and exchanged views on the main issues, major constraints of GIS applications in developing regions, as well as the future orientation of the GIS applications in the regions. At the beginning of the symposium, Mr. Sakue Matsumoto, Chairman, Agriculture, Forestry and Fisheries Research Council, Ministry of Agriculture, Forestry and Fisheries gave the welcome address, following the opening address delivered by Dr. Nobuyoshi Maeno, Director General of JIRCAS.

The symposium consisted of two keynote speeches and three sessions as follows. As keynote speakers, Andrew K. Skidmore, ITC, Netherlands and Tsuyoshi Akiyama, Gifu University, Japan, gave lectures on the application of GIS and remote sensing technology for agro-environmental issues in developing regions.

Session 1 reviewed the current status of the development of global data sets and models for agro-environmental sciences. Session 2 dealt with the applications of GIS for agro-environmental issues in various developing regions. During the session, eight presentations covering different geographic environments (Nepal, Indonesia, P. R. China, Mongolia, Colombia, Thailand and Japan) were given. In Session 3, the current status of education and training in the field of GIS was considered. Following the general discussion, Dr. Grant Scobie, Director General of CIAT, delivered the closing address.

The proceedings of the symposium will be published by JIRCAS in early 2000.

<WORKSHOP>

The ICRISAT/JIRCAS International Workshop on "Food Security in Nutrient-Stressed Environments: Exploiting Plant Genetic Capabilities"

The ICRISAT/JIRCAS international workshop on "Food Security in Nutrient-Stressed Environments: Exploiting Plant Genetic Capabilities" organized by the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) and Japan International Research Center for Agricultural Sciences (JIRCAS), was held at ICRISAT-Patancheru, India during the period of September 27-30, 1999.

This workshop marked the culmination of the activities of the Government of Japan Special Project Phase III (1994-1999) on "Sustainable Cultivation of Upland Crops in the Semi-Arid Tropics." The Project funded by the Economic Affairs Bureau, Ministry of Agriculture, Forestry and Fisheries of Japan had been implemented for 15 years since its initiation in 1984 at ICRISAT. During the 15-year period, scientists conducted research aimed at improving crop nutrient and water uptake and utilization efficiency through field management practices and/or by exploiting morphological, physiological and genetic systems to improve the adaptation of ICRISAT mandate crops to the low-nutrient and low-moisture environments of the semi-arid tropics. During the Project, research fellows, visiting scientists and scholars were trained and the technical skill of the supporting staff was eventually upgraded. In conclusion, the Project helped to increase the productivity of upland crops in the semi-arid tropics through research, and enhanced the knowledge base of the mechanisms of phosphorus and nitrogen acquisition by crops. The Project also helped to strengthen interdisciplinary efforts among scientists from Japan and their counterparts at ICRISAT.

From 23 international and national institutes, and universities of 16 countries, more than 50 scientists including 10 scientists from Japan participated in the workshop. Dr. L. D. Swindale, Interim Director General of ICRISAT, who helped initiate the Project in 1984, delivered the welcome address and Dr. T. Hamazaki gave closing remarks. After the Government of Japan Special Project activities were reviewed by the Project leader Dr. J. J. Adu-Gyamfi *et al.*, 31 papers were presented during 4 sessions. Session 1 dealt with the theme "Breeding for low-nutrient environments: is it sustainable?" covering crop physiology, breeding and socio-economic aspects. During Session 2, genotypic variability and mechanisms of nutrient uptake and use efficiency of crop plants in low-nutrient environments were outlined. The research achievements of the Project were presented in this session. During Session 3, the methodology for genetic manipulation of nutrient availability in low-nutrient environments was reviewed while the theme "Combining genetic improvement with natural resources management in low-nutrient environments" was considered during Session 4.

The workshop was successful due to the effort of the organizing committee of ICRISAT to ensure a high standard of paper presentation and discussions. I would like to thank the ICRISAT staff and all the participants in the workshop for their contributions.

The proceedings of the workshop will be published by ICRISAT/JIRCAS within this fiscal year.

Participants in the workshop and the Project staff at ICRISAT

(Tadao Hamazaki)

Workshop and Mid-Term Evaluation Meeting on Northeast Thailand Project

The Workshop and Mid-Term Evaluation Meeting on the Northeast Thailand Project titled: "Comprehensive Studies on Sustainable Agricultural Systems in Northeast Thailand" were held at the International Training Center for Agricultural Development (ITCAD), Department of Agriculture (DOA) in Khon Kaen on September 23 and 24, 1999.

This collaborative project is focused on the area of rainfed paddy fields in Northeast Thailand and aims at the development of technology for

the promotion of sustainable agricultural systems that combine farming with animal husbandry. The project was launched in April 1995 and it will last until the end of March 2002.

The workshop was held on the first day. There were 67 participants including 13 persons from Japan. Thai participants were mainly from Bangkok and from Khon Kaen Province. There were 9 research organizations from Thailand and 5 from Japan. The researchers who had been engaged in the project described the research activities and research highlights. Major topics were as follows: 1. Evaluation and effective utilization of environmental and biological resources in the region. 2. Development of sustainable crop production systems. 3. Improvement of livestock feeding management with locally available feed resources. 4. Development of postharvest technologies for local agricultural products. 5. Economic evaluation of multiple cropping and livestock farming.

On the second day, a field trip and the mid-term evaluation meeting took place at the Khao Suan Kwang Demonstration Farm in the morning and at ITCAD in the afternoon, respectively. About 30 participants joined the morning session in the field and they listened to the outline of the field trials conducted by the researchers. Participants showed a keen interest in the field trials and also in the small-sized agricultural machines and attachments such as soil manipulator, binder, drill seeder and subsoiler, etc. which were displayed at the farm.

The mid-term evaluation meeting was held after the field visit with committee members engaged in various research fields. The outline of the overall project and five research themes was given by concerned scientists prior to the discussion. It was generally agreed by the committee members that satisfactory progress had been made so far, and that for further development of the project, much closer linkage among the project scientists and more active input from socio-economic aspects would be required.

(Masaaki Suzuki)

PEOPLE

Dr. Terunobu SUZUKI, a forestry scientist, became Director of JIRCAS's Forestry Division on October 1, succeeding Dr. Kiyoshi Tanaka who was appointed Director of the Research Coordination Division, Forestry and Forest Products Research Institute. Dr. Suzuki worked as a Senior Research Scientist in the Research Coordination Division, Forestry and Forest Products Research Institute (1997 - 1999) after carrying out studies at the National Amazon Research Institute in Brazil as a team-leader of the Brazilian Amazon Forest Research Project of JICA.

Dr. Osamu ITO who spent three years at the International Rice Research Institute as Director of the Agronomy, Plant Physiology and Agroecology Division returned to JIRCAS on October 1, 1999. He joined the Research Information Division and will be mainly in charge of coordinating the research collaboration between JIRCAS and several research organizations in Thailand, which has been actively promoted for many years.

<AWARD>

Dr. Noguchi Received the 1999 Friendship Award of P. R. China

Dr. A. Noguchi, Director of Crop Production and Postharvest Technology Division, received the 1999 Friendship Award from the State Administration of Foreign Experts Affairs, P. R. China, on account of his major contribution to the implementation of the JIRCAS-China Project titled: "Development of Sustainable Production and Utilization of Major Food Resources in China."

Research Project "Farming Systems in Mekong Delta"

- a Workshop at JIRCAS -

Shigeo Matsui

Under the research project on "Evaluation and Improvement of Farming Systems Combining Agriculture, Animal Husbandry, and Fisheries in the Mekong Delta" a workshop was held on December 8-9, 1997 in JIRCAS International Conference Room to review the project and to develop a closer cooperation with Vietnam organizations. Six researchers from Vietnam headed by Dr. Vo-Tong Xuan, Director, Farming Systems R&D Institute, Cantho University were invited. The meeting started with opening remarks by Dr. Maeno, Director General, JIRCAS and the keynote address of Dr. Vo-Tong Xuan titled "History and future farming systems in the Mekong Delta". Then 4 sessions followed:

In session 1, the farming systems were described with 3 case study reports presented by Mr. Nguyen Xuan Lai, Dr. D. N. Thanh and Mr. Duong Van Ni. Rapid increase in rice production and constraints were outlined. Mr. Ni, Farming Systems R&D Institute reported that in the case of Hoa An village, the introduction of *Melaleuca* trees into farming systems had enabled to plant two crops of rice a year in an area with strongly acidic soils. In session 2 which dealt with technology development, Mr. T. Kon, Tohoku National Agricultural Experiment Station, Dr. S. Yoshihara, National Institute of Animal Health and Dr. M. Wilder from JIRCAS reported on current achievements and constraints in rice production, swine husbandry, and aquaculture, respectively. In session 3, reports by Dr. Yamazaki, Rakuno Gakuen University and Mr. Kosugi, JIRCAS stressed the need for organizing farmers into farmers' cooperatives because credit and/or collective commodity marketing are indispensable for the future development of farming systems. In session 4, Mr. Le Thanh Duong, Farming Systems R&D Institute discussed the problems on the promotion of sustainable agriculture. Mr. N. Vromant, VVOB, Belgium working at the same institute, reported about rice-fish farming systems with emphasis placed on proper water management. Mr. R. Yamada, JIRCAS outlined his plan of research on farm management.

Although rice production has markedly increased in the Mekong Delta, farmers' incomes and living standards have remained low. The workshop concluded that the development of sustainable farming systems which combine rice cultivation, animal husbandry and aquaculture is definitely important. It was also stressed that the creation of viable credit and marketing channels as well as the promotion of technology transfer, etc. is the key to further development of agriculture in the Mekong Delta.

Among the participants, Dr. Matsuno, Tokyo University of Agriculture, Dr. Cho, Kyushu University, Dr. Furukawa, Kyoto University and Dr. Oe, Tokyo University of Agriculture and Technology, old friends of Dr. Vo-Tong Xuan enjoyed their reunion.

Prior to the Workshop, Dr. Maeno, Director General of JIRCAS had attended the ceremony marking the 20th anniversary of CLRRI held at O Mon, Cantho, Vietnam on December 2. He expressed his deep gratitude for the cooperation in the project.

JIRCAS RESERACH HIGHLIGHTS

Collaborative Research with ICIPE:

Edible Insects in East Africa

Shigemi Yagi

More than 500 insect species are used for human consumption in the tropical and subtropical regions of the world. In Africa, many species of insects have been used as traditional foods among indigenous people and have played an important role in the history of human nutrition. Many insects usually considered as crop pests such as locusts, grasshoppers, weevils and some termite species have been used as important food sources. Interviews with 9 main Kenyan ethnic groups and field surveys in western Kenya revealed that at least 8 insect families representing 6 orders are eaten. The major orders of edible insects include *Isoptera* (termites), *Orthoptera* (locusts, grasshoppers, crickets), *Coleoptera* (beetles), *Hymenoptera* (honey bees), *Lepidoptera* (moths) and *Diptera* (lakeflies). The most common edible insects are the termites which are highly appreciated by practically every ethnic group in Kenya. The sexual winged forms (reproductive forms) of termites are frequently caught for food.

Our research in the Maragoli area in western Kenya has shown that villagers can easily distinguish species and the emergence patterns of termites. They apply various methods for catching termites. In one method, they build a tent-like structure consisting of branches and leaves to cover some of the emergence holes (*Photo 1*). By closing the other holes, the termites have to emerge from the holes in the tent structure which has an opening on one side to which the flying termites are attracted by sunlight, artificial light or moonlight. Near this opening, a receptacle is placed to collect the termites. In another method they introduce a light source inside a bucket lined with wet slippery banana leaves, and then the bucket is placed near an active mound. Attracted by the light, termites drop in the bucket. In the dry season, termites can be induced to come out when stimulated by fumes of smoke from burnt dried leaves of specific wild plants or the slow rhythmic vibrations created by striking stones or by beating a large piece of wood with two sticks. A similar drumming technique for collecting termites has been reported in Uganda.

[Photo1 : A termite trap along the road in Maragoli area in western Kenya.](#)

Termites are prepared in various ways for eating. In Enzaro village, Maragoli, it is popular to lightly fry the termites in their own fat over a low heat, add a little salt and sometimes remove the wings. Fried winged termites are tasty after being dried in the sun and they can be consumed for a rather long period of time. In some areas, termites are used as gifts for marriage. Raw termites are also frequently eaten. In some areas of western Kenya, sun-dried termites are packed in various containers and sold during the rainy season in the local food markets. They are sometimes transported over long distances to urban markets of East African large cities such as Kisumu, Kampala or even Nairobi (*Photo 2*).

[Photo2 : Termites sold in an open market in Kampala, Uganda.](#)

Our field surveys, suggest that termites play an important role in daily food consumption in the Maragoli

area in the rainy season, when there is a shortage of maize supply. We concluded that the termites are especially valuable for children and pregnant women which require a high calory diet and nutritious food. Research should be further promoted to create an awareness about the importance of insects as a good and cheap source of lipids and animal protein.

Collaborative Research with IITA:

Traits for Drought Tolerance in Cowpeas

Iwao Watanabe

Three cowpea accessions (TVu 11979, 11986, 12348), which were identified as highly drought-tolerant, yielded about one ton of grain per ha in the dry season at Kano in Sudan Savanna. This trial encouraged farmers to cultivate drought-tolerant cowpea varieties to alleviate food shortage in the dry season and their acreage under cultivation has been increasing in drought-prone areas of Sudan Savanna. However, some of the agronomic traits of these accessions should be further improved. In the breeding programs for tolerance to drought, information on causative traits for the tolerance is important for the selection of progenies after crossing. Therefore, physiological studies were conducted to compare tolerant and susceptible lines.

1. Distribution percentage of dry matter to roots was higher in the tolerant lines. Root weight of these lines increased steadily even at maturity in contrast with the considerable decline in the susceptible ones after flowering. This deep-rooting trait enables plants to collect residual soil moisture receding downwards day by day and to grow vigorously in the dry season. This trait adversely affects the production of grains under well-watered conditions, due to the lower distribution percentage of dry matter to pods. These tolerant lines, therefore, should be recommended as specific cultivars for drought-prone areas or for the introduction of a new cropping system in the dry season.
2. Transpiration rate of tolerant lines under lethal water stress was lower than that of susceptible ones. This trait for economical use of water allows tolerant lines to survive for a longer period of time under lethal water stress.
3. No difference was observed among cowpea lines in the water use efficiency, measured by the increase in the dry matter per unit amount of water lost through transpiration. Photosynthesis/transpiration ratio was also almost the same among the cowpea lines tested. These results suggest that the vigorous growth of tolerant lines in the dry season described earlier must have been due to the active absorption of water and not to the efficient use of water.
4. There are two types of drought in Sudan Savanna. One is the initial drought at the seedling stage. At this stage, roots are short yet and no available moisture remains in the root zone except for the moisture supplied by current precipitation. In this type of drought, therefore, seedlings are faced with lethal water stress. The only strategy for survival until the next rain is the economical use of water. The other type is the terminal drought at the ripening stage due to delayed planting caused by late arrival of the rainy season. At the ripening stage, a fairly large amount of available water remains in deep soil layers. In this type of drought, therefore, the strategy for completing the life cycle and getting seeds for the next generation is the continued absorption of water associated with the deep-rooting traits. In the long history of adaptation of cowpeas to drought-prone areas, they must have acquired the two traits simultaneously, that is the trait for economical use of water under lethal water stress and that for deep-rooting.

Collaborative Research with CIAT:

Mechanism of Adaptation of Upland Rice Genotypes to Highly Weathered Acid Soils of Savannas in South America

*Kensuke Okada and Albert J. Fischer**

Tropical humid savannas which extend over 240 million hectares in South America are covered with highly weathered acid soils (Oxisols and Ultisols). A crop-pasture rotation has been introduced to these under-exploited ecosystems as a sustainable cropping system, in which upland rice is an important component due to its relative tolerance to acidity and infertility of soils. Since upland rice displays a wide range of genotypic differences in tolerance to soil acidity, the lack of suitable screening techniques had hampered rapid development of breeding. Aluminum has been considered to be the major limiting factor for plant growth in acid soils in general, but in the case of savanna soils, deficiency of other nutrients complicates the situation. Therefore, JIRCAS-CIAT collaborative project initiated since 1992, attempted first to identify the major limiting factors for the growth of upland rice on acid savanna soils, then to analyse the mechanism controlling the genotypic differences in the tolerance, in order to contribute to the promotion of efficient methods of breeding of upland rice for tropical savannas.

Field experiments on the response to liming were conducted using both tolerant and susceptible genotypes over a period of 4 years at two sites in the Eastern Plains of Colombia (Llanos Orientales). The acidity of the top soil was found to increase during crop growth due to the accumulation of KCl and urea which were applied sequentially according to farmers' practice. The yield of the tolerant varieties did not respond to lime application, while that of the susceptible ones declined at a very low rate of liming ($< 300 \text{ kg ha}^{-1}$), at which the relative yield (the ratio of yield at low lime rate to the yield at high lime rate (3 t ha^{-1})) of the susceptible varieties correlated significantly ($p < 0.05$) only with the amount of exchangeable Ca of soil (Fig. 1-C).

Other indicators of soil acidity such as soil pH and amount of exchangeable Al did not show any significant correlation with yield decline in the susceptible varieties, and further, the tendency was opposite in terms of indication of soil acidity (Fig. 1-A, B). Al saturation which is the indicator most widely used for soil acidity, was not correlated significantly, either (Fig. 1-D). These results suggested that the amount of exchangeable Ca should be used as indicator of soil acidity for upland rice, rather than Al-related parameters. This finding has a practical implication for the selection of stressful sites for on-site field screening.

Then pot experiments for lime response were conducted using top and subsoils of savanna. In addition to other soil chemical characteristics, aluminum concentration in the soil solution was measured. First, it was found that soil acidity increased gradually as in the case of field experiments, and that where the growth was more suppressed, the soil acidity was more pronounced because the salts were not absorbed

by plant roots but accumulated. Therefore, although the growth of plants was apparently negatively correlated with the concentration of Al in the soil solution, it was found that the high aluminum concentration was not the cause but rather the result of the growth retardation. Also, no varietal differences were detected in the response to Al concentration in the soil solution. Second, total Ca supply (exchangeable Ca of original soil plus applied Ca as lime) determined the total growth even when the results of both top and subsoils were combined. The adaptation of the tolerant variety to low Ca conditions was attributed to the low requirement of Ca when Ca in soil started to be deficient.

Since it was concluded that Ca absorption rather than direct Al toxicity is the key factor which differentiates the degree of tolerance, the relative affinity of Ca and Al to the root cell wall (at the level of which these two elements compete) was investigated by measuring the ion exchange and chelating characteristics of the root tip surface. It was found that the lower interference of Al in the Ca retention by the root cell wall was the main reason for the high efficiency of uptake and utilization of Ca for tolerant varieties.

These results indicate that the better growth of the tolerant varieties at the low lime rate was due to their tolerance to a low Ca supply rather than to tolerance to high Al in acid soils, which has a direct implication in determining the target of both field and laboratory screening tests. It was suggested that the ion exchange and chelating characteristics of the root cell wall should be used as criteria for acid soil tolerance.

China-Japan Joint Workshop Held on "Migration and Management of Insect Pests of Rice in Monsoon Asia"

The rice planthoppers are international insect pests of rice, which undertake long-range migrations from tropical to temperate rice areas in Asia. The collaborative research project on "Long-range migration of rice insect pests in monsoonal East Asia" between JIRCAS and National Agro-Technical Extension and Service Center (NATESC), P. R. China was initiated at China National Rice Research Institute (CNRRI) in 1992. The project which enabled to clarify the dynamic process of the rice planthopper migrations from Indochina to Japan *via* South China, was successfully terminated in January, 1997. In the same year, JIRCAS and CNRRI agreed to continue the research collaboration on rice planthoppers, shifting the research focus from migration to management for the subsequent 5-year period.

Taking this opportunity, JIRCAS organized the China-Japan Joint Workshop on "Migration and Management of Insect Pests of Rice in Monsoon Asia" in collaboration with CNRRI and NATESC to review the collaborative research project and to promote the new JIRCAS-CNRRI project on "GEU-based IPM (Integrated Pest Management) for migratory insect pests of rice in China". The Workshop was held during the period 27-29, November, 1997 at CNRRI. Eighteen speakers were invited, including 7 overseas participants from Korea, Laos, Myanmar, Philippines, Taiwan and Vietnam. The Workshop started with introductory remarks on the management of insect pests of rice in China by NATESC, and reviews of planthopper migration studies in Japan and China by JIRCAS and CNRRI, respectively. The Workshop program was divided into the migration and IPM sessions. A study report on computer simulations of windborne migrations developed by JIRCAS, and 6 case studies on migrations to South and Central China, Taiwan, Ishigaki Island, and Korea were presented in the "Migration Session". The "IPM Session" consisted of 4 country reports on the ecology and management of rice planthoppers and other insect pests in Vietnam, Laos, and Myanmar, and 2 papers on theoretical approaches for sustainable pest management in rice ecosystems. In the "Closing Session", monsoon-linked long-range migrations of rice planthoppers, practical significance of insect resistance in rice in IPM, and new paradigms for rice pest management were highlighted and subjected to discussions. (*Kazushige Sogawa*)

3rd Seminar on *Brackish Water Project* Held in Malaysia

On December 8-9, 1997, the 3rd "Brackish Water Project" seminar was held in the Conference Room of the Institute of Postgraduate Studies and Research, University of Malaya in Kuala Lumpur, Malaysia. This seminar is held annually as a part of the comprehensive project on "Productivity and Sustainable Utilization of Tropical and Subtropical Brackish Water Mangrove Ecosystems." The project aims to evaluate the productivity of such areas and identify the criteria for sustainable utilization. The west coast of Peninsular Malaysia was selected as the study area due to the presence of various types of mangrove forests. Counterpart organizations include the Fisheries Research Institute (FRI), the University of Malaya (UM) and the Forest Research Institute of Malaysia (FRIM).

Subjects addressed in the seminar were as follows: 1) Water quality, 2) Forest and litter fall, 3) Food web, 4) Meio and macro-fauna, 5) Socio-economic aspects and policy, and 6) Fish and prawns. About 40 scientists from Japan, England, and Malaysia participated in the seminar, and fourteen papers were presented.

During the 3rd seminar, Professor T. K. Mukherjee, Dean, Institute of Postgraduate Studies and Research, University of Malaya gave a welcome address, Dato' Mohd. Mazlan b. Jusoh, Director General, Department of Fisheries gave an opening address, and Dr. Shiro Uno of JIRCAS made closing remarks.

During the two days' seminar, it was concluded that the research surveys conducted in 1996-1997 in the unexploited mangrove brackish water area had been completed and that in future the surveys should be concentrated in areas subjected to deforestation such as the Lumut mangrove area (Dinding river) in Perak State. The 5th JIRCAS International Symposium:

Postharvest Technology in Asia – A Step Forward to Stable Supply of Food Products –

The symposium on “Postharvest Technology in Asia” organized by JIRCAS will be held in Tsukuba, Japan during the period of September 9-11, 1998.

In Asia, agricultural research so far has been mainly centered on the improvement of crop production itself to achieve self-sufficiency in food in order to support the growing population of the respective countries. It is anticipated that, in the near future, the food supply problems will become more complex as patterns of food consumption have improved in the region along with the increase of income and social development.

Postharvest technology, which encompasses issues ranging from harvesting methods in farmers’ fields to food processing, should be more emphasized to prevent crop losses and for utilizing agricultural products efficiently to meet the changes in the food demand, especially the demand for processed foods. Food industries are closely related to crop production in the region but due to the lack of proper technology, sound progress of the food industry can not be fully achieved. In this Symposium, the development of the food industry in Asia will be reviewed and the basic technical problems involved for future progress will be outlined.

The Japan International Research Center for Agricultural Sciences (JIRCAS) is implementing collaborative projects in Asian countries and “postharvest technology” should receive more attention in future research collaboration. Development of “postharvest technology” could contribute to securing a stable supply of food products in addition to the increase of agricultural income and improvement of the diet in the developing regions of Asia.

The symposium program consists of a keynote speech and three sessions as follows:

Keynote Speech

Keiji Kainuma (BRAIN, Japan)

Session 1: Main Priorities and constraints in postharvest technology in Asia

Priorities and constraints of postharvest technology:

- | | |

PEOPLE

New Visiting Researchers in Okinawa

Nine visiting researchers will participate in JIRCAS Visiting Research Fellowship Program in Okinawa to carry out collaborative research focused on important topics related to tropical agriculture until September, 1998.

- Development of techniques for environmental control by using plants and microorganisms specific to the tropics and subtropics

El Khawas Hussein (Egypt) **Wang Bujun** (China)

- Studies on the mechanism of heat tolerance of tropical and subtropical and microorganisms specific to the tropical and subtropical crops

Liu Jian (China) **Yakubov Bakhtiyor** (Uzbekistan)

- Identification and evaluation of self-tolerant crops

Safdar Hussain Shah (Pakistan) **Li Chengyun** (China)

Sumanasinghe Vithanaarachchige Ariyawanse(Sri Lanka) **Masood M. Shahid** (Pakistan)

- Evaluation and development of long-term conservation techniques of genetic resources of vegetatively propagated crops in the tropics and subtropics

Narinder Pal Singh Dhillon (India)

Dr. Iwao Watanabe Biological Research Division was appointed as Deputy Director General of the Food and Fertilizer Technology Center in Taipei. He is going to assume the post from April 7, 1998. Dr. Watanabe has worked as senior researcher in the field of plant physiology and cultivation management for the Tropical Agriculture Research Center and JIRCAS since 1990. During this time, he was based at the International Institute for Tropical Agriculture for the collaborative research on drought tolerance in cowpea from 1990 to 1992. Dr. Watanabe received an award from the Japanese Society of Tropical Agriculture on March 27, 1998 for his research at IITA (related article in Research Highlights). The award is given to a researcher in recognition of his contribution to agricultural research for the tropics.

[Photo : Dr. I. Watanabe with Mr. Akin at IITA Kano station, Nigeria.](#)

Dr. Akinori Noguchi, a food scientist, became Director of JIRCAS's Crop Production and Postharvest Technology Division on March 1, succeeding Dr. Koji Kawashima who became Professor at Seitoku University. Dr. Noguchi worked as a Research Coordinator for China in JIRCAS's Research Information Division (1996-1998) after carrying out studies at the National Food Research Institute as the Head of Food Engineering Laboratory.

Social Sciences at JIRCAS

Kunio Tsubota

Director, Research Information Division

One basic feature that differentiates JIRCAS from its predecessor, the Tropical Agriculture Research Center (TARC) is the increased role of social sciences in the research activities. This reflects the fact that food and agriculture problems are becoming more global, complex and inter-linked. Even for research and development projects, many developing countries often express their concern about the socio-economic implications, sustainability, and environmental aspects of the developed technologies. It is widely recognized that these issues can be better addressed through a close collaboration between natural and social scientists.

The recent trend of JIRCAS to place more emphasis on multidisciplinary and comprehensive projects follows the same line. JIRCAS is convinced that project goals are better achieved if social scientists work together with natural scientists before and during the project. Social scientists are often expected to play a bridging role in a multidisciplinary project by considering individual technologies within a broader context of the socio-economy of the countries concerned. Nowadays agro-economists and rural sociologists are expected to play an important role in the JIRCAS comprehensive projects.

In the Mekong delta project, agro-economists are evaluating the sustainability and expansion capacity of the specific crop-livestock-fish farming system. This would assist, in particular, the natural scientists who are dealing with technological problems relating to pig raising and aquaculture. In the northeastern Thailand project, economists are projecting the demand for livestock products and analysing the comparative advantage of various farm and non-farm sectors, while other researchers carry out studies on the improvement of cropping systems as well as feed supply capacity including the use of sugarcane by-products as cattle feed. A rural sociologist and economists are carrying out preliminary studies to assess the validity of the farming systems research approach in Indonesia which may result in a more efficient dissemination of improved technologies.

Apart from the social scientists engaged in the collaborative projects overseas, some JIRCAS economists are conducting more general studies at the headquarters, including world demand-supply projections and policy simulations based on econometric models. The models can illustrate possible changes in world commodity markets under different scenarios. As an example, by linking these models with national models, we expect that more precise predictions will be made for specific commodities such as soybean in Brazil. Attempts are also made to modify the models so that environmental factors can be incorporated

The methodologies used by JIRCAS social scientists vary. Many rely on econometric methods while some use farm budget or cost-benefit analysis. Others adopt more qualitative or institutional approaches including farming systems research.

In spite of the growing demand, currently JIRCAS has only a few social scientists in its staff. To fill the gap, two institutes affiliated to MAFF, the National Research Institute of Agricultural Economics and the National Agriculture Research Center, assign their economists and sociologists to work as short-term visiting researchers in JIRCAS projects abroad. Some visiting foreign researchers who stay at JIRCAS also assist JIRCAS social scientists in such fields as econometric analysis or country economic studies.

Economic Models for Brazilian Farm Management

Hideki Ozeki

JIRCAS has been implementing the collaborative research project titled "Development of Agro-Pastoral Systems in the Subtropical Area of Brazil" with EMBRAPA in Brazil since 1996. As part of this project, Dr. Yoshihiko Sugai and myself have been constructing economic models in collaboration with several economists of EMBRAPA for evaluating the Brazilian agro-pastoral sector from both micro and macroeconomic viewpoints. The selection of appropriate models is an important issue. In this study, three models were used for evaluating the sector at different levels. The models consist of 1) evaluation model for agro-pastoral systems at farm level, 2) spatial equilibrium model at regional and national levels (EMBRAPA) and 3) input-output model for agro-industries at national level. Each model can work independently, but will be linked by using simulation results from the other models as exogenous variables. In addition, 4) assistant external systems for the three economic models supply exogenous factors.

The first evaluation model for agro-pastoral systems, based on revised linear programming method, aims at evaluating the financial superiority of improved agro-pastoral farming systems i.e. the mixed, multiple-cropping systems with crop-pasture rotation. It examines the optimum resource allocation to the farm of the new technology.

The second spatial equilibrium model has been developed by EMBRAPA to evaluate the new agricultural technology and policies at the national level. It takes account of the geographic conditions as well as economic conditions and thus calculates the optimum allocations of production units including agro-pastoral ones. A trial calculation (SEA/EMBRAPA, 1998) shows that optimization of present resource allocation raises the quantity of grain production by 20% over the actual level of the 1993~95 period. If 70% of the farmers were to adopt the improved technology, grain output would increase by 53%. Though the farmers in the grain production area are willing to introduce the improved technology, poor transportation network discourages their activities and leaves the potential unexploited.

The model is built mainly for the grain sector presently, but in the near future, plans are made to include the livestock sector too. Moreover, geographic information system (GIS) will be introduced into this model to visualize the large output produced by the simulation.

The third input-output model for agro-industries evaluates the impact of the changes in the macroeconomic conditions, for instance, the changes in total agricultural output, grain import prices, etc. Especially it enables to analyse quantitatively the nation-wide relationships among agriculture, food processing industries and other related industries. As the categorization of input-output tables published by IBGE (Instituto Brasileiro de Geografia e Estatística) is too simple, the tables were rearranged based on a definite mathematical model. Fig. 1 depicts a part of the estimation results. It assumes first that the soybean exports could increase by 1 million tons as a result of changes in the agricultural policy or trade policy. In the first scenario, 1 million tons of soybean are assumed to be exported as grains (CASE 1). In this scenario, 167 million R\$ of GDP (Gross Domestic Product) could be induced mainly in the soybean production sector, while the impact on the other industries and services is likely to be negligible. The second alternative assumes that 1 million tons of soybean are exported in the form of soybean products (oils, card, etc.) (CASE 2). In this scenario, 283 million R\$ of GDP will be induced in the soybean

production sector, the vegetable oils industry and other industries. This trial calculation suggests that the economic impact of exports as "processed and value-added products" will be larger and broader than in the case of "primary or raw materials".

The fourth assistant external systems include the 1995 Agricultural Census published by IBGE and the world food model developed by JIRCAS. We plan to incorporate the results of former large statistics and the latter into the economic models and to develop a data bank of census results to enable researchers to retrieve these data easily.

Projecting the Future World Food Situation

Osamu Koyama

The situation of food supply and demand in the future is a matter of serious concern. The issues currently addressed are whether agriculture in the world will be able to continue to supply adequately food to the increasing population, and whether the present regional imbalances in food supply will be solved in the future. If these issues are solved, what will be the price level and the technological level? To answer these questions, many research organizations are conducting analyses on the future food supply and demand situation. JIRCAS also examines the future orientation of agricultural technology development, analyses domestic and overseas policies for agriculture and conducts projection studies.

For the past 35 years, mankind has succeeded in achieving a food production level above population increase. The relative price of grains has declined almost consistently. Thus, many projections relying on long-term past trends all reach optimistic conclusions. However, the recent trends, mainly those of grains, have led to some discrepancies about the future situation. In the late 1980s, the world food output per capita began to decrease, along with issues related to the degradation of the global environment, stagnation in technical development and lower investment in agriculture. Consequently discussions about the world production potential have been rekindled.

Econometric models are widely used in many projections. In the models, the relationship among various factors to the food supply and demand is translated into formulae in an econometric way using past and present data. The International Food Policy Simulation Model (IFPSIM) used at JIRCAS is such a model (Fig. 1). It consists of a combination of 14 main food commodities models. It covers the entire world divided into 31 countries and regions.

[Fig. 1. Data flow chart of IFPSIM \(example of cereals for a region/country\). \(36KB\)](#)

The external conditions given to the model and the parameters in the model determine the outcome of the projections. Especially important are the rates of population growth, income rise, technological changes related to yield per unit acreage, etc. Income elasticity, the factor indicating the impact of income on demand for food, plays a decisive role, too. According to the tentative baseline projection to the year 2020, the rate of increase of grain production will amount to about 2% per year, a higher value than the estimated population growth. The demand for soybeans and livestock products is estimated to be much higher than the population increase. The key to a higher food supply in the future is a higher yield per unit area. The yield level is markedly affected by, among others, the ratio of irrigated areas and that of areas planted with high-yielding varieties. In addition, the input of fertilizers and agricultural chemicals will be an important factor in the future. Further econometric analyses of these elements are required.

Fig. 2 shows the outcome of several scenarios studies, one of the advantages of model analysis. In the scenario where the rate of increase of the yield of crops will gradually decline to half of the recent trend owing to the environmental issues and limited supply of resources, it is anticipated that world grain prices continue to rise. In the second scenario a wide crop failure of grains and soybeans is predicted leading to high prices of agricultural commodities. It is feared that such high price levels will adversely affect low-income countries relying on inexpensive imported food. In the third scenario where it is predicted that prices will decrease, it is assumed that economic growth will slow down. However, it

should be noted that lower food prices do not always result in a higher nutrition level.

[Fig. 2. Simulation of grain price \(index: 1992=100\). \(36 KB\)](#)

In a quarter of century from now, the need for increasing food production may become less acute than presently. However, it may not be possible to continuously increase production or to keep the current production level in future without sacrificing resources and the global environment. On the other hand, even an optimistic forecast warns that the 800 million undernourished population in the world may not decrease appreciably. Through the modeling studies attempts are made to examine the overall direction of problems facing world agriculture. The outcome of these studies should provide a clearer view of the issues which may become beyond control unless serious attention is being paid now.

Research Collaboration with CASER Focusing on the Farming Systems Research Experiences in Indonesia

*Junko Goto and Henny Mayrowani**

CASER, the Center for Agro-Socio-Economic Research, and JIRCAS have started a new collaborative research project. This new study currently titled "A study on the farmer-state linkages in upland farm development in Indonesia" aims to trace the history of FSR development in Indonesia and to conduct an in-depth case investigation of the extent of farmers' participation in the on-going FSR activities. Here, we would like to introduce briefly the background and key questions of our proposed research.

Since the heyday of the Green Revolution in the 1970s, a farming systems approach has become a popular exercise among researchers, extension workers, and agricultural officials working in and for the developing countries throughout the world. Though diverse in methods and applications, it emphasizes a farmer-first attitude and bottom-up participatory procedure as well as a multi-disciplinary team play. Indonesia is no exception. The history of farming systems-oriented research in Indonesia can be dated back to the period of cropping systems research in the early 1970s under the strong influence of IRRI. Agricultural research in those days focused mainly on lowland, i.e., rice production, so that the large growing population would not go hungry. FSR gradually expanded to rainfed areas and, to some extent, to less-favored agricultural areas such as swamp areas and upland areas.

The diversity of agroecosystems and the complexity of traditional agricultural practices prevailing in Indonesia offered an ideal ground for field investigations. Over the years, FSR incorporated various new challenges for the agricultural research community by exploring crop-livestock integration, agroforestry practices, rice-fish production combination, and so forth. Some latest studies also emphasize social and economic issues such as gender perspectives, credit institutions, and marketing strategies for farming households and communities. What can we extract from this rich, yet, rather unexplored history of research efforts? How was the English term "farming systems research" interpreted and adopted? How can we find the interaction between the foreign influence and the indigenous elements? And how can we identify the current position of farming systems research in Indonesia? These are our basic questions.

We would like to elaborate a little on the "who" question--the main actors in the implementation of FSR in Indonesia. In the 1970s and early 1980s, the technical and financial assistance from outside the country played an important role in disseminating the concept of farming systems approach, training the researchers and extension workers, and formulating various on-farm research projects. The degree of foreign commitment may vary from one project to the other. Nevertheless, the Indonesian research institutes under the Agency for Agricultural Research and Development (AARD) of the Ministry of Agriculture became the core organizations for FSR activities.

AARD organizations have undergone several changes during the past quarter of century reflecting the changing needs and priorities for agricultural research of the people and the government. Historically, the current Central Research Institute for Food Crops (CRIFC) has been the leading institute in organizing FSR, while other institutes such as Animal Sciences Institute, Horticulture Research Institute, and CASER also took part in the FSR activities as supporting institutes. In spring 1995, as part of the effort to decentralize the AARD system and to promote locally adaptive research, Assessment Institutes for

Agricultural Technology (AIATs) were established throughout the country to carry out region-specific research and extension. CASER was assigned to supervise the activities of AIATs in conjunction with CRIFC and other AARD institutes. Thus, AIATs have become the leading agents for the promotion of farming systems approach. At present, SUTPA (*Sistem Usahatani Berbasis Padi dengan Orientasi Agribisnis*) program, rice-based market-oriented farming systems research program, is the best known operation for most AIATs. Yet, AIAT activities are not limited to lowland, rice-based areas. In spite of the abundant evidence of high expectation for their work, there seems to be a lack of information regarding their day-to-day operation, coordination with local governments and other agents, and linkage and interaction with local farmers. Who will work with AIATs in specific localities? How do local farmers perceive their efforts? We would like to adopt a case analysis approach in answering these questions.

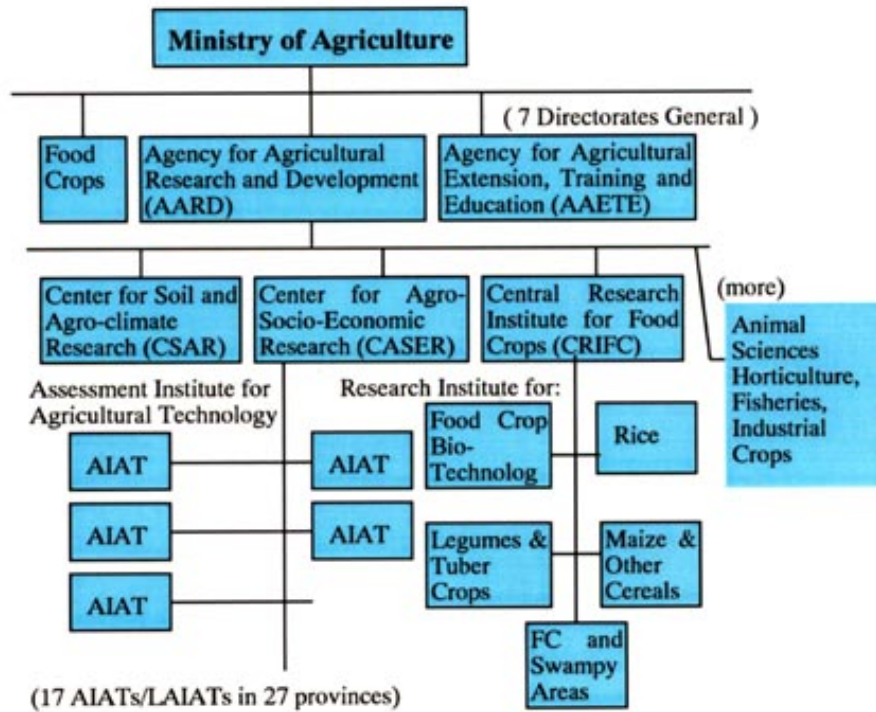

Since 1995, CASER has organized several research projects on various aspects of AIATs activities with some assistance provided by ISNAR and IBRD. Compared to this rather large-scale, top-down examination, the proposed study should adopt a low-key, bottom-up approach in clarifying the role of AIATs, the challenges and limitations they face, and possible innovations and improvements in the existing system. We will use the case of an on-going farming systems research project for upland areas conducted in West Java as a window and the broader historical review as background. We expect that this study will generate a dialogue across disciplines and enhance communication and coordination between researchers and extension workers.

Demand for Livestock Products and Feed in Southeast Asian Countries: Preliminary Projections

Hiroaki Kobayashi

The trend of feed demand in so-called "Dynamic Asia" will play an important role in this field. The current study aimed at estimating the potential demand for livestock products and feed in the near future in some Southeast Asian countries, i.e., Thailand, Indonesia, the Philippines and Malaysia.

We attempted to estimate the demand for livestock products and subsequent feed demand, maize in particular by a simple model. Detailed analyses of feed grains production will be conducted in future studies. Although the model in this study is still incomplete, we estimated the potential demand for maize for feed use in the above four countries up to the year 2004. The ongoing model comprises 43 equations. Feed production in these countries seems to have peaked in recent years, and the potential demand in the future may affect the world grain market directly (Fig. 1).

[Fig. 1. Balance of feed grains: Thailand. \(37KB\)](#)

Table 1 shows the estimated results of demand functions of livestock products. While income elasticities of demand for meat and eggs in Thailand are 0.22 and 0.21, respectively, the elasticities of other livestock products are relatively high, indicating that a larger increase in demand associated with economic growth can be expected. Price elasticities of demand for meat and eggs are estimated to be very low, i.e., in the range from -0.01 to -0.12 , because we used maize prices in the world market as proxies of those of the final products. Price elasticities for dairy products were estimated to be much higher.

[Table 1. Results of estimation of elasticities of demand \(4KB\)](#)

Using the estimation results of demand functions, we projected the potential demand for livestock products under the following three scenarios:

Scenario I: Economic growth rates follow the past trend during the period from 1983/84 to 1993/94, except for 0% for the Philippines. Exchange rates are fixed at the 1994 levels.

Scenario II: Economic growth rates are halved, with 0% for the Philippines. Exchange rates are fixed at the 1994 levels.

Scenario III: Economic growth rates are the same as those in Scenario II. Exchange rates are fixed at the March 1998 levels after 1998.

Then we linked estimation results of domestic production of livestock products to a potential demand for feed, i.e., maize. The amount of products was converted to an equivalent of protein contents in this linkage. We handled only maize, because it is the dominant element of feed grains, and the share of maize was in the range of 82-88% in the four countries. The next main component is rice bran or wheat bran which hardly responds to changes in the demand for feed.

Some of the preliminary results are summarized in Table 2 and the potential demand for maize forecast

for each scenario is as follows:

Scenario I: Malaysia continues to lead in terms of per capita consumption of livestock products. Per capita consumption of meat and eggs in Thailand does not increase appreciably, reflecting the relatively low income elasticities estimated. Sharp increases in meat consumption in the Philippines are generated only by the trend variable, which may lead to an overestimation to some extent. The consumption of maize in these four countries, which is deduced from livestock production, is predicted to increase roughly by 6 million metric tons (mt) from 11.9 million mt in 1994 to 17.9 million mt in 2004.

Scenarios II & III: It is obvious that the increase in consumption of the various livestock products will be lower than that predicted in Scenario I. The difference between the results of Scenario II and those of Scenario III is deduced from the difference in the prices of the products according to the lower exchange rates. We observe that economic growth is the main factor in promoting consumption of livestock products, except in the case of the Philippines where 0% economic growth is assumed. The devaluation of currencies affects more seriously the consumption of dairy products. The total maize consumption is forecast to increase by roughly 4.5 million mt to 17.5 million mt in the year 2004 in Scenario II and by roughly 4.1 million mt to 16.1 million mt in Scenario III.

[Table 2. Projections of potential demand for livestock products \(8KB\)](#)

International Meetings Organized by JIRCAS

International Contribution of Japan and ILRI to World Animal Production Research

Joint workshop of JIRCAS with International Livestock Research Institute (ILRI) was held on February 13, 1998 in the International Conference Room of JIRCAS.

The main purpose of this workshop was to discuss matters related to the future strategy and orientation of livestock research, as well as to enhance the relations in collaborative research not only between ILRI and JIRCAS but also between ILRI and other Japanese institutes in charge of animal sciences.

Collaborative research between the Tropical Agriculture Research Center (TARC) and former International Laboratory for Research on Animal Diseases (ILRAD) and International Livestock Center for Africa (ILCA) and subsequently between JIRCAS and ILRI covers a history of 18 years. In 1980, TARC initiated a joint study on theileriosis with ILRAD in Kenya. During these 18 years, JIRCAS sent 8 researchers on long-term assignments and 7 short-term visiting scientists.

Japanese researchers dispatched to ILRAD and ILRI had conducted basic research for developing a new vaccine to prevent theileriosis. They obtained excellent results in investigations on the transmission of theileriosis. JIRCAS also sent a researcher to develop statistical methods for evaluating the productivity of milk and meat, and the adaptability of African cattle to their environment.

ILRI is a new institute established in 1995 after the fusion of ILRAD and ILCA among the CGIAR Centers. It has attempted to extend its scope of research activities to Asian developing countries under a new mandate.

This workshop was organized by the Agriculture, Forestry and Fisheries Research Council Secretariat of MAFF, Japan, JIRCAS and ILRI in collaboration with the National Institute of Animal Industry, National Grassland Research Institute and National Institute of Animal Health under the sponsorship of Japan Livestock Technology Association.

The workshop emphasized the importance and significance of the future strategy and orientation of livestock production research in Asian developing countries. Also valuable information was exchanged throughout the discussions, which enabled to deepen mutual understanding and collaborative relations between the Japanese and ILRI scientists toward the 21st century. (*Eitaro Imaizumi*)

Seminar on "No-tillage Cultivation and Future Research Needs" for the New Soybean Project

JIRCAS has initiated a research collaboration with MERCOSUR countries for a 10-yr (1997-2006) project titled: "Comprehensive Studies on Soybean Improvement, Production and Utilization in South America". For the implementation of the collaboration, Dr. Nobuyoshi Maeno, Director General of JIRCAS visited Brazil, Paraguay and Argentina in March 1998 and signed the Record of Discussions Relating to Research Collaboration with the Ministry of Agriculture and Livestock, Paraguay (MAG) and the National Institute of Agricultural Technology, Argentina (INTA). With the Brazilian Agricultural

Corporation (EMBRAPA), this project is the second comprehensive project following the "Agro-Pastoral Project" which has been carried out since 1996.

To commemorate the initiation of the project, the seminar titled "No-tillage Cultivation and Future Research Needs" was held on March 5-6 in Foz do Iguassu, Brazil under the joint organization of JIRCAS and the Centro Tecnológico Agropecuario en Paraguay (CETAPAR-JICA). It was the 1st JIRCAS seminar on soybean research in South America. From 6 countries, 60 scientists participated and exchanged views on the current situation of and future prospects for no-tillage cultivation system as well as on the potential demand and uses of soybean. The proceedings of the seminar will be published by JIRCAS. (*Makie Kokubun*)

USM-JIRCAS Joint International Conference on "Acacia Species-Wood Properties and Utilization" in Malaysia

The International Conference on "Acacia Species-Wood Properties and Utilization" organized by Universiti Sains Malaysia (USM) and JIRCAS was held in Penang, Malaysia during the period March 16-19, 1998.

Fifty scientists from 7 countries, participated in the conference and discussed the current situation of *Acacia mangium* utilization. During the meeting, the need for carrying out further research on the wood properties of *Acacia mangium* and promoting a better utilization of the species was emphasized. Twenty five papers and 6 posters were presented in the 4 sessions. In a post-conference tour, most of the Japanese participants observed a movable sawmill set up in the thinning area of a 11 years *Acacia mangium* plantation in Selangor, Malaysia. (*Koichi Yamamoto*)

JIRCAS also organized a workshop on "Water Management and Agriculture in Malaysia" to which representative from relevant organizations in Malaysia were invited during the period March 25-27, 1998.

In addition, delegates from Indonesia, Malaysia, the Philippines and Thailand participated in a workshop on "Aquaculture and Environmental Problems in Southeast Asian Countries" organized by JIRCAS during the period March 26-30, 1998.

During these two workshops' discussions were held to further promote collaborative research activities between some of these organizations and JIRCAS.

Next

Forthcoming Workshop

JIRCAS/IPGRI Joint International Workshop:

Cryopreservation of tropical plant germplasm

JIRCAS and International Plant Genetic Resources Institute (IPGRI) are jointly organizing an International Workshop entitled: "Cryopreservation of tropical plant germplasm: Current research progress and applications". This workshop will take place at JIRCAS in Tsukuba, Japan from the 20 to 23 October, 1998.

In the traditional method of conserving the genetic resources of recalcitrant seed species and vegetatively propagated crops, whole plants are maintained in the field. There are, however, several serious problems with field genebanks, including exposure to natural disasters, attacks by pests and pathogens, and high maintenance costs. The Global Plan of Action for the Conservation and Sustainable Utilization of Plant Genetic Resources for Food and Agriculture has identified the development of safe and cost-effective techniques for the long-term conservation of these problem species as a priority research area.

For long-term conservation of problem species, cryopreservation is the only method currently available. Dramatic progress has been made over recent years in the development of new cryopreservation techniques and cryopreservation protocols have been established for over 100 different plant species. However, cryopreservation of tropical and sub-tropical species has been less extensively investigated than that of temperate species.

An increasing number of National Programmes in the tropics are initiating research activities in this area. The workshop will provide a unique opportunity for cryopreservation researchers to gather and meet leading scientists in this field, and to discuss numerous aspects of cryopreservation of tropical plant species. The objectives of the Workshop are:

- To assess the current state of the art, present application of and existing problems with cryopreservation of plant germplasm, with emphasis placed on tropical species
- To identify priority areas for collaborative research, technology development, transfer and application

The tentative program of the workshop which will include oral and poster presentations is as follows:

- 1 - fundamental aspects of cryopreservation
- 2 - case studies (cells, embryos, pollen and apices)
- 3 - applications of cryopreservation in the genebank context
- 4 - country reports
- 5 - general discussion

PEOPLE

Takahiro INOUE, a soil scientist, became Director of JIRCAS's Research Planning and Coordination Division on April 1, 1998, succeeding Dr. Keiji Ohga who became Professor of Tokyo University. Before joining JIRCAS, Dr. Inoue was Director of the Department of Research Planning and Coordination at Kyushu National Agricultural Experiment Station. As a TARC (predecessor of JIRCAS) member, he carried out "Studies on the Increase of Productivity of Upland Soils in Thailand" in collaboration with the researchers of the Department of Agriculture of Thailand from 1980 to 1984.

Kenji MURAKAMI became Director of JIRCAS's Administration Division on April 1, 1998. He was until recently Deputy Director of the Policy Planning Division, Fisheries Agency, Ministry of Agriculture, Forestry and Fisheries (MAFF). He also worked at the Economic Affairs Bureau and Agricultural Structure Improvement Bureau previously.

Tsuguhiko HOSHINO, a wheat and barley breeder, became Director of JIRCAS's Biological Resources Division on April 1, 1998, succeeding Dr. Teruo Ishige who was transferred to MAFF's Research Council Secretariat. During his former assignment at Chugoku National Agricultural Experiment Station, he was head of the Research Planning Section. In 1986 and 1987, he spent two and three months, respectively, at ICARDA as visiting scientist.

Building New Structures for Collaborative Research

Nobuyoshi Maeno
Director General

During the time of the Tropical Agricultural Research Center (TARC), the predecessor of JIRCAS, collaborative research was conducted primarily in individual fields of research with particular research organizations in specific countries. There is no doubt that, based on unidisciplinary collaborative research efforts under such institute-to-institute relationships, we have obtained numerous valuable research results.

However, when TARC was reorganized into the present Japan International Research Center for Agricultural Sciences (JIRCAS) in 1993, the scope of our research objectives and, concomitantly, the number of partner countries and regions in our cooperative research program widened considerably. In order to respond to this newly expanded mandate within the constraints of limited resources, an emphasis on collaborative research and research structures differing from those previously utilized became necessary. As a result, a variety of new initiatives have been undertaken since the start of JIRCAS. One such initiative involves efforts to strengthen comprehensive research programs aimed at systematic multidisciplinary research in complement to the unidisciplinary approach characteristic of the past. At present, comprehensive research projects are underway in Thailand, Vietnam, Malaysia, the People's Republic of China, Brazil, Indonesia, etc.

As the scope of our research has broadened from unidisciplinary to multidisciplinary, the number of research organizations in partner countries with whom we maintain relationships has also quite naturally expanded. Consequently, institution-to-institution relationships of the past have become what might be called government-to-government relationships. As a result, relationships with partner countries have become more formalized and systematized.

These changes have allowed JIRCAS to pursue a broad range of additional international initiatives, some of which are described below.

Multinational Initiatives

In one new initiative, we have developed structures allowing us to implement research in collaboration with multiple countries regarding research problems spanning broad areas. Our collaborative soybean research project with the MERCOSUR countries (Brazil, Paraguay, and Argentina) provides one example. It marks our attempts since the days of TARC to move from cooperative relationships with individual countries toward cooperative multilateral relations within which we can work together with several countries simultaneously. Through these efforts, we have become better able with limited research resources to implement efficient and effective collaborative research for addressing problems common to several countries.

Furthermore, in the South American soybean project, we have created new research systems amenable to the participation of experts outside those organizations formally affiliated with the Ministry of Agriculture, Forestry and Fisheries. These arrangements might be described as the practical application of the power of post-doctoral research, as they allow JIRCAS to complement the abilities of its own staff by adopting, for relatively long periods of time, outside experts to assist with multinational research projects. Many of these researchers have previously accumulated invaluable experience in conducting collaborative research in targeted areas of the developing world.

Additionally, in our comprehensive project on the "Sustainable Production and Utilization of Major Food Resources in China," we have made possible the participation of researchers from Japanese prefectural agricultural research organizations, which often conduct research highly relevant to the developing areas with which JIRCAS is most concerned. Now, in cooperation with JIRCAS, these organizations can take advantage of opportunities to dispatch personnel overseas and develop links with foreign countries.

Through these initiatives, the Center hopes to be able to plan for further expansion in the ranks of researchers interested in international agricultural research collaboration, particularly with developing countries.

New Cooperative Relationships with CGIAR Centers

Since the beginning of Fiscal Year 1997, we have been promoting a project on "New technologies for agricultural research" in cooperation with the International Service for National Agricultural Research (ISNAR). The project will be funded with a special allotment to ISNAR from the Japanese Ministry of Foreign Affairs, but JIRCAS has been selected to cooperate in the implementation of technical matters. This marks for us a new cooperative relationship with one of the international research organizations under the umbrella of the Consultative Group on International Agricultural Research (CGIAR). Up to this point, we have had relationships in which JIRCAS researchers are dispatched to CGIAR research organizations and utilize available research infrastructure to implement particular research projects. Hereafter, however, it will be necessary to expand these types of new cooperative relationships.

With the restructuring of TARC into JIRCAS, our mandate has grown. Because it would prove difficult to respond to this new mandate using only established methods, new structures for research cooperation are becoming increasingly necessary. Therefore, in the future, by commissioning research to organizations in developing countries and by devising a variety of other new structures, we hope to realize more efficient, effective cooperative research.

Government of Japan Special Project at ICRISAT

Hiroshi Nakano

JIRCAS scientists have been involved in the Government of Japan (GOJ) Special Project carried out at the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India. In the research project, since 1994, the collaborative studies with ICRISAT scientists have dealt with the "Physiological and Genetic Adaptation of Sorghum and Pigeonpea to Low Nutrient Availability in the Semi-arid Tropical Environment". Mandate crops of ICRISAT are pigeonpea, sorghum, pearl millet, etc. which are cultivated in areas where the soil and climatic conditions are very severe in Asia and Africa. Drought stress in rainfed agriculture and low level of soil nutrients are the main constraints for the production of the crops in these areas. Many new varieties and hybrids of sorghum and pigeonpea have been released by ICRISAT and national institutes of tropical countries but these modern varieties require good cultivation conditions to perform well. However, many farmers can not use inputs for the production of such low income crops. Sorghum and pigeonpea are cultivated mainly under rainfed conditions and without fertilizer application. Recently many studies have been conducted to develop technologies for increasing the yield in low fertile land without irrigation and with limited application of fertilizer, that is, technologies for low input and sustainable agriculture. Scientists of the previous GOJ special project teams at ICRISAT also directed their attention to such research and they investigated the mechanisms whereby sorghum, pigeonpea, etc. take up low available soil nitrogen and phosphorus. We intended to expand the soil and plant nutrition studies by introducing genetic aspects.

Sorghum and pigeonpea were investigated through two main approaches; 1) screening of genotypes which are highly adapted to low nitrogen and low phosphorus contents in soil and 2) plant nutrition studies on nitrogen and phosphorus uptake and translocation and assimilation in the crop organs. Varieties of both crops show a wide genetic diversity in terms of plant morphological and physiological characteristics. For example, plant height which widely ranged from 50 cm to 300 cm reflected the high genetic diversity of the sorghum germplasm (**Photo 1**).

[Photo 1: Local sorghum variety with a long stem \(50KB\)](#)

ICRISAT preserves many germplasm accessions of both crops. We anticipate that some germplasm useful for the enhancement of adaptability to low available nitrogen and phosphorus will be identified in the large gene bank. Field screening tests of varieties of both crops have been carried out in experimental fields with low nitrogen and phosphorus fertility at the ICRISAT campus (**Photo 2**).

[Photo 2: Screening test of sorghum varieties at ICRISAT campus \(30KB\)](#)

The results indicated that genetic diversity could be detected in the adaptability of sorghum and pigeonpea to low soil phosphorus and in the adaptability of sorghum to low soil nitrogen availability. On the other hand, physiological studies on phosphorus uptake and assimilation in sorghum showed that there were genotypic differences in the "production efficiency of phosphorus" that is expressed by the plant biomass production per unit amount of phosphorus absorbed by roots. On the other hand, nitrogen studies in sorghum showed that the roots of some of the varieties display a high activity in soil nitrogen uptake, especially after the heading stage. We expect that these findings will contribute to further development of the studies carried out within the framework of the GOJ Special Project at ICRISAT.

Research on Mangrove Forests in Matang Forest Reserve, Malaysia

Ochiai Yukihito

About 200 km north of Kuala Lumpur, the capital city of Malaysia, the Matang Mangrove Forest Reserve near Taiping city extends over 40,711 ha. This forest reserve is famous for its sustainable management. With a 30-year rotation, *Rhizophora apiculata* (one of the major species of mangrove there) can be harvested for charcoal and also planted at the same time as harvest.

JIRCAS comprehensive research project entitled: "Productivity and Sustainable Utilization of Brackish Water Mangrove Ecosystems" is being carried out in this area. This project is implemented jointly by the Fisheries and Forestry Divisions of JIRCAS, University of Malaya, Fishery Research Institute of Malaysia and Forest Research Institute Malaysia. The participants in the project carry out investigations on mangroves, crabs, plankton, fish, human activities, etc. to evaluate the concept of sustainable management of mangrove forests.

The term "mangrove" refers to the plant community in an intertidal area. Mangroves capture and intercept any objects and organisms flowing from the upper stream, hence their importance for the production of fishery resources as well as their role in the protection of the environment.

Every organism in a mangrove forest depends on the mangroves and productivity depends on that of the trees. As a part of this project, the Forestry Division of JIRCAS has analysed the litter fall in three different types of mangrove forests. Litter fall refers to anything that falls from mangrove trees. Three types of forests including a) mixture of *Avicennia* spp. and *Sonneratia* spp., b) *Rhizophora* spp. and c) *Bruguiera* spp. are common mangrove forests in this area. The distance separating type a) from the sea is shortest, followed by b) and c). According to the measurement of the water level, the maximum water level of type a) is about 90 cm above the land surface and that of type b) is 70 cm during the spring tide (**Fig. 1**).

[Fig. 1. Water level of forest type a\) mixture of *Avicennia* spp. and *Sonneratia* spp. and forest type b\) *Rhizophora* spp., measured from November 11 to 20, 1996. \(24KB\)](#)

Type a) is under water 16 hours a day during the spring tide and 10 hours a day during neap tide, type b) 11 hours and 8 hours, while even during the spring tide, type c) is slightly above the water level most of the time. The difference in the type of vegetation is considered to be resulted from the water level.

Total weight of litter fall in types b) and c) is very similar (**Fig. 2**), while that of type a) is half that of b) and c). Despite the difference in total weight, the rate of leaf weight is similar in all the forest types. The leaves account for 56-58% of the total weight, which implies that leaves are the major components of litter fall in all the forest types, followed by branches.

[Fig. 2. Litter fall of three different forest types from January 1996 to January 1997. \(25KB\)](#)

The mangrove tree is unique not only by its shape but also by the movement of the fallen leaves. In lowland and hill forests which occur in Peninsular Malaysia, most of the fallen leaves are decomposed on the forest floor. On the other hand, in a mangrove forest, many fallen leaves are flown to the sea by water during both spring and neap tides in type a). In type b), the fallen leaves are flown by water during the spring tide although most of the leaves remain during the neap tide. Most of the leaves remain during both spring and neap tides in type c). The movement of the leaves determines the fertility of the soil and food chain of the mangrove ecosystem.

Although the flora of mangrove forests is relatively simple compared to that of the other forest types in Malaysia, it prevents the land from sinking in water and protects the sea from pollution with trash. Unfortunately, mangroves are disappearing rapidly due to the development of fish or prawn ponds and other human activities. Matang can be an outstanding example of sustainable forest management.

Development of SURIMI Made from Freshwater Fish Meat in China

Yutaka Fukuda

It is no exaggeration to say that a new source of animal protein appeared in the latter half of the 20th century, namely freshwater fisheries resources produced mainly by aquaculture technology in inland water regions of China. The freshwater fisheries catches have increased rapidly after the economic reform movement, and reached 10,780,000 tons in 1995. This amount corresponds to about 10% of the world total catches and about 43% of the Chinese total catches. Freshwater fisheries play a significant role in the diversification of the food production structure in the world. Therefore, the developing countries which face a lack of animal protein are being encouraged by this success in China.

On the other hand, regardless of the rapid increase of the catches of freshwater fisheries resources, the infrastructure relating to the distribution, storage and processing is not well developed in China. Since most of the freshwater fishes are transported as live fishes without any treatments, their distribution sphere and storage period are very limited. Recently, postharvest loss of freshwater fishes has become significant. If this problem is not addressed, the plan for increasing the production of food resources in China might be jeopardized.

To improve the postharvest problems, JIRCAS launched a collaborative research project entitled "Development of Technology for Utilization of Freshwater Fisheries Resources" with the Shanghai Fishery University in 1996. We are promoting the development of processing technology for frozen "surimi" from freshwater fish meat. Surimi is originally a Japanese term and an intermediate foodstuff with high potential for long frozen shelf-life and for the production of a variety of texturized products such as crab analog. Surimi is generally manufactured by applying a simple technology through the washing of the minced meat by water, dehydration, and mixing with cryoprotectants.

We carried out studies on the gel-forming ability of the surimis made from Silver carp, Bighead carp and Grass carp, which are the main freshwater fish species in China, compared with Alaska pollack surimi, a typical commercial marine fish surimi which accounts for more than 60% of the production in the world.

The three-dimensional configuration of the gel strength which depended on the heating temperature and time was classified into two types (**Fig. 1**). That is, the surimi of Silver carp and Bighead carp showed the shape of a U character as in the case of Alaska pollack, while that of Grass carp showed the shape of a plateau.

[Fig. 1. Gel-forming properties of surimis of freshwater fishes in China and Alaska pollack depending on the heating temperature and time. \(26KB\)](#)

The surimis of Silver carp and Bighead carp form a gel by heating at low temperature (around 30°C) and high temperature (around 85 °C), though the gel tends to collapse by heating at an intermediate temperature (around 60 °C). The formation of a gel of fish surimi by heating at a low temperature is called "setting". The strength of setting gels of both surimis was further enhanced by subsequent heating at 85 °C for 30 min (two-step heating), though being slightly inferior to that of Alaska pollack. Consequently, it was demonstrated that Silver carp and Bighead carp surimis display a high gel-forming ability, though it is necessary to select a narrow range of heating temperatures.

Next, Grass carp surimi displays a wide range of optimum heating temperatures and time zones, though it does not show the setting phenomenon and the enhancing efficiency by two-step heating. Consequently, it was concluded that Grass carp surimi which forms a gel in a wide range of heating temperatures, is more advantageous although the gel-forming ability is lower than that of the former two.

We were able to determine that the main freshwater fish species of China can be utilized as raw materials of surimi.

Introduction of Small Machinery into Upland Cropping Systems in Northeast Thailand

Photos: (121KB)

a): Seeding of corn with rotary drill seeder

b): Cutting of green manure with flail mower

c): Weeding with soil manipulator

d): Herbicide application with shoulder broadcaster

Improvement of field operations is indispensable for the development of sustainable agriculture since crop production largely depends on human labor. Therefore, it is necessary to reduce heavy work and to develop efficient production systems to increase the income of farmers.

Recently, within the framework of the collaborative research project entitled: "Comprehensive Studies on Sustainable Agricultural Systems in Northeast Thailand", JIRCAS has introduced several agricultural machines consisting of a tractor and attachments, and some small items of equipment to facilitate field operations. The tractor (25ps) was purchased in Thailand and four attachments, i.e., rotary tiller, drill seeder, flail mower and boom sprayer were sent from Japan. Soil manipulator or small hand tractor and shoulder broadcaster for crop tending between rows of crops were also introduced.

For the setting-up of machinery and guidance for operation, an expert in agricultural machinery Mr. Haruo Tamura, Head of Field Management Section, Crop Production and Postharvest Technology Division, JIRCAS was dispatched to Thailand. To complete the technology transfer, a demonstration entitled "Use of small machinery in farming" was held on June 17, 1998 at Khao Suan Kwang Demonstration Farm, International Training Center for Agricultural Development (ITCAD) to illustrate the use of this machinery for field operations. Some 60 people from agricultural administration, extension offices, research institutes and Khon Kaen University participated in the demonstration and exchanged views on farm mechanization. Highlights of the demonstration are as follows.

Land preparation with rotary tiller drew a great deal of attention. Although mechanized disk plough is commonly used for tillage to plant cassava or sugarcane, soil is not fine enough for seed bed preparation for legumes, vegetables or corn. It was shown that the use of a rotary tiller enabled to improve labor by fine harrowing of the field. Drill seeder, attached to the back of a rotary tiller, can perform the following operations: grooving, fertilizer application, seed laying and soil compaction in a single operation. This system is useful to save labor and also to secure good germination of crop seeds through elaborate land preparation and constant depth of seeding. Flail mower is used for cutting weeds or green manure into small fragments. Many questions were raised on the suitability of the machinery for green manure application or mulching since management of organic matter is laborious under tropical conditions. Boom sprayer is used for the application of pesticides or herbicides by tractor drive. Application is uniform and accurate with the use of a boom which extends horizontally over a distance of 5 m.

Soil manipulator for weeding and ridging and shoulder broadcaster for the application of granular pesticides and fertilizer are used for crop tending. Small and light body is suitable for transportation to the field and for the operation without requiring much experience. Price and means of introduction were the main interest of the participants in terms of availability of the machinery.

Although the purpose of machinery introduction in this project was mainly for the convenience and promotion of field research, the demonstration may have attracted the attention of the participants to the possibility of developing agricultural mechanization in Northeast Thailand. However, prior to the introduction of such machines, it is necessary to conduct a detailed economic analysis on the advantages of agricultural mechanization along with studies on soil erodibility in this region and on the design of machines most adapted to the conditions prevailing in Northeast Thailand.

Opening Ceremony of JIRCAS Beijing Office

On June 10, 1998, Japan International Research Center for Agricultural Sciences (JIRCAS) held the official opening ceremony of the JIRCAS Beijing Office. Actually, in November 1997, JIRCAS had opened the office in a room of Beijing Friendship Hotel near the Chinese Academy of Agricultural Sciences (CAAS) after consultation with the bureau concerned of the People's Republic of China (P. R. C.).

[Photo 1: Dr. N. Maeno, DG of JIRCAS, giving his address at the opening ceremony of the JIRCAS Beijing Office \(25KB\)](#)

From Japan, 15 persons including Mr. Sakue Matsumoto, Chairman, Agriculture, Forestry and Fisheries Research Council (AFFRC), Ministry of Agriculture, Forestry, and Fisheries (MAFF), Mr. Toshiaki Namba, Director, International Research Division, AFFRC, Dr. Nobuyoshi Maeno, Director General, JIRCAS, and the members of the Embassy of Japan at Beijing, attended the ceremony.

From P. R. C., 31 persons were on hand to celebrate the occasion. Main guests were Mr. Lu Ming, Vice Minister, Ministry of Agriculture, Mr. Gan Zuofu, Minister-Counselor, the Embassy of P. R. C. at Tokyo (former Deputy Director General, Department of International Cooperation, Ministry of Agriculture), Mr. Du Ying, Director, Department of Policy, Reform & Law, Mr. Wang Youtian, Assistant Counselor, Department of Science and Technology, Ms. Chen Fengrong, Deputy Director, Department of Agricultural Resources Management and Regional Planning, Ms. Ye Zhen Qin, Deputy Director General, Department of Agriculture, Mr. Liu Guangming, Research Center for Rural Economy, Professor Lu Fei Jie, President, CAAS, the staffs of the Institutes of CAAS, the members of Jilin Academy of Agricultural Sciences, the members of institutes affiliated to the Chinese Academy of Sciences, and Mr. Wang Wenzhe, President, China National Food Industry Association. Representatives of the Chinese press such as the Hsinhua News Agency, Renmin Ribao (the People's Daily News) and the Farmers' Daily News were also invited.

The ceremony started with opening remarks by Mr. Matsumoto followed by addresses by Vice Minister Lu, and then by Dr. Maeno. Dr. Maeno emphasized, in his address, that JIRCAS planned to collaborate actively in solving "problems in agricultural fields" which are a major issue in P. R. C. Dr. Maeno mentioned that such an objective could be achieved based on the results obtained during the studies carried out formerly by the Tropical Agriculture Research Center (the predecessor of JIRCAS) or JIRCAS in collaboration with various research institutes of P. R. C., including the development of rice varieties with cold or disease tolerance, and of high-yielding varieties through the utilization of genetic resources at Yunnan Academy of Agricultural Sciences, as well as the first comprehensive research project with P. R.C. (from 1997 to 2003) on the "Development of Sustainable Production and Utilization of Major Food Resources in China" by integrating the existing collaborative research projects.

Returning the compliment, CAAS President Professor Lu delivered a congratulatory address in which he stated that he expects that the new Japan-China comprehensive research project will be successful and contribute to further development of Japan-China collaboration in research in the field of agriculture.

The new comprehensive research project is composed of wide-ranging research fields from social sciences to natural sciences, involving 10 research institutes of P. R. C., 8 research institutes of MAFF including JIRCAS, and several prefectural research institutes. Exchange of information and researchers between P. R. C. and Japan along with the opening of the Beijing office should contribute to further promoting the Japan-China research collaboration.

International Symposium on "Plant Signaling"

The International Symposium on "Plant Signaling: Molecular Responses to Environmental Stimuli and Stress" organized by Japan International Research Center for Agricultural Sciences (JIRCAS), in conjunction with the RIKEN Institute and BRAIN (Basic Research Activities for Innovative Biosciences) was held at JIRCAS, Tsukuba, on August 12, 1998. This symposium was organized to gather scientists who are focusing their research on plant signal transduction and responses to the biotic and abiotic environmental stresses and exchange information and ideas for the future.

[Photo: Discussions at the International Symposium on "Plant Signaling" \(23KB\)](#)

In recent years, food supply and environmental deterioration problems on a global scale have become increasingly critical, especially in the developing regions. Biotechnology could be a useful method to increase food production through the development of crops with improved tolerance to biotic and abiotic environmental stresses. To develop stress-tolerant crops, basic research on plant molecular biology is important. Recently, considerable progress has been made in understanding how plants sense and respond to various stimuli in their environment.

Molecular and genetic approaches have led to considerable progress in elucidating how environmental stimuli and stress elicit the production of second messengers, how plant cells perceive the messengers, as well as in the induction of specific responses and the physiological consequences. The most active scientists in the area of research on molecular responses to environmental stimuli and stress were invited to present papers at the symposium. From 10 countries, 191 scientists participated in the symposium. Dr. Nobuyoshi Maeno, Director General of JIRCAS and Dr. Keiji Kainuma, Vice President of BRAIN gave the welcome address. A keynote lecture was delivered by Prof. Nam-Hai Chua, Rockefeller University, USA and 10 foreign scientists from USA, France, Germany, England, Austria and 4 Japanese scientists presented papers during the three sessions as follows: Ethylene signaling and biotic stress response, ABA signaling and water stress response and Short talks. The symposium was successful and valuable information was exchanged throughout the discussions.

PEOPLE

Takasuke ISHITANI, an agricultural chemist and expert in postharvest technology, became Director of JIRCAS's Research Planning and Coordination Division on September 1, 1998, succeeding Dr. Takahiro INOUE who was appointed Deputy Director General, Tohoku National Agricultural Experiment Station (TNAES). Before joining JIRCAS, Dr. Ishitani was Head of the Department of Research Planning and Coordination at TNAES. He has gained an extensive experience in the field international collaboration in agriculture and fisheries, as a lecturer for various training courses on postharvest technology in China, Peru, India and ASEAN countries and as a guest speaker at international meetings.

Mitsugu SHIMIZU, veterinarian (animal virology), succeeded Dr. Eitaro IMAIZUMI as Director of JIRCAS's Animal Production and Grassland Division on September 1. He carried out research at the National Institute of Animal Health (NIAH) (1968-1995). During his assignment at NIAH, Dr. Shimizu was posted as a visiting scientist at USDA, Plum Island, USA for two years (1973-1975) and was involved in the JICA's animal health projects in Mexico (1981-1982, 1985-1986 and 1992). Before joining JIRCAS, he was Head of the Planning Section, Department of Planning and Coordination, NIAH.

Improving Heat Tolerance of Crops

Masaharu Yajima

Associate Director for Research, Okinawa Subtropical Station, JIRCAS

The Okinawa Subtropical Station of Japan International Research Center for Agricultural Sciences (JIRCAS Okinawa) is located in Japan's southernmost city, Ishigaki. By taking advantage of the subtropical climate, research is being carried out to develop techniques which will contribute to the promotion of agriculture in the tropical and subtropical areas.

Heat tolerance is one of the major themes taken up at the Station to promote and increase crop production in those areas. For example, vegetables are mainly cultivated during winter and spring in Okinawa and it is very difficult to grow temperate vegetables during the summer season.

Therefore, attempts were made to overcome this shortcoming at the Station through the evaluation of the germplasm collected from Southeast Asian countries and foreign research institutions including CIAT, USDA, etc. By screening the germplasm for heat tolerance, a heat-tolerant snap bean variety "Haibushi" was eventually developed (Haibushi means "southern star" in Okinawa dialect). We anticipate that "Southern Star, Haibushi" will pave the way for the development of crop varieties with higher heat tolerance by conducting further research on the mode of inheritance of heat tolerance and physiological mechanisms.

Therefore, the five-year research project entitled: "Inheritance and Physiological Mechanism of Crop Heat Tolerance and Development of Heat-tolerant Crops" has been initiated in collaboration with research teams from several universities since the end of September, 1998. This project is financed by Bio-oriented Technology Research Advancement Institution (BRAIN). Dr. Yoshinobu Egawa, Head of Crop Introduction and Cultivation Laboratory, JIRCAS-Okinawa is assuming the leadership of the project. This project consists of four research teams with the following themes and research contents.

(1) Genetic and physiological mechanisms of crop heat tolerance during the reproductive process(JIRCAS-Okinawa)

By comparing the heat-tolerant genotype of a crop with heat-sensitive genotypes, the following aspects will be studied: 1) the stage at which plants are most sensitive to high temperature during the reproductive process, 2) the organs or tissues which are damaged by high temperature, 3) growth response of heat-tolerant genotypes under high temperature conditions, 4) QTL mapping and genetic regulation of heat tolerance of crops.

Under heat stress conditions, small-heat-shock-proteins (sHSP) are sometimes observed in plant. Role of sHSP and their function under heat stress are also studied by this team.

(2) Improvement of heat tolerance by functional modification of mitochondria (Ryukyu University)

Active oxygen sometimes injures organic substances inside the cell. Injury is mainly generated at the level of mitochondria and its generation is accelerated under high temperature conditions through the process of respiratory electron transport chain in mitochondria. In this research, the physiological and genetic role of mitochondria will be specified with reference to heat tolerance of crop at the mitochondria-DNA level and attempts will be made to develop heat-tolerant crops by functional modification of mitochondria.

(3) Gene transfer for heat tolerance and functional analysis of its recombinant (Nagoya University)

Under stress conditions such as cold or salinity, some of the tolerant plants show an accumulation of glycine betaine inside the cells. It is considered that this accumulation is related to some protection mechanisms from environmental stresses. Transgenic rice plants which harbor the pathway of glycine betaine synthesis are expected to be heat-tolerant due to a similar mechanism. This team will examine the transgenic plants to clarify further mechanisms of plant response to heat.

Since it is assumed that crop productivity decreases under high light intensity, gene expression of heat tolerance will also be examined by transferring related genes for controlling photo-respiration and elimination of active oxygen. Through collaboration with other teams, heat tolerance-related genes will be transferred into tomato and other plants.

(4) Functional characterization of acetylcholine-esterase for heat tolerance of plants (Tokyo University of Agriculture)

Acetylcholine (Ach) is a well-studied chemical transmitter in the synaptic junction for the opening of cation-selective channels in nerve synapses of animals. In plants, it is known that Ach is induced by environmental stimuli, such as heat stress, salinity stress and gravity, affecting calcium ion concentration and safranin transport. Especially, heat stress induces an elevation of calcium ion concentration and activity of acetylcholine-esterase (AChE) in plant cells. Further research on the function of Ach and AChE will be studied and transgenic

plants will be produced by isolating the AchE gene to develop heat-tolerant plants.

Through this research project, we hope to elucidate physiological aspects of "Heat Tolerance of Crops" and to contribute to crop breeding in order to develop heat-tolerant crops.

5th JIRCAS International Symposium on Postharvest Technology in Asia Was Held in Tsukuba

The 5th JIRCAS International Symposium on "Postharvest Technology in AsiaA step forward to stable supply of food products" organized by Japan International Research Center for Agricultural Sciences (JIRCAS) in cooperation with the National Food Research Institute (NFRI), National Agriculture Research Center (NARC), Food Forum Tsukuba and Nestle Science Promotion Committee was held in Tsukuba during the period 9-10 September, 1998.

[Photo 1: Speakers with other participants \(from right to left, the sixth person in the front line: Mr. Sakue Matsumoto, the fifth person in the next line: Dr. Keiji Kainuma, the fourth person in the same line: Dr. Nobuyoshi Maeno\) \(27KB\)](#)

Although the development of technology for increasing crop production, remains essential, "postharvest technology" was selected as theme for the symposium by JIRCAS for the first time, since the development of postharvest technology is becoming increasingly important.

Indeed in Asia, it is anticipated that, in the near future, the food supply problems will become more complex as patterns of food consumption have improved in the region along with the increase of income and social development. Postharvest technology should be more emphasized to prevent crop losses and for utilizing agricultural products efficiently to meet the changes in the food demand, especially the demand for processed foods. Food industry is closely related to crop production in the region but due to the lack of proper technology, sound progress of the food industry can not be fully achieved. In this Symposium, the development of the food industry in Asia was reviewed and the basic technical problems involved in future progress were outlined.

From 21 countries including African countries, nearly 230 scientists and administrators, (59 from abroad) gathered and exchanged views on the main priorities and constraints of postharvest technology in Asia, and on the current situation and future orientation of technology for grain storage/preservation and food industries in Asia.

Mr. Sakue Matsumoto, Chairman, Agriculture, Forestry and Fisheries Research Council gave the welcome address. A keynote speech was delivered by Dr. Keiji Kainuma (former Director General of JIRCAS), Vice President, Bio-oriented Technology Research Advancement Institute (BRAIN), Japan, and 18 papers were presented during the three sessions.

JIRCAS is implementing collaborative projects in Asian countries and "postharvest technology" should receive more attention in future research collaboration. Development of "postharvest technology" could contribute to securing a stable supply of food products in addition to the increase of agricultural income and improvement of the diet in the developing regions of Asia.

The Proceedings of the Symposium will be published by JIRCAS.

Photosynthesis in Longan and Mango as Influenced by High Temperatures under High Irradiance

*H. Fukamachi**, *M. Yamada***, *S. Komori**, and *T. Hidaka**

**Okinawa Subtropical Station, JIRCAS*

***Persimmon and Grape Research Station, National Institute of Fruit Tree Science*

The combination of high temperature and irradiance is a common characteristic in the tropical and subtropical regions. Fruit species originating in those regions may be adapted to these climatic conditions, but the differences in adaptability to these conditions are not well-known. The objectives of our studies were 1) to compare gas exchange characteristics of longan and mango leaves upon exposure to high temperature and irradiance and 2) to examine the mechanisms contributing to the variation in the response of the net photosynthetic rate to high temperature and irradiance.

Leaves of 2-year-old longan and mango seedlings were exposed to high irradiance ($2000\frac{1}{4}\text{molem}^{-2}\text{esec}^{-1}$) provided by metal halide lamps at $70\pm 5\%$ RH. Temperature was raised by increments of 3°C every 1.5 h, from 30 to 36°C . Net assimilation rates decreased for both species as temperature increased, but the decline was greater in longans than in mangoes (**Table 1**). As temperature increased, stomatal conductance decreased and intercellular CO_2 concentration increased for both species, especially longans. A significant positive correlation was found in longan between stomatal conductance and net assimilation rate at 30 and 33°C , but not at 36°C . In mangoes, the correlation coefficient was significant at all 3 temperatures. Intercellular CO_2 concentration and net assimilation rate were not closely related at 30 and 33°C , but showed a strong negative correlation at 36°C in both species. These results indicate that the decline in net assimilation rate was caused by non-stomatal limitations at high temperatures. In further experiments, the extent of decline in the chlorophyll fluorescence ratio (variable (Fv) to maximum fluorescence (Fm)) caused by high temperature treatment (up to 45°C) was greater in longans than in mangoes (**Table 2**), suggesting that mango leaves are more tolerant of high temperatures than are longan leaves.

Antioxidant and Antimutagenic Properties of Some Edible Thai Plants

Kazuhiko Nakahara* and Gassinee Trakoontivakorn**

*Crop Production and Postharvest Technology Division, JIRCAS

**Institute of Food Research and Product Development, Kasetsart University, Bangkok, Thailand

Several hundreds of native plant species are used for daily diet in Thailand as vegetables, fruits, spices and condiments. Many of them are also employed for traditional medicine. Edible plants in Thailand are rich in phytochemicals such as vitamins, terpenoids, flavonoids, alkaloids, organosulfur compounds, pigments and other phenolics. Since such phytochemicals exhibit various biological activities, it has been suggested that edible plants in Thailand may play a role in the prevention of human chronic diseases as well as cancer. In this regard, the "functionality" of such edible plants is being emphasized. However, since this aspect has been investigated in only a few Thai plants, under the JIRCAS Visiting Research Fellowship Program at Tsukuba, a total of 47 species (48 samples) of edible plants from Thailand were collected and their methanolic extracts were analyzed in relation to two important functions, antioxidant activity and antimutagenicity. The results are summarized as follows.

1. Antioxidant activity

Molecular oxygen is easily converted to reactive free radicals called "oxygen free radicals" (ORF) *in vivo*. ORFs are formed by the transfer of one electron to the oxygen molecule during various physiological processes such as respiration chain, oxygenase reactions and cellular immunization reaction. ORFs damage the cell membrane, cytosolic molecules and genes, and they are associated with the incidence of various chronic diseases, *i.e.* heart diseases, thrombosis, hypertension and cancer. It has been suggested that the ingestion of dietary antioxidants that suppress the ORF production or scavenge ORFs may prevent harmful effect of ORFs. Some phytochemicals, *i.e.* flavonoids, pigments and antioxidative vitamins, are known to be potent antioxidants. We determined the antioxidant activity of methanolic extracts from edible Thai plants by the β -carotene bleaching method. The data obtained are summarized in **Fig. 1**. We found that more than 70% of Thai plant species showed a very high (+++) and high (++) antioxidant activity, while only one-third of common edible plants in Japan exhibited a high activity. Especially, three plant species (4 samples) showed a significantly potent activity. "Pak kra doon" (**Photo 1**; *Careya sphaerica* Roxb.), a leafy vegetable, exhibited the highest activity (121.0 mg BHA equivalent /g dry weight). The leaf of "Pak sa meg" (*Syzygium gratum* Wall.), and the fruit and the leaf of "Kra thin" (*Acacia farnesiana* Willd.) also showed a high activity (40.2, 38.8 and 44.7 mg BHA equivalent /g, respectively).

[Fig. 1. Antioxidant activity \(upper\) and antimutagenicity \(lower\) of edible plants in Thailand and Japan. \(22KB\)](#)

2. Antimutagenicity

Heterocyclic amines and polyaromatic hydrocarbons are considered to be the major cause of cancer due to their potent carcinogenicity. They are formed during the daily cooking process and commonly occur in food. Burnt grilled fish or smoked foods contain a mutagenic heterocyclic amine, 3-amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (Trp-P-1). Trp-P-1 acquires genotoxicity after being converted to N-hydroxy Trp-P-1 by hepatic enzyme cytochrome P450 monooxygenases (P450). N-hydroxy Trp-P-1 is easily transformed to its radical, which reacts with DNA to induce frame-shift mutation. In the present study, we examined the suppressive activity of Thai vegetables towards the mutagenicity of Trp-P-1 with *Salmonella typhimurium* TA98 in the presence of S9 mix. *S. typhimurium* TA98 is a mutant of *Salmonella* bacteria that requires histidine to grow (*his*⁻), owing to mutation in a gene for histidine biosynthesis, and S9 mix is a mutagen-activating metabolic enzyme system from rat liver homogenate containing P450. The activated mutagen induces reverse mutation, and resulting wild-type revertants (*his*⁺) can grow in the histidine-deficient medium. If a plant extract inhibits the reverse mutation, the number of wild-type revertants must decrease. By this method, we observed that several plant extracts have a potent inhibitory effect on the mutagenicity of Trp-P-1 (**Fig. 1**). The methanolic extracts from 1.25 mg of freeze-dried "Pak pai" (**Photo 2**; fragrant knotweed; *Polygonum odoratum* Lour.), that is a common condiment in Thailand and Vietnam, suppressed 96% of the mutagenicity of 50 ng Trp-P-1, followed by "Pak chee" (coriander; *Coriandrum sativum*; 94%), "Hoom yae" (*Trachyspermum roxburghianum* Craib; 92%) and "Pegah" (Indian trumpet flower; *Oroxylum indicum* Vent.; 90%).

The antioxidant activity (AA) was classified into four ranks by the inhibitory activity: +++, very high (≥ 20 mg BHA equivalent /g); ++, high (20 - 3.6 mg BHA eq./g); +, low (3.6 - 0.75 mg BHA eq./g); -, negative (≤ 0.75 mg BHA eq./g). The antimutagenicity; +++, very high ($\geq 80\%$); ++, high (80 - 60%); +, low (60 - 40%); -, negative ($\leq 40\%$).

Collaborative Research on Interspecific Hybrids of Rice at WARDA

Fig. 1. WARDA and its member countries

Rapid demographic expansion and urbanization in Africa led to changes in food preference toward rice and bread which can be more easily prepared than traditional food-stuffs. These patterns are especially evident in West Africa where the substitution of rice for coarse grains and traditional root and tuber crops has fueled growth in demand at an annual rate of 5.6% between 1961 and 1992.

The demand for rice in sub-Saharan Africa is growing faster than for any other major food staple, with consumption increasing across all the socioeconomic classes. Rice is no longer a luxury food and the poorest urban households in West Africa derive larger shares of their cereal-based calories from rice than do higher income households, and rice purchases account for a greater part of their total cash expenditure. Rice availability and rice prices impact directly on the welfare of the poorest West African consumers who experience the lowest rate of food security.

The increase of rice production in Africa is hampered by a number of constraints, including diseases and pests, weed infestation, inadequate water management, soils with a low fertility, and lack of suitable varieties. In sub-Saharan Africa, farmers cultivate two species of rice, African rice (*Oryza glaberrima*) and Asian rice (*Oryza sativa*). Although *O. sativa* is preferred by African farmers due to its higher yield potential, *O. glaberrima*, the indigenous domesticated species, has several advantages over *O. sativa*, such as high weed competitiveness, resistance to drought, soil acidity, rice yellow mottle virus, African rice gall midge. Most of the improved varieties currently available to farmers have been developed from Asian *O. sativa* germplasm recently introduced that has yet acquired little resistance to the stresses prevailing under the environmental conditions of West Africa.

Following the initial breakthrough at WARDA in producing fertile progenies of interspecific hybrids, an Africa/Asia joint research project on interspecific hybridization of rice was initiated in January 1997, under the aegis of the Japan/United States Common Agenda for Cooperation. Funding and technical assistance were provided by the Government of Japan, the United Nations Development Program (UNDP), and the Rockefeller Foundation. The main objective of the project is to improve the welfare of rice producers and consumers by developing rice varieties adapted to low input-management through interspecific hybridization, that are well suited to resource-poor farmers in West Africa.

The new interspecific progenies include a significant percentage of intermediate types combining the seedling vigor, high tillering and weed suppression traits of *O. glaberrima* with the panicle and grain type characteristics of *O. sativa* and are considered to be promising as new breeding materials. Further efforts for combining a high-yielding ability and stress tolerance are now being emphasized at WARDA.

Within the framework of the WARDA's mid-term strategies, JIRCAS initiated a collaborative research project at WARDA from April this year to implement the hybridization project by sending senior researchers to WARDA to take up the following research topics:

- 1) Genetic and eco-physiological characterization of indigenous rice varieties and interspecific progenies, with emphasis placed on tolerance to drought and acid soil conditions.
- 2) Studies on socio-economic aspects in relation to the sustainability of lowland rice cultivation in West Africa.

International Workshop on "Cryopreservation of Tropical Plant Germplasm"

The intensive exploration and collection activities in recent years have resulted in the rapid increase of plant germplasm collections throughout the world. The development of safe and cost-effective techniques for the long-term conservation of the collections, especially recalcitrant seed- and vegetatively propagated species is considered as a priority research area.

For long-term conservation of the problem species, cryopreservation is the only method currently available. Dramatic progress has been made in recent years in the development of new cryopreservation techniques, and cryopreservation protocols have been established for over 100 different plant species. However, cryopreservation of tropical and sub-tropical species has been less extensively investigated than that of temperate species.

Against this background, Japan International Research Center for Agricultural Sciences (JIRCAS) and International Plant Genetic Resources Institute (IPGRI) jointly organized the International Workshop on "Cryopreservation of Tropical Plant Germplasm - Current research progress and application-" held at JIRCAS, Tsukuba during the period 20-23 October, 1998.

In an increasing number of National Programmes in the tropics there has been a growing awareness of the importance of cryopreservation and research activities in this field have been initiated recently. Thus the workshop was timely in providing a unique opportunity for cryopreservation researchers to get together to exchange information and to discuss numerous aspects of cryopreservation of tropical plant species. From 29 countries, 93 scientists including scientists from the International Agricultural Research Centers i.e. IPGRI, CIAT, CIP, IITA, INIBAP participated in the workshop. Dr. Nobuyoshi Maeno, Director General of JIRCAS gave the welcome address and key note addresses by Prof. Akira Sakai (Professor of Emeritus, Hokkaido University) and Dr. Florent Engelmann (IPGRI) were delivered, followed by 41 oral presentations and 51 posters.

Session I dealt with "fundamental aspects of cryopreservation," including ultra-structural studies on cell adaptation to freezing and studies on molecular mechanisms of plant freezing tolerance. During Session II, cryopreservation techniques involving cells, pollen, embryos, meristems were outlined. During Session III, application of cryopreservation protocols to germplasm conservation was reviewed while during Session IV, the "current status of cryopreservation research and future perspectives of its application in natural programs" were considered.

The workshop was successful with active discussions to assess the current status of research, present application of and existing problems with cryopreservation of plant germplasm with a strong focus on tropical species, and to identify priority areas for collaborative research, technology development, transfer and application. It was also pointed out that the workshop could be a good start for setting up a network, even informal, in the field of germplasm conservation to facilitate international research collaboration. The proceedings of this workshop will be published early next year.

JIRCAS Fellowship Program: Welcoming New Visiting Researchers

Seventeen Visiting Researchers are participating in the JIRCAS 1998 Visiting Research Fellowship Program to carry out collaborative research at Tsukuba and Okinawa.

Tsukuba: Short-term (5 months at National Institute for Agrobiological Resources)

Dr. Dea de Lima Vidal	Univ. of Zaragoza, Brazil	Economic and breeding evaluation of animal genetic resources in developing countries
Dr. Lawrence Misa Aboagye	Plant Genetic Resources Center, Ghana	Evaluation of diversity for a starch synthetic gene in wheat
Dr. Irina Olegovna Vvedenskaya	N. I. Vavilov, All Russian Inst. of Plant Industry, Russia	Molecular basis of protein markers in wild relatives of crops
Dr. Dennis Yeo	National Inst. of Agrobiological Resources, Singapore	Development of strategy to generate male-sterile plants using transcription

Tsukuba: Long-term (2 years at JIRCAS, Tsukuba)

Dr. Joseph Gogo Dubouzet	Former Post Doctoral Fellow at Hokkaido National Agric. Exp. Station, Philippines	Molecular analysis of drought stress responses in rice
Dr. Vipaporn Na Thalang	Kasetsart Univ., Thailand	Chemical and biological evaluation of Thai Vegetables (Family <i>Leguminosae</i>)
Ms. Do Thi Thanh Huong	Cantho Univ., Vietnam	Physiological studies on reproduction and osmoregulation in the giant freshwater prawn, <i>Macrobrachium rosenbergii</i>
Mr. Jianjun Guo	Research Center for Rural Economy, Ministry of Agric., China	Economic analysis on food consumption of Chinese farm households

Okinawa: Long-term (1 year at JIRCAS Okinawa Subtropical Station)

Dr. Bujun Wang	Inst. of Crop Breeding and Cultivation, China	Methane emission and carbon cycling in rice fields as affected by elevated atmospheric CO ₂ concentration and environmental factors
Dr. Md. Abdul Karim	Inst. of Postgraduate Studies in Agric., Bangladesh	Interactive effect of thermal and irradiance stresses on some physiological and biochemical parameters of grain legumes and mango
Dr. Narinder Pal Singh Dhillon	Punjab Agric. Univ., India	Genetic variation and relationships in sweet potato populations detected with RAPD and AFLP markers
Dr. Liu Jian	Shandong Teacher's University, China	Cloning the heat tolerance-related genes from tomato reproductive tissues
Dr. Armando Rubio Calderon	Instituto Nacional Autonomo de Investigaciones Agropecuarias Iniap, Ecuador	Evaluation and characterization of oligofructan content in yacon germplasm
Dr. Xinwen Hu	Chinese Academy of Trop. Agric. Sci., China	Development of microsatellite markers in snap beans
Dr. Charuwan Bangwaek	Prachinburi Rice Res. Center, Thailand	Enzymes activities related to sugar accumulation in sugarcane
Dr. M. Arumugam Pillai	Tamilnadu Agric. Univ., India	Screening of cDNA library for salt tolerance gene in rice
Ms. Maribel Regla Quintana Sanz	Inst. of Pastures and Forages Research, Cuba	Evaluation of genomic diversity of sugar-related enzyme genes in sugarcane genetic resources

International Collaborative Studies Undertaken by JIRCAS Fisheries Division

-Promotion of Sustainable Fisheries Industry Together with Agriculture, Animal Production, and Forestry-

Kunihiko Fukusho

Director, Fisheries Division

•@

The Fisheries Division is in charge of research on marine and freshwater fisheries resources management, aquaculture, fisheries products processing, which are major themes for international collaboration. The researchers of the Division are engaged in the following research fields:

Dr. Yutaka Fukuda (fisheries products processing), Dr. Shigeo Hayase (squid ecology), Dr. Motoyuki Hara (fish genetics), Dr. Marcy N. Wilder (crustacean endocrinology), Dr. Satoshi Suyama (marine fish ecology), and Mr. Masashi Sekino (freshwater fish culture).

Several seminars and workshops on fisheries resources management and aquaculture were held prior to the initiation of the international collaborative studies in the field of fisheries sciences to identify priorities. The main orientation of effective collaborative studies was eventually defined as follows:

- 1) Development and improvement of technology for sustainable fisheries industry compatible with environmental protection
- 2) Japan's contribution to Asian countries as one of the Asian countries (First step; subsequently researchers will be sent to other regions such as South America, Africa, etc.)
- 3) Promotion of integrated and comprehensive multidisciplinary studies involving agriculture, animal production, and forestry fields
- 4) Collaboration with the organizations belonging to the Consultative Group on International Agricultural Research (CGIAR) such as ICLARM (International Center for Living Aquatic Resources Management) and Regional International Organizations like the SEAFDEC (Southeast Asian Fisheries Development Center)
- 5) Attempts to address urgent issues in the field of aquaculture

The Fisheries Division has started to implement collaborative research projects in five Asian developing countries in order to develop a technology for sustainable production of fish, methods of fish culture compatible with the preservation of the environment, and methods for efficient utilization of fisheries products. Title, duration, and counterpart organization of these collaborative studies are as follows:

- 1) Development of sustainable aquaculture technology in Southeast Asia (1994-1999). Faculty of Fisheries, Kasetsart University, Thailand
- 2) Evaluation and improvement of farming systems combining agriculture, animal husbandry, and aquaculture in the Mekong Delta (1994-1999). College of Agriculture, Cantho University, Vietnam
- 3) Production and sustainable utilization of tropical and subtropical brackish water ecosystems (1995-2000). Fisheries Research Institute, Forestry Research Institute, and Faculty of Science, University of Malaya, Malaysia
- 4) Study on the utilization and processing of freshwater fishes in China (1995-2000). College of Food, Shanghai Fisheries University, China
- 5) Study on the ecology and life history of coastal fishes (1995-2000). Central Research Institute for Fisheries, Indonesia

The 4th collaborative study will be incorporated into a new comprehensive project entitled •gDevelopment of sustainable production and utilization of major food resources in China•h 1997. Furthermore, a new collaborative study •gDevelopment of methods for the diagnosis and prevention of penaid viral diseases•h is scheduled to start in Asian countries in 1997.

The Division also is actively participating in the JIRCAS Visiting Research Fellowship Program at Tsukuba, and has invited distinguished researchers from developing countries in the field of prevention of fish diseases. The researchers who participate in the Program are expected to be key scientists for collaborative studies in the future.

Although the Division has a small number of researchers, it is supported by nearly 430 scientists affiliated to the Fisheries Institutes of the Fisheries Agency, and will also implement joint research programs with other Divisions of JIRCAS.

Current Research at Okinawa Subtropical Station

Tadaaki Yamashita

Director, Okinawa Subtropical Station

The Okinawa Subtropical Station is the only national research organization that carries out agricultural research under subtropical conditions in Japan. The Station is located in Japan's southernmost city, Ishigaki (2100 Km southwest from Tokyo). By taking advantage of the subtropical environment, research is carried out in order to develop techniques which should contribute to the promotion of agriculture in the tropical and subtropical areas. Research at the Station covers various fields relating to the production of tropical crops, including breeding and cultivation methods, plant nutrition, soil management, plant physiology and pathology, biotechnology, etc. At the Station, researchers from developing countries are engaged in collaborative studies for optimum utilization of bioresources for conservation of the environment and sustainable agricultural production in the tropics. Since the establishment of the Station in 1970, significant results have been obtained and emphasis has been placed on the enhancement of research activities to develop a new technology aimed at securing food production and preserving the tropical environment.

Explore, Conserve and Utilize Biodiversity

To alleviate the constraints associated with the expansion of areas with salinity problems, salt-tolerant crops are identified using rapid and simple methods. A large variation in salinity tolerance was observed among cultivated varieties of rice originating from all over the world. Salinity-tolerant varieties were geographically distributed mainly in Bangladesh, Malaysia and West African countries at higher frequencies. Isozyme analysis showed that the esterase allele *Est-2* is one of the genetic markers of salinity tolerance in rice.

For long term storage of vegetatively propagated plant germplasm, cryopreservation is a useful method. Protocols for the stable cryopreservation of germplasm of tropical crops, especially root crops such as taro, yams and sweet potato were developed. By successful cryopreservation of shoot meristems of taro (*Colocasia esculenta* (L.) Shott.), on average, 80 percent of the shoot tips could be stored in liquid nitrogen after dehydration treatment using vitrification solution. Most of the surviving shoot meristems developed shoots and roots normally.

Palatability of flour-derived food is considered to be influenced by amylose in wheat. For amylose

synthesis, waxy protein is responsible and three waxy proteins (Wx-A1, Wx-B1, Wx-D1) are present in wheat. Analysis of 1,960 accessions of wheat germplasm enabled to detect a Chinese wheat variety which lacked the Wx-D1 protein. From a cross between the Chinese wheat variety and a Japanese wheat variety which was deficient in both Wx-A1 and Wx-B1 proteins, a wheat variety lacking waxy proteins was produced. This variety does not contain amylose and may become a novel material for food use.

Aiming at Sustainable Agricultural Production

In the global atmosphere, concentration of methane is increasing and methanogenic bacteria are biological producers of the gas. Application of rice straw and cellulose has resulted in a considerable increase in methane emission from subtropical paddy fields as well as an increase in the populations of methanogenic bacteria. Methanogenic colonies in cultures of the bacteria showed a blue auto-fluorescence. Currently the populations of methane-oxidizing bacteria in the soil and rice rhizosphere are being investigated and attempts are made to isolate them in order to utilize them as methane-oxidizers for biological control of methane emission.

Soil loading due to erosion in coastal marine environments is a serious problem. For the alleviation of erosion hazards in pineapple fields, the effects of organic mulch, cover crops, and nontillage planting were investigated. Results indicated that a cover crop, weeping lovegrass (*Eragrostis curvula*), on the lower edge of the slope reduced soil loss to a negligible level.

New cultivar of snap bean, •gHaibushi•h (*Phaseolus vulgaris* L.), was released in 1995. •gHaibushi•h was bred through pure line selection from Malaysian germplasm. It shows a superior heat tolerance compared with the local cultivars and gives a high pod yield in the subtropical area of Japan where vegetable production in summer is difficult. The plant type is indeterminate and young pods are light green.

Papaya leaf distortion mosaic potyvirus (PLDMV) damages papaya plants in the subtropical zone of Japan. The DNA complementary to the 3•f-terminal region of PLDMV RNA was cloned and sequenced. Papaya ringspot potyvirus (PRSV) is an other potyvirus which was isolated from papaya in Japan. Results of sequencing of cDNA of PLDMV supported the classification of PLDMV as a distinct member of the genus Potyvirus.

Physiological Studies To Overcome Environmental Constraints

Heat tolerance in tropical fruit crops was determined by chlorophyll fluorescence. This method has been widely used to examine the variation in tolerance of photosystem II to high temperature. Chlorophyll fluorescence test revealed that pineapple, cherimoya, sugar apple, and coconut palm were tolerant to heat whereas Java apple, rose apple, and longan were sensitive among 25 tropical fruit crops.

Some plants experience iron deficiency chlorosis when grown on alkaline calcareous soils. This problem can be overcome by using resistant cultivars. In chickpea (*Cicer arietinum*) and mungbean (*Vigna radiata*), some cultivars developed iron deficiency chlorosis when grown on alkaline soil while others did not exhibit visible symptoms. It was revealed that the resistant cultivars were able to lower the pH around the root in response to iron deficiency, resulting in the solubilization of insoluble iron.

Areas with problem soils such as saline, acid sulfate, sandy soils, etc. are continually increasing in the tropics and subtropics. Hydroponics may be a suitable alternative for crop production in such regions. We developed a new apparatus for crop production, which does not require the use of electricity. In this

system, supply of nutrients is achieved through capillary action, and the amount of nutrient solution can be reduced by using a floating valve system.

-JIRCAS RESERCH HIGHLIGHT-

Estimation of DNA Marker Effects in Marker-Quantitative Trait Loci (QTL)-Association Analysis

*Kenji Togashi**

•@

African indigenous cattle display a high degree of resistance to many diseases including trypanosomiasis. In particular, tsetse-transmitted trypanosomiasis is the major constraint on livestock and agricultural production in Africa. Currently, tsetse infestation covers an area of 11 million km² in Africa, accounting for about 37% of the surface of the continent. It is considered that 7 million km² of the area would otherwise be suitable for livestock and mixed agriculture without detrimental effect on the environment, if trypanosomiasis could be controlled. Over a period of several thousand years, certain breeds of cattle such as N'Dama and West African Shorthorn have developed the ability to thrive in tsetse-infested areas where there is a high risk of trypanosome infection. Consideration is now being given to the use of trypanotolerant breeds of domestic animals as an approach to sustainable livestock development in tsetse-infested areas.

The gene responsible for the resistance to trypanosomiasis is currently being identified at ILRI (International Livestock Research Institute) by using crosses between the trypanotolerant N'Dama and zebu cattle breeds, e.g. the Boran. The procedure to estimate the effect of DNA markers linked to the gene responsible for trypanosomiasis was developed as a joint study between JIRCAS and ILRI. Based on the procedure, the degree of effects of DNA markers was found to be highly correlated with the degree of relationship of the true and estimated marker effects. For example, the relationship was even more significant by limiting the number of markers depending on the degree of effects of DNA markers to the top 30 markers than by using all the markers (Table 1). This finding indicated that selection should be based on the use of DNA markers with more pronounced effects, since the markers with poor estimation and negligible effects only create noise for selection.

•! Present address : Hokkaido National Agricultural Experiment Station, Animal Production Division

-JIRCAS RESEARCH HIGHLIGHT-**Development of Sustainable Aquaculture Technology in Southeast Asia***Motoyuki Hara*

Recently, in the Southeast Asian countries, especially in Thailand, an intensive form of aquaculture has been promoted in order to increase product volume in accordance with economic growth, and such an intensive form of aquaculture has rapidly spread. As a result, production from aquaculture, especially in relation to prawns, has markedly increased in a short period of time ([Fig. 1](#)). However, in some countries and regions, this intensive form of aquaculture had to be reduced or discontinued because of the occurrence of diseases affecting cultured species. It was eventually recognized that it is difficult to maintain a high productivity using intensive aquaculture. In order to achieve sustainable production for aquaculture in Southeast Asia, it is necessary to promote basic studies relating to aquaculture sciences, such as genetics, physiology, pathology and dietetics of fish and prawns. JIRCAS considers that technologies for the promotion of sustainable aquaculture can be developed through basic studies relating to aquaculture sciences.

The collaborative studies covering a five-year period were initiated in 1994 between the Japan International Research Center for Agricultural Sciences (JIRCAS) and the Faculty of Fisheries, Kasetsart University, Thailand. In the first half period of the research program, genetic studies were emphasized as one of the approaches to promote basic studies relating to aquaculture sciences.

At first, in order to develop methods for the detection of genetic variability for breeding, a manual for isozymic analysis for 20 aquatic animal species of economic importance in Thailand fisheries was prepared. The genetic variability of wild populations of catfish (*Clarias macrocephalus*) was analysed using this manual.

The wild population of catfish collected from five localities indicated in [Fig. 2](#) was analysed by using as markers the genes at eleven loci controlling nine enzymes. As a result of isozymic analysis, it was found that the populations examined were genetically independent of each other, because most of the pairs of five populations showed significant differences in all the allele frequencies at more than one locus. Furthermore, based on the genetic distances among the six local populations of catfish, the dendrogram showed that genetic relationships of the populations could be determined ([Fig. 3](#)). The relationships between the populations of Prachin Buri and Chachoeng Sao, or Pattani and Yala were very close genetically, whereas the relationship between the Chiang Rai and Pattani (or Yala) populations was genetically distant. A vertical dotted line was drawn across the dendrogram to delineate a group with a distance of 0.01. The genetic distance of 0.01 was considered to correspond to a local race level based on the results of analysis of many kinds of animals. Using this vertical dotted line, the five local populations were divided into two groups, which indicated the differentiation of local races into north/central and south groups.

This species was strongly related to the geographical distance or geographical regions in Thailand. Thailand consists of three regions i.e. central plain, northeastern plain and southern plain, and the three wide regions could be differentiated as a whole, which suggests the possibility of genetic segregation of wild populations.

It is important to identify a local race for breeding, since hybridization among local races can lead to

heterosis, and the productivity could be increased. Thus the productivity could be increased by using breeding technologies for two species of economic importance for aquaculture.

The steady increase in the world population requires that sustainable and higher productivity be promoted. The increase of productivity through breeding may lead to sustainable production. However, to promote sustainable aquaculture, it is necessary to develop technologies adapted to the regions.

-JIRCAS RESERCH HIGHLIGHT-**Ecophysiological Characteristics of Tropical Tree Species**

Yutaka Maruyama

•@

Dipterocarps are the main timber-producing trees in Malaysia. Most of the dipterocarps are slow-growing, late successional species, and require moderate shade for optimum growth at the early stage. It is generally considered that dipterocarp seedlings are not suitable for open planting because of their low adaptability to environmental stresses associated with exposed sites. On the other hand, fast-growing pioneer species require strong sunlight for their establishment. In this study, ecophysiological characteristics of these tree species were examined to compare their drought resistance and adaptability to environmental stresses such as heat and light.

The leaf water relation parameters showed that the capacity for maintaining a positive turgor was low in shaded and well-watered nursery seedlings of dipterocarps. On the other hand, leaves of exposed trees were well adapted to water stress morphologically, being smaller and thicker, as well as by their ability to maintain a positive turgor through osmotic adjustment. The rate of net photosynthesis (P_n) was lower in dipterocarps than in the fast-growing species such as acacia and teak. However, in a dipterocarp, *Hopea odorata*, P_n was similar to that of fast-growing species and the trees exhibited a very high water use efficiency (WUE). Decrease in P_n in response to non-optimum temperatures was relatively moderate in *H. odorata* and *Shorea platyclados*, suggesting that gas exchanges of these species were stable under variable temperatures. Among the dipterocarps, *H. odorata* and *S. platyclados* could be recommended as suitable species for open planting. Midday depression of stomatal conductance (G_w) was observed in most of the species examined. G_w started to decrease when the leaves were exposed to full sunlight and when the vapour pressure difference between the leaf and the ambient air (VPD) was above 0.01 Pa/Pa. Since photosynthetic CO_2 uptake is strongly controlled by stomatal opening, P_n of dipterocarps was limited by the reduction of G_w . However, the reduction of the transpiration rate (T_r) was relatively small because of the increase of VPD, which stimulates evapotranspiration, with increasing temperature and decreasing air humidity. In contrast, G_w of *Acacia mangium*, a well known fast-growing and drought-tolerant species, remained relatively constant even under full sunlight and when the VPD was above 0.01 Pa/Pa, resulting in a high T_r at midday. Leaf water potential ($f_{\mu w}$) was low, or more negative, at noon when T_r was high. In tall mature trees, the difference in the gravitational potential ($f_{\mu g}$) could also cause a lowering of $f_{\mu w}$ in the upper canopy. In addition, low soil-to-leaf hydraulic conductance (L) in tall trees limited the water uptake from soil. The resulting lower minimum $f_{\mu w}$ in tall trees can lead to enhanced water stress, and lower G_w and P_n than in smaller trees. In *A. mangium*, L was remarkably high. High L enabled this species to maintain a less negative $f_{\mu w}$ for the same transpiration rate compared to dipterocarps. By keeping the water deficit low through high L , *A. mangium* maintained a high G_w during the day when the transpiration rate was high.

These results indicate that the slow growth of dipterocarps may be attributed to the relatively low rates of net photosynthesis and midday stomatal closure. Low L of dipterocarps can limit water availability and lower leaf water potential, especially in the mature tall trees. Nursery-grown seedlings of dipterocarps were more susceptible to water stress because of their relative inability to maintain a positive turgor. To enhance their ability to cope with water stress, it is recommended that nursery-grown dipterocarps be

preconditioned to drought and direct sunlight prior to transplanting. Partial shading after transplanting is also recommended in order to avoid excessive water loss and to stabilize stomatal conductance and rates of gas exchange in the daytime.

-JIRCAS RESEARCH HIGHLIGHT-

Determination of Site Factors that Promote the Regeneration of Tree Species

Hiroyuki Tanouchi

•@

Although there is an abundance of commercial species in the hill forests of Peninsular Malaysia, the regeneration of tree species does not necessarily succeed in the forests left alone after selective logging. The more valuable of these species is *Shorea curtisii*, which is distributed on the ridges and upper slopes. To develop and further improve techniques for the regeneration of *S. curtisii*, the relationship between the regeneration dynamics and environmental factors needs first to be analysed. We set up a 4 ha (400m•~100m) plot in 1994. The plot which was logged selectively five years ago was located on a west-facing slope of Semangkok area (500 m asl; 3•<37'N, 101•<44"E). Dataset of an old-growth forest next to the plot was used for comparison. The density and size distribution of the saplings in both forests were not significantly different. Most saplings in the logged-over forest were established before logging, indicating that logging had not affected appreciably the mortality. However, there were few saplings along the logging roads. Though the canopy in the tree layer was not closed yet, stemless palms (*Eugeissona tristis*) formed a dense canopy in the shrub layer in the logged-over forest. Under the deep shaded conditions (relative canopy openness < 2%), most of the saplings had not developed a main shoot and they extended lateral branches (left, Photo 1). The saplings around the gap of the old-growth forest and at the site without palms showed an adequate upper growth (right, Photo 1).

The palms in a 1 ha plot were removed for improving the light conditions of the saplings (Photo 2). The relative canopy openness was 1.7% and 4.3% before and after removal, respectively. There were no morphological changes in the saplings until six months after removal, then many saplings initiated upper growth. Some saplings which lacked a main shoot elongated new shoots. Removal was estimated to be an effective method at a low cost. Moreover effects of soil compaction and erosion on the regeneration were analysed.

The techniques employed to examine the factors influencing the regeneration of the species will be adopted for studies on some of the more commercial species in the hill forests. Results from these studies will be used to develop silvicultural tending techniques for improving regeneration in logged-over hill forests. This study was carried out as part of a collaborative project between Forest Research Institute, Malaysia and JIRCAS.

2nd Seminar on •gBrackish Water Project•h Held in Malaysia

Shigeyuki Kawahara

•@

The seminar is held annually as a part of the comprehensive project •gProductivity and Sustainable Utilization of Tropical and Subtropical Brackish Water Mangrove Ecosystems•h. Tropical and subtropical brackish water areas, usually with developed mangrove forests, are an important habitat for fisheries resources. The project aims to evaluate the productivity of such areas and identify the criteria for sustainable utilization. The West coast of the Malay Peninsula was selected as the study area due to the presence of different types of mangrove forests. Counterpart organizations include Fisheries Research Institute (FRI), Forest Research Institute Malaysia (FRIM) and University of Malaya (UM).

The 2nd seminar was held in a meeting room of FRI's aquarium in Penang on December 5, 1996. Four subjects were taken up during the seminar as follows: ‡@Mangrove forest, meiofauna and macrobenthos, ‡APrawn and fish, ‡BRunoff of soil into the brackish waters, and ‡CSocio-economic aspects in the mangrove areas. About 30 scientists from Japan and Malaysia participated in the seminar, and nine papers were presented. Also, Dr. Kato, Director General of the Seikai National Fisheries Research Institute, introduced the Ishigaki Branch, which is the only site for studies on subtropical fisheries in Japan.

During the 1st seminar, which was held in Kuala Lumpur just one year ago, almost all the presentations dealt with reviews of previous studies (JIRCAS Working Report No. 4), because the project had just started at that time and it was considered that such reviews would contribute significantly to the execution of the project. During the 2nd seminar, the papers from the two JIRCAS researchers on long-term assignments (Dr. Hayase at FRI and Mr. Ochiai at FRIM) and seven JIRCAS researchers on short-term assignments dealt with the collaborative studies carried out with their Malaysian counterparts.

However, the comprehensive project is expected to produce integrated results in addition to the results obtained in each respective field. For integration, material/energy flow should cover the sequence from leaves in mangrove forests to crab/seashells along rivers and phyto/zooplankton and fish/shrimps in water. For such interdisciplinary studies, close collaboration between researchers in different fields is essential and it is obvious that the seminar held annually may enable to achieve this objective.

•@

Plants Respond to Environmental Conditions

Zhu Weiming

Institute of Agrobiological Genetics and Physiology, Jiangsu Academy of Agricultural Sciences, Nanjing, China

Drought, low temperature, high salt level, insects and pathogens are some common environmental stresses to which plants are often exposed. Plants are different from animals, and since they are immobile, they have developed unique mechanisms to avoid these environmental stresses.

Plant molecular biologists have been interested in studying the mechanism(s) of plant defense systems and improving their resistance to these environmental stresses by using molecular biological techniques and plant engineering. During the past several years, I studied the resistance of transgenic plants to insects in cotton and vegetables. Now I am carrying out studies on plant response to dehydration with my Japanese colleagues. Main object of our studies is to determine how plants respond to environmental stresses, such as drought, cold and high salt at the molecular level. We have isolated several genes that respond to drought, cold and high salt stresses at the transcriptional level, and analysed their function. Now, we are trying to identify new genes that encode regulatory factors for the response to drought, cold, high salt level using yeast one-hybrid system. We are also analysing their function using transgenic tobacco and *Arabidopsis* plant system.

Yellow Butterfly Species (Genus *Eurema* Hubner) Causing Serious Defoliation in Forest Plantations of Albizzia, *Paraserianthes falcataria* (L.) Nielsen, in the Western Part of Indonesia

Ragil S. B. Irianto^{*}, *Kazuma Matsumoto* and *Kusdi Mulyadi*^{**}

•@ Albizzia, *Paraserianthes falcataria*, is a fast-growing multi-purpose tree widely planted in Southeast Asia. Outbreaks of a pierid butterfly species of the genus *Eurema* occasionally occur in albizzia plantations, leading to severe defoliation. The butterfly species had so far been identified either as *E. blanda* or *E. hecabe*, and some authors assigned it to both species. We investigated *Eurema* species occurring in forest plantations of albizzia in five localities in Sumatra, Java, and Kalimantan, and identified four species, *E. blanda*, *E. hecabe*, *E. alitha* and *E. sari*. When the yellow butterflies were abundant, *E. blanda* predominated. The population of *E. blanda* fluctuated widely, decreasing in the dry season and increasing in the rainy season, sometimes resulting in a population outbreak and total destruction of the foliage in the plantation. On the other hand, the population levels of *E. hecabe* and *E. alitha* were more stable, and *E. sari* seldom occurred. These species are therefore considered to be of minor importance as a pest of albizzia. *E. hecabe* which has been frequently reported to be a serious defoliator of albizzia could have been mistaken for *E. blanda*. *E. hecabe* and *E. alitha*, which had been mistaken for *E. hecabe* did not occur together in our samples.

Soil Loss from Pineapple Fields and Control

Kazuo Sugahara

•@For the last three decades, soil loading due to erosion in coastal marine environments has been serious in the Ryukyu Islands resulting in damage to the coral reefs surrounding these islands. The above soil loss can be ascribed to large-scale pineapple cultivation. Pineapple fields are located mainly on acidic red and yellow soils and receive an annual average rainfall of 2,100 mm with a slope ranging from 20 to 150 m in length and from 0 to 8•K in gradient. Since the growth of pineapple plant is very slow, fields are not covered for a long time, so that soil erosion in pineapple fields becomes a serious problem. Rill erosion occurs frequently along roadsides because of agricultural practices, such as spraying of chemicals and shipping of products.

[Photo 1 : Effect of cover crops on the prevention of soil erosion in pineapple fields](#)

•@A set of four plots was used for the investigation of the effect of cover crops on the prevention of soil erosion from October 1993 to September 1994. Ground nut (*Arachis pintoï*) and weeping lovegrass (*Eragrostis curvula*) were selected as cover crops. Each of them was planted on the lower edge of a slope. After the grasses grew well, soil erosion was effectively reduced. The alleviation of soil loss in the plots with ground nut and weeping lovegrass was 1/680 and 1/110 of the control plot, for 12 months after planting of pineapple. Another set of four plots was used for the investigation of the effect of nontillage planting on the prevention of soil erosion from October 1994 to September 1995. In the plot of nontillage planting, pigeonpea (*Cajanus cajan*) was cut down at about four months after the seedling stage, and then pineapple was planted without plowing. Nontillage planting reduced soil erosion effectively from October 1994 to May 1995. However, the effect disappeared after June 1995, because the residues of pigeonpea decomposed during this period. The alleviation of soil loss in the plot of nontillage planting was 1/14 of the control plot for 8 months after planting of pineapple. In conclusion, we recommend that farmers employ cover crops and practice nontillage planting for the protection of the soil surface. Organic mulch is less suitable because of the scarcity of labor and materials.

Studies on Geographical Distribution of Leaf-Cutting Ants and Damage to Agriculture Caused by the Ants in Brazil

•@

Katsuya Ichinose

•@Leaf-cutting ants cut parts, especially leaves, of plants for cultivation of fungi, on which their immature forms feed (Photo 1). Due to this harvesting behavior, the ants are recognized as one of the most important pests in Central to South America, though neither the geographical distribution of the ants nor their damage to agriculture is well-documented. We carried out surveys on the geographical distribution of leaf-cutting ants in Brazil from 1993 to 1996 and the distribution of the species in various regions, their density and the extent of the damage to agriculture caused by the respective species were eventually elucidated.(Fig 1) Along with the survey on the distribution and density of leaf-cutting ants in the regions, we asked farmers at some locations whether they encountered problems with leaf-cutting ants or not. The information enabled to determine the presence or absence of damage by the ants.

•@The leaf-cutting ants rated as serious pests for agriculture in Brazil are as follows: *Acromyrmex balzani*, *Ac. fracticornis*, *Ac. landolti*, *Ac. striatus*, *Atta bisphaerica*, *At. capiguara*, *At. cephalotes*, *At. goiana*, *At. laevigata*, *At. sexdens* (Photo 1). Comparison of the data with those obtained previously suggests that the distribution of the species listed in Table 1, especially *At. capiguara*, and *At. goiana*, had expanded in these decades to regions where few or none of them had been found or reported in the past. Scientists point out that incipient (less than one year old) nests of these ants (Photo 1) are very susceptible to and easily destroyed by tillage. Hence damage by the ants may increase with the adoption of nontillage cropping which is currently recommended by agricultural institutes in Brazil. Similarly the incidence of *At. cephalotes*, *At. laevigata*, and *At. sexdens* in the Amazon region may increase with the progression of logging or land development. Thus damage to agriculture by leaf-cutting ants in regions where there is at present little or no problem is likely to increase with time.

•@Hence, we have to pay attention to the expansion of the distribution of leaf-cutting ants for the control of the ants.

[Table 1. Distribution of leaf-cutting ants](#)

Wide Adaptability of New Rice Cultivars in Yunnan Province of China

Kazuo Ise, Sun Youquan, Liu Jishin*, Zhou Tiande*, Satoru Kudo**,*

*Yoshihiro Sunohara***, and Jiang Zhinong**

•@

•@The collaborative research project for rice breeding using a wide diversity of genetic resources has been conducted in Yunnan Province of China since 1982. The new rice cultivars developed through the joint project have been widely grown in and around the province. In 1996, the total acreage of these cultivars covered more than 170,000 ha, accounting for nearly 20% of the total rice-growing area in Yunnan.

•@In 1996, two rice cultivars, •eHexi 34•f and •eHexi 35•f, were developed and newly released by the project; they will be officially registered by the Yunnan provincial government. Hexi 34 was developed from the cross •eYunxi 2•f/•eDianyu 1•f, and Hexi 35 from the cross •eHexi 15•f/•eHexi 4•f. The pedigree of these new cultivars, can be traced to some Japanese rice genetic resources: a high-yielding cultivar •eTodorokiwase•f, a cool weather-resistant cultivar •eNarukaze•f, blast-resistant germplasm accessions •eBL 1•f and •eBL 6•f, and others.

•@The principal reason for releasing these two cultivars is that they display a higher yielding ability than that of current japonica-rice cultivars grown in Yunnan, which is the most important factor in crop production in China. Hexi 34 and Hexi 35 performed very well in the uniform trials conducted at twelve sites representative of the japonica-rice growing areas in the central and northern parts of Yunnan. In twenty-four tests across twelve locations during a two-year period, the average yield of Hexi 34 and Hexi 35 was 8.55 and 8.80 t ha⁻¹, respectively, compared with 7.10 t ha⁻¹ for the standard cultivar •eYunkeng 9•f.

•@We conducted a statistical analysis of adaptation based on the data of the uniform trials using the linear regression method and principal component analysis. The regression coefficients on the mean yield of each environment of Hexi 34 and Hexi 35 were smaller than those for other tested cultivars. The findings indicate that these cultivars are well adapted to various kinds of environments in Yunnan. The results of principal component analysis also revealed the high-yielding characteristics and wide-adaptability of Hexi 34 and Hexi 35.

•@The cooking and processing qualities of Hexi 34 and Hexi 35 are superior to those of the standard cultivar •eYunkeng 9•f in Yunnan. Milled kernels of Hexi 34 and Hexi 35 are nonglutinous and nonaromatic; they are translucent in contrast to those of Yunkeng 9, which show a pronounced white belly. Taste panelists rated Hexi 34 and Hexi 35 as satisfactory in the sensory tests of steamed rice. Recently, the living standard in urban areas of China has been rapidly rising, resulting in a remarkable increase in the demand for rice with good taste. These two new cultivars should meet the demand for good quality rice.

•@Finally, we should pay careful attention to the shift in the frequency of the blast fungus races, because Hexi 34 and Hexi 35 exhibit a race-specific resistance to rice blast disease. These cultivars could be widely grown in and around the Yunnan Province, because of their high yielding ability and high grain quality as mentioned above. However, breakdown of the blast resistance is common in many rice-growing areas, often shortly after the release of cultivars with race-specific resistance. Rice blast is the most devastating disease in Yunnan japonica-rice growing areas. We should develop breeding strategies for durable resistance to reduce the impact of rice blast disease by using the abundant rice genetic resources of Yunnan and Japan.

Identification of *Meloidogyne* Species Including a New Species Based on Enzyme Phenotypes in Thailand

Yukio Toida

- @Species of root-knot nematodes (*Meloidogyne* spp.), the most important pests of crops among nematodes in Thailand, were identified based on the phenotypes of esterase and malate dehydrogenase by electrophoresis, which are more reliable than those based on morphological characters of the female perineal pattern.
- @Two distinct bands of esterase (Est: A2) and one or three bands of malate dehydrogenase (Mdh: N1, N3) were observed in *M. arenaria*. One clear broad band of Est (VS1) in *M. graminicola*, one band each (N1, I1) of Est (I1) and Mdh (N1) in *M. incognita*, and three bands of Est (J3) and one band of Mdh (N1) in *M. javanica* were revealed respectively (Table 1). Two of the nematode populations examined did not show any band pattern of the enzyme.
- @The population collected from a weed in Bangkok displayed three bands of Est and two bands of Mdh, suggesting the presence of an unrecorded species in Thailand (Photo 1).
- @The population collected from mulberry plants in Udon Thani which exhibited one band of Est and two bands of Mdh (Photo 1) belonged to a new species based on the specific phenotypes of esterase and malate dehydrogenase and the unique morphological characters of the female perineal pattern (Photo 2). This is the second record of a new species of *Meloidogyne* in Thailand since the discovery of *M. microcephala* (Cliff *et al.*, 1984). The new species occurred in large numbers in mulberry fields at Udon Thani Sericulture Research Center and also on some ornamental plants around this area.
- @As mulberry plants in this area are seriously damaged by this species (Photo 3), methods of control against the nematode attacking mulberry should be developed.

JIRCAS Symposium on Status and Requirement of Minerals in Ruminants in Thailand

-Current Knowledge and Future Research-

Tomoyuki Kawashima

•@The role of animal industry is becoming increasingly important in the agricultural sector due to the strong demand for protein in Thailand. The annual rate of increase of milk production in the country was the highest in Asia and the Pacific region in the past decade. The consumption of commercial concentrate feed as well as supplement feed has increased very rapidly.

•@JIRCAS had dispatched two researchers (K. Nishimura, T. Kawashima) to carry out collaborative studies in the field of animal nutrition with the Department of Livestock Development (DLD), Thai government. The field of mineral nutrition was one of the key subjects in their projects. It is still not clear, however, whether the formula applied for the commercial mineral supplements is the most suitable for the conditions in Thailand, as the information both on the mineral contents in the feed and on the requirement of minerals by animals in Thailand is very limited.

•@Therefore, the JIRCAS symposium entitled •gStatus and requirement of minerals in ruminants in Thailand -Current knowledge and future research-•hwas held on May 9, 1997 in Bangkok, Thailand, aiming at presenting research results on mineral nutrition in the country in order to determine the general characteristics of the mineral status of cattle and buffalo in the country and to identify the research themes required for the future. The symposium was divided into the following three sessions:

1. Identification of mineral status in animal production
2. Influence of minerals on ruminant physiology and productivity
3. General discussion on "Future research strategies on mineral nutrition in Thailand".

•@The proceedings will be published as JIRCAS Working Report Series.

[Photo 1: Participants in, and presentation, at the symposium](#)

People

•@

•@**Akihiko Nishiyama** became Director of JIRCAS's Administration Division on April 1. He was until recently Deputy Director of International Trade and Tariff Division, Ministry of Agriculture, Forestry and Fisheries (MAFF). He also served as Consul at the Consulate-General of Japan in Los Angeles, USA (1991-1994) as well as at MAFF's Research Council Secretariat.

•@**Teruo Ishige** became Director of JIRCAS's Biological Resources Division on April 1, succeeding Dr. Shoji Miyazaki who was transferred to the National Institute of Agrobiological Resources (NIAR). Dr. Ishige, a plant cell biologist, worked successively as Head, Plant Cell Breeding Laboratory of NIAR (1988-1995) and Senior Research Coordinator of MAFF's Research Council Secretariat (1995-1997).

•@**Eitaro Imaizumi**, an animal nutritionist, succeeded Dr. Hirofumi Hayakawa as Director of JIRCAS's Animal Production and Grassland Division on April 1. He initiated his research career at Hokkaido National Agricultural Experiment Station (1963-1981). During his former assignments at JIRCAS (formerly TARC), he served as Research Coordinator (1987-1990) and Head of Research Planning Section (1990-1993), after working on animal nutrition in Malaysia (1981-1983).

•@**Shiroh Uno**, a biological oceanographer, replaced Dr. Kunihiko Fukusho as Director of JIRCAS's Fisheries Division on April 1. Dr. Uno carried out most of his research work on coastal ecology at Nansei National Fisheries Research Institute (1974-1982) and Seikai National Fisheries Research Institute (1983-1994). Before joining JIRCAS, he was Director of Japan Marine Science and Technology Center (1994-1997).

OBITUARY

•@We were saddened to learn that Dr. **Noboru Yamada**, first Director General of the Tropical Agriculture Research Center (TARC, reorganized to JIRCAS in 1993), passed away on 18 May 1997 at the age of 85. Dr. Yamada, who graduated from The University of Tokyo (1938) and then spent most of his research career at the National Institute of Agricultural Sciences, was a distinguished crop physiologist and his work on the physiological mechanism of flooding tolerance of rice plants had been highly evaluated by the scientific community.

•@Dr. Yamada also served successively as an expert under the Colombo Plan, as Regional Officer of FAO in Bangkok and as a consultant to the Asian Development Bank. In 1970, he became the first Director General of TARC. Through his scientific achievements and strong commitment to the promotion of international collaboration in the field of agriculture, Dr. Yamada displayed the leadership required for laying a firm foundation for the activities of TARC and subsequently JIRCAS.

The 4th JIRCAS International Symposium

Sustainable Agricultural Development Compatible with Environmental Conservation in Asia

Hisataro Horiuchi

•@The 4th JIRCAS International Symposium on•gSustainable Agricultural Development Compatible with Environmental Conservation in Asia•horganized by Japan International Research Center for Agricultural Sciences (JIRCAS) in cooperation with the National Agriculture Research Center (NARC), National Institute of Agro-Environmental Sciences (NIAES), National Research Institute of Agricultural Economics (NRIAE) will be held at Tsukuba Science City during the period August 26-28, 1997. The subject of the symposium covers the current situation of and future prospects for sustainable agricultural development in Asia.

•@This symposium attempts to highlight the swelling demand for food, the decline in food self-sufficiency and to discuss possible solutions that would enable to achieve sustainable food production and preserve the environment simultaneously. In many Asian countries, recently, rapid economic growth has been altering the balance between food supply and demand. On the demand side, the rising household incomes and population are causing an overall expansion of food demand and a shift in its composition. On the supply side, the •gGreen Revolution•h that had led to a remarkable increase in food production in Asia since the 1960s seems to be losing its momentum. Asian agriculture is also being confronted with many serious environmental constraints associated with the increased application of chemical inputs, urbanization, deforestation and desertification. One may wonder to what extent Asian green resources and technologies will be able to sustain the swelling demand for food. With the huge population in Asia, a decline in food self-sufficiency would make the world food market more volatile. This symposium attempts to highlight these issues and to discuss possible solutions.

•@The symposium consists of a keynote speech and three sessions (1, 2, 3). The keynote speech delivered by Dr. George H. L. Rothschild, Director General of IRRI, Philippines is entitled: •gMain Issues for Sustainable Agricultural Development in Asia•h. The theme of Session 1 covers •gFood Problems in Asia•hPapers to be presented include :

- Brief Introduction by Chairperson. Wen S. Chen (Taiwan)
- Asian Food Supply-Demand Situation from Global Perspective. Osamu Koyama (Japan)
- Food Problems and Outlook in China. Ke Bing Sheng (China)
- Food Problems and Outlook in Southeast Asia. Nipon Poapongsakorn (Thailand)

•@ The theme of Session 2 covers •gAgriculture and Environment in Asia•h. Papers to be presented include:

ISNAR-JIRCAS Meeting was held at JIRCAS

•@The Japan International Research Center for Agricultural Sciences (JIRCAS) and International Service for National Agricultural Research (ISNAR) jointly organized a •gProject Planning Meeting on Research Management•h which was held in Tsukuba during the period 24-27 March, 1997. The objective of the meeting was to discuss priority themes in the project on two subjects: the Management of Information and the Management of Biotechnology. During the meeting the strategies by which research managers and policy makers in Asia recognize the importance of information technology and biotechnology were discussed. During the meeting discussions were also held on the preparation of a series of seminars for the research managers who are responsible for the drafting of information and biotechnology programs. In addition to the participants from ISNAR, including Dr. Stein Bie, Director General, and JIRCAS, heads of the representative NARSs and several ASEAN (Association of Southeast Asian Nations) countries attended the meeting.

Development of Sustainable Production and Utilization of Major Food Resources in China

Akinori Noguchi

Photo 1: Signature of Comprehensive Agreement; Li Xia-fen(left), Deputy DG of Department of International Cooperation, MOA and Yoshihiko Kotaka(right), Research Councillor, AFFRC

The first comprehensive collaborative research project for China was launched on May 28, 1997 by the signature of a Comprehensive Agreement between JIRCAS, Agriculture, Forestry and Fisheries Research Council (AFFRC), Japan and Ministry of Agriculture (MOA), the people's Republic of China on the occasion of the 16th meeting of Japan-China Agricultural Science and Technology Exchange Group held in Tokyo. This project is entitled "Development of Sustainable Production and Utilization of Major Food Resources in China" and will be continued for seven years from 1997.

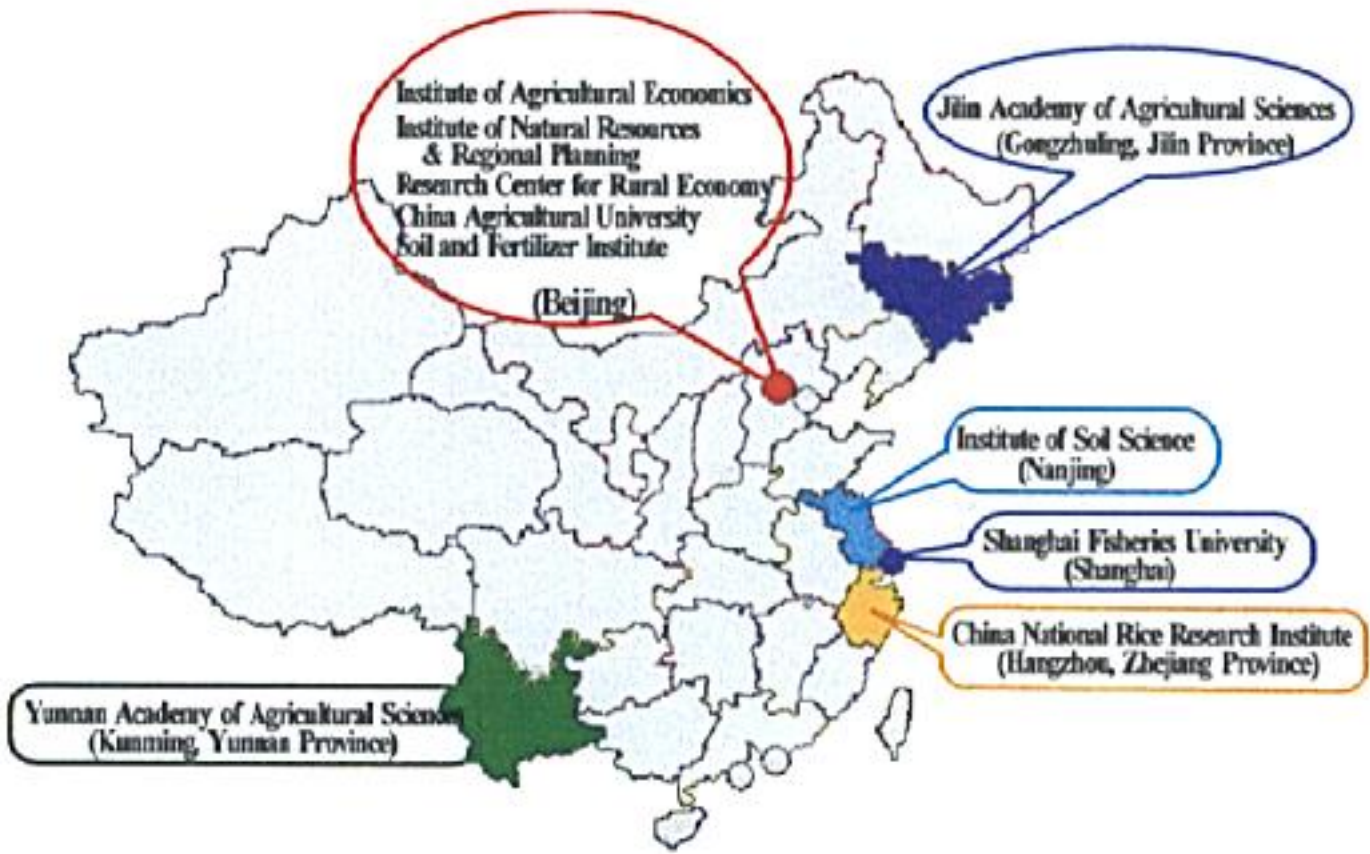

The report entitled "Who Will Feed China? Wake-up Call for a Small Planet" (L. Brown, 1995) triggered the increased concern about China's future food problems. Many Chinese and foreign researchers have carried out a large number of analyses and projections on China's food future, focusing most of their studies on the grain sector and they published reports. No consensus can be found in the reports on food production and demand, probably due to differences in assumption, date and estimation approaches. Nevertheless, the following consensus is that the demand will increase continuously over the next three decades and the supply can not meet the demand, and thus ever rising import will occur.

Major factors influencing food production in China, will include cultivated land, the yield of grains and some constraints such as poor quality of farmland, weak response to fertilizer and small-scale farm structure. It is inevitable that more farmland will be diverted to non-farm uses in the process of rapid economic development and newly reclaimed land and increased cropping index do not seem to alleviate the continued tendency of a decrease of the cultivated land area. The yield is significantly lower in China than in more advanced countries. On the other hand, major factors influencing the food demand will include population expansion, population structure change due to the rural-urban migration, income growth, price of agricultural products and poor infrastructure.

This project aims to develop technologies for sustainable production and utilization of major food resources in China such as rice, soybean, corn and freshwater fishes in order to respond the increasing expectations for high-quality dietary life caused by the development of the Chinese economy and the increase of people's purchasing power. More specific objectives of this project are; **1**: to develop an effective production and distribution system of agricultural produce to cope with the changing supply and demand structure of foods, which is based on the following studies; **1**) evaluation of the dissemination of new technologies in selected areas and their effects on the rural and individual farmer's economy, **2**) modeling for the supply and demand of foods in selected areas and analysis of the structure of the corresponding farming areas and agricultural production, **3**) more sustainable and effective control systems designed for better supply and demand of major food products among selected areas. **2**: to develop technologies for sustainable and stable production of major food resources, based on the following studies; **1**) evaluation on existing gene resources and development of new crop species, **2**) development and evaluation of environment-friendly agricultural technologies. **3**: to develop food technologies for improved utilization and distribution of major food resources, based on the following studies; **1**) quality evaluation of major food resources and development of new food ingredients from them, **2**) improved preservation and distribution technologies for major food resources.

The research subjects taken up in this project will require the collaboration of each component for the progress of the project.

JIRCS Visiting Research Fellowship Program: Review of five years of operation

Shigeo Yashima

1 JIRCAS visiting Research Fellowship Program

The International Collaboration Research Section(ICS)was established in Okinawa Subtropical Station in 1991 with the special mission to promote the Visiting Research Fellowship Program. Five Japanese researchers were engaged in the following four research projects with ten visiting researchers from developing countries invited on a one to two-year tenure.

- 1.Environmental control by using plants and microorganisms
- 2.Mechanism of heat tolerance of crops with emphasis placed on vegetable crops
- 3.Indentification and evaluation of salt tolerance in rice varieties.
- 4.*In vitro* conservation of genetic resources for vegetatively propagated crops.

2 Visiting researchers

Up to date, a total of 50 visiting researches from 14 countries have participated in the program as indicated below. Development of a research network between ICS and these researchers should be ICS's priority to further promote the program.

India(8 researchers)

China(7 researchers)

Indonesia(5 researchers)

Thailand (5 researchers)

Nigeria(5 researchers)

Philippines(5 researchers)

Vietnam(4 researchers)

Bangladesh(3 researchers)

Burkina Faso (2 researchers)

Egypt(2 researchers)

Brazil(1 researchers)

Ghana(1 researchers)

Malaysia(1 researchers)

Pakistan(1 researchers)

[Photo 1: The visiting researchers hold meeting on their respective research fields](#)

3. Research activities during the five-year period

1) Environmental control by using plants and microorganisms

Methane emission from paddy fields treated with rice straw and cellulose was measured by a chamber method under the subtropical climatic conditions. Ecological studies included the enumeration of population and isolation of methanogenic bacteria (MGB) and methane-oxidizing bacteria (MOB) which produce and oxidize methane, respectively in paddy fields. The findings for the studies led to the development of a model ecosystem of methane production and oxidation which should enable to elucidate the interaction between the activities of MGB and MOB in the co-culture system. Final target is the development of techniques to regulate methane emission in the rice rhizosphere by using MOB.

2) Mechanism of heat tolerance of crops with emphasis placed on vegetable crops.

Physiological characteristics and genetic variability of heat tolerance were investigated. It was found that proline contents and membrane thermostability can be used as indices for the screening of heat tolerance in cabbage (*Brassica oleracea*). The effects of nitrogen and potassium concentrations under heat stress in cabbage were studied. Application of high nitrogen or potassium levels increased heat tolerance of cultivars.

Genotype variation in reproductive responses, including gamete development and function, to heat stress in chickpea (*Cicer arietinum*) and pigeonpea (*Cajans cajan*) was examined. The variation was limited among cultivated. The variation was limited among cultivated genotypes in both crops.

However, a congenial wild relative of pigeon pea, *Atylosia scarabaeoides*, sets many pods and seeds under heat stress conditions.

3) Identification and evaluation of salt tolerance in rice varieties

The Salinity Tolerance project aims finally to develop a breeding method to produce salinity-tolerant varieties of crops, using advanced technologies at the molecular level. Under this project, so far, genetic and geographical variations in salt tolerance in cultivated rice were investigated. Recent studies have been focused on the physiological characteristics of photosynthesis and anti-oxidative mechanisms of salt-tolerant indigenous varieties and wild relatives of cultivated rice. Molecular cloning and characterization of salt tolerance genes from rice were also investigated.

4) *In vitro* conservation of genetic resources for vegetatively propagated crops

Cryopreservation is considered to be a practical and efficient tool for long-term storage of plant germplasm. The project aims to develop techniques for the efficient and stable cryopreservation of vegetatively propagated tropical crops.

Vitrification method, a simple method using highly concentrated solution of cryoprotectants to dehydrate explants, was selected among different strategies for cryopreservation. Basic conditions of the vitrification method were investigated in detail and the cryopreservation protocols of *in vitro* grown shoot tips of taro, banana, yams and sweet potato were successfully developed with 60-100% of post-thaw survival. The shoot tips cryopreserved by these protocols resumed growth and developed shoot

directly without intermediate callus formation.

Mechanism Uplifting of Saline Groundwater in Phra Yuen Area, Northeast Thailand

*Masayuki Imaizumi**

In Northeast Thailand, salt accumulation in soil is considered to be derived principally from saline groundwater. Several theories have been proposed for salinization in Northeast Thailand. All of them indicate that salinization is related mainly to the presence of a few rock salt strata of the Mahasarakham formation which are widespread in Northeast Thailand. One of the problems to be solved is how salt of the rock salt strata can reach the ground surface. The understanding of the mechanism of uplifting of saline-groundwater in Northeast Thailand should contribute to the development of technologies for the utilization of ground water and the evaluation of water resources in Northeast Thailand.

Phra Yuen area which is a salt-affected area was selected for studying the relationship between the geological structure and groundwater flow. Piezometers were installed at every intersecting point of a regular 1km grid. Intersecting points were set up at 16 stations in total (A1-A16). At each intersecting point, 3 investigation wells 5, 10 and 15 meter in depth were set up for monitoring the groundwater level (potential head), electric conductivity (EC), and temperature of the groundwater.

Lineament analysis, upper structure of the Mahasarakham formation, and distribution level of the gravel layer in the Quaternary laterite deposits revealed the presence of G1, F1, F2 and F3 faults. Saline groundwater at A1, A5, A9 and A13 station was supplied from the G1 faults (Fig.1) and that at A11 station from the F1 fault. However, all the faults were not involved in the passage of saline groundwater.

[Fig.1. Electric conductivity distribution geological sections in April, 1995](#)

[Fig.2. Fluctuation of monthly precipitation, groundwater level, and electric conductivity at A5 station](#)

EC value increased rapidly when the groundwater level decreased below 187.4 meter above sea level (Dead Level) at A5 (Fig.2) The iso-potential line of 187 meter in the vicinity of A5 showed an eastward direction in April, 1995 so that the flux of the groundwater moved up. On the other hand, the equi-potential line of 189 meters showed a westward direction in September, 1995. It is suggested that the flux of the groundwater there moves down and when the groundwater level decreases below the Dead Line, the flux of upward groundwater may reach the maximum volume. Saline groundwater may rise from the underground through the fault crack.

* Present Address: National Research Institute of Agricultural Engineering

Wetwood of *Acacia Mangium* in Malaysia

Koichi Yamamoto, Othaman Sulaiman and Rokiah Hashim**

Acacia mangium Willd. is native to North Queensland, Australia. Since it was introduced to Malaysia as an exotic species in 1996, it became one of the major plantation species for timber and pulp production. *A. mangium* is a fast-growing tree of good form that grows on degraded soils. Recently the occurrence of some defects such as heart-rot and wetwood, however, has been reported. In spite of its importance for sustainable timber resources in the future, comprehensive characteristics of *A. mangium* wood have not been fully documented. In this study, the occurrence and characteristics of wetwood were examined to analyse the basic wood properties of *A. mangium*. Forty one trees from 6 sites in Malaysia were surveyed.

Most of the trees except for those in the Byram Forest Reserve had higher moisture contents in the inner heartwood than in the adjacent middle or outer heartwood and sapwood (Table 1). Presence of wetwood in tropical plantation wood species has not been reported yet. In most of the tree species the moisture content is lower in heartwood than in sapwood. An increase in moisture in the heartwood region is usually referred to as wetwood, which corresponds to an abnormal type heartwood caused by decay or wound. In most cases in *A. mangium*, wetwood was free of decay, which was confirmed by light and scanning electron microscopy. Only one sample in Rawang displayed heart-rot in the inner heartwood.

The density of wood near the pith is lower than in the surrounding outer heartwood. These result suggest that in *A. mangium* juvenile wood occurs near the pith. The lower density in juvenile wood leads to a higher moisture content, as wood with a lower density can retain more water. Difficulty in drying *A. mangium* could be related to the high moisture content in heartwood.

[Fig.1. Radial distribution of potassium content of *A. mangium* stem from 4 different sites \(Bidor, Byram, Kota Kinabalu and Rawang\). Maximum values were always detected in the outermost sapwood and then decreased toward the sapwood-heartwood boundary. No obvious variations were observed in the heartwood. Arrows show the boundary between sapwood and heartwood.](#)

[Table 1. Average moisture contents\(%\) of *A. mangium* at various sites](#)

As a close relationship between inorganic element concentration and moisture content in wetwood has been described in the literature, the distribution of inorganic elements in this species was investigated. Radial distribution of 4 major elements alkali metals and alkaline earth metals from sapwood to heartwood in stem was analysed using inductively coupled plasma spectroscopy. Wood specimens from 4 plantation sites, showed a similar pattern of K and Mg distribution. The concentration of K and Mg decreased gradually from the outer sapwood toward the outer heartwood, and did not show significant variations within the heartwood (Fig.1). Radial distribution of Na and Ca did not show any obvious trend. All of the samples displaying wetwood (Rawang; March 96 and Bidor) or not displaying wetwood (Byram; Dec.95 and Kota Kinabalu; Jan 97) generally showed a lower content of total inorganic elements in heartwood than in sapwood. The close relationship between inorganic element concentration and moisture content was described in wetwood of temperate species, but had not been recognized in *A. mangium*. The characteristics and origin of wetwood may differ between temperate and tropical species.

Based on the results of decay and inorganic element concentration, wetwood occurring in *A. mangium* was considered not to be an abnormal type of heartwood, wetwood seems to be an intrinsic characteristic of *A. mangium*. The origin of water in wetwood of *A. mangium* should be clarified in the future.

The First Collaborative Research Project of JIRCAS in Central Asia

-Studies on Grassland Management in Kazakhstan-

Kenji sato

Central Asia is one of the new research areas targeted for collaboration with JIRCAS Kazakhstan which is a pasture (steppe) country and the largest country (about 2.71 million Km²) in Central Asia is famous for the steppe and Oasis Silk Road. In this country, the new JIRCAS collaborative research project with the Kazakh Institute of Agriculture (KIA) started from July 1996. KIA is located in the southeastern part of Kazakhstan near the capital city of Almaty.

Our project has two objectives: 1) development of technology for sustainable management of grassland and 2) development of technology for sustainable animal production. Research contents are as follows:

1) Development of technology for sustainable grassland management

- (a) Evaluation of grassland vegetation based on vegetation maps and field surveys
- (b) Monitoring of grassland production in relation to animal grazing
- (c) Identification of indigenous herbage tolerant of drought and cold stress
- (d) Analysis of soil characteristics related to grassland production
- (e) Technology for restoring degraded grasslands by the introduction of suitable forage crops

Photo 1: Resting after survey in the steppe near Kirghistan

Photo 2: Boys riding on a horse in the steppe of Kazakhstan

2) Development of technology for sustainable animal production

- (a) Analysis of genetic characteristics and biological function of indigenous animals
- (b) Effective utilization of supplemental feeds for animals
- (c) Development of methods for estimation of milk and meat quality and quantity
- (d) Market survey for animal products

We are currently attempting to improve degraded areas into ecologically sound pastures using the oversowing method (including seed pellets) which does not require cultivation for the establishment of forage crops. This year, we plan to analyse the relation between soil fertility and grass production on the steppe as well as to improve the degraded steppe using seed pellets and to investigate the changes in the socio-economic structure of agriculture within the framework of our project.

-JIRCAS RESEARCH HIGHLIGHT-

New Varieties of Cucumber and Strawberry Resistant to Diseases China

Keita Sugiyama*

Under the collaborative project on "Breeding of disease resistant vegetable in sub-tropical China, 1991-1995" between the Shanghai Academy of Agricultural Sciences, People's Republic of China and JIRCAS, new varieties of cucumber and strawberry resistant to diseases were eventually developed in China.

1) New cucumber varieties 'Hu 116' and 'Hu 119'

'Hu 116' (photo 1) was found to display a high level of resistance to *Fusarium oxysporum* sch. f. sp. *cucumerinum* and *Pseudoperonospora cubensis* Rostowzew both in laboratory tests and in the field. 'Hu 116' bears many female flowers and its yield is about 10 to 15% higher than that of 'Sinkofushianri 11'. The fruit length is about 21 to 24 cm.

The skin is deep green with few nodules and spines. 'Hu 119' exhibits a similar degree of resistance to *F. oxysporum* and *P. cubensis* to that of 'Hu 116'. Although 'Hu 119' shows a lower female flower bearing capacity than 'Hu 116', stable harvest can take place during the growing period. Like in the case of 'Hu 116', the fruit quality is good.

'Hu 116' and 'Hu 119' are adapted to semi-forcing culture all over the Shanghai area as well as in the Zhejiang, Jiangsu, Shandong, Sichuan areas, etc.

Photo 1 : 'Hu 116'

2) New strawberry varieties 'Shenxu No. 1' and 'Shenxu No. 2'

The total yield of 'Shenxu No. 1' until April was higher than that of 'Toyonoka' or 'Hokouwase'. The fruit is large, about 11-14g, conic in shape with a shiny scarlet skin. The Brix value of the soluble solids in the fruits ranged for 8 to 10. Since the flesh is firm and the skin is hard, this new variety is suitable for transportation. 'Shenxu No.2' (Photo 2) is a very early variety. The harvesting season of 'Shenxu No. 2' is earlier than that of 'Toyonoka'. The fruit is large, about 10-11 g in weight, conic in shape with a very shiny scarlet skin color. The fruit is very sweet, moderately sour and very juicy, with a good taste.

'Shenxu No.1' and 'Shenxu No.2' display a higher resistance to *Colletotrichum acutatum* Immonds and *C. fragariae* Brooks than 'Hokuwase'

'Shenxu No.1' and 'Shenxu No.2' are adapted to forcing culture all over the Shanghai area.

People

Shigeo Yashimma, irrigation engineer, replaced Dr. Tadaaki Yamashita as Director of JIRCAS's Okinawa Subtropical Station on July 3. He was until recently Head of International Collaboration Research Section at the Station. Dr. Yashima carried out research as international staff at the International Irrigation Management Institute (IIMI) during the period 1992-1996, after being engaged in a collaborative research project between Muda Agricultural Development Authority (MADA), Malaysia and the predecessor of JIRCAS, the Tropical Agriculture Research Center (TARC) during the periods 1971-1974 and 1979-1984.

Kozo Fujisaki, former International Research Coordinator of JIRCAS on August 1 and became professor at Obihiro University of Agriculture and Veterinary Medicine. He was in charge of the planning and coordination of the collaborative projects involving research on grassland, animal production and health, and was in launching the project for the "Development of Sustainable Agro-pastoral Systems in the Subtropical Area of Brazil".

Dr. Maeno, DG of JIRCAS Attended CGIAR Mid-Term Meeting 1997

Dr. Nobuyoshi Maeno, Director General, JIRCAS attended the CGIAR (Consultative Group on International Agricultural Research) Mid-Term Meeting which was held in Cairo, Egypt from 26 May to 30 May.

The meeting started with opening remarks by H. E. Youssuf Wally, Deputy Prime Minister of Egypt. In the remarks Professor Wally expressed his full support for the work of the CGIAR and its importance to developing countries.

The main theme of the meeting was the presentation of the Centers' Medium Term Research Plans (MTP) for 1998-2000. To deepen the discussion about the individual centers' MTP, each was considered in parallel session. In the sessions of IRRI (International Rice Research Institute) and WARDA (West Africa Rice Development Association), Dr. Maeno was designated as the chairperson and he emphasized the importance of rice production in the world and introduced the cooperation activities between both centers and JIRCAS.

During the meeting, Dr. Maeno and Dr. Pedro A. Sanchez, Director General, ICRAF (International Center for Research in Agroforestry) signed the MOU between ICRAF and JIRCAS. He also discussed future collaborative activities with the directors general of other centers.

Photo1: Parallel sessions of IRRI and WARDA (The third person from left: Maeno)

The meeting ended with the endorsement of MTPs and reached an agreement that the centers should further promote biotechnology research.

On his way back from Cairo, Dr. Maeno stopped in Rome and visited IPGRI (International Plant Genetic Resources Institute) and FAO to exchange opinions about the possibility of collaboration in the field of preservation of plant genetic resources and prevention of cattle diseases.

JIRCAS International Symposium was Held in Tsukuba

The 4th JIRCAS International Symposium on " Sustainable Development Compatible with Environmental Conservation in Asia" organized by Japan International Research Center for Agricultural Sciences (JIRCAS) in cooperation with the National Agriculture Research Center (NARC), National Institute of Agro-Environmental Sciences (NIAES) and National Research Institute of Agricultural Economics (NRIAS) was held in Tsukuba during the period 26-28 August, 1997. From 15 countries, 214 scientists and administrators, including 27 from abroad, met together and exchanged views on the current situation of and future prospects for sustainable agricultural development in Asia. Mr. Sakue Matsumoto, Chairman, Agriculture, Forestry and Fisheries Research Council gave the welcome address. A keynote speech was delivered by Dr. George Rothschild, Director General of IRRI and 16 papers were presented in the three sessions. The proceedings of the symposium will be published by JIRCAS.

Photo1: General discussion at the symposium.

Comprehensive Studies on Soybean Improvement, Production and Utilization in South America

Makie Kokubun

Soybean, *Glycine max*, is considered to be one of the major crops for human life, especially as oil resource for human consumption and as protein resource for livestock feed. The increase of soybean production has been very rapid compared with that of other major crops for the last three decades (Table 1) and the continuous growth is considered to be very important for the stabilization of the world food supply.

Soybean production in South America, mainly in the MERCOSUR countries such as Brazil, Argentina and Paraguay, accounts for approximately one-third of the total world production (Table 2), and thus the MERCOSUR countries play a major role as leading soybean export countries. However, soybean production in South America has been mostly carried out under environmentally vulnerable conditions such as arid, acid soils with low fertility level. Also, the history of soybean production in these countries is relatively short since cultivation was initiated on a large scale only in the 1960s. It is anticipated that in future growth retardation due to continuous cropping, outbreaks of diseases and pests and soil erosion may adversely affect soybean production in this area. Therefore, research efforts focused on the development of sustainable and more efficient systems of soybean production in South America should be promoted to address these constraints.

[Photo 1: Soybean field in Paraguay \(January, 1997\)](#)

Japan has a long history of soybean cultivation and its use as material of traditional foods. Until now, soybean research in Japan had played an important role worldwide along with the results stemming from research applied in several collaborative research projects implemented by JIRCAS and JICA (Japan International Cooperation Agency). In Brazil, JIRCAS initiated in 1996 a research project entitled "Comprehensive Studies on the Development of Sustainable Agro-Pastoral Systems in the Subtropical Zone of Brazil" in which soybean will be the main crop for the development of mixed, multiple-cropping systems. Also, the Centro Tecnológico Agropecuario en Paraguay (JICA-CETAPAR), which was established in 1962 for extending technical assistance to the Japanese immigrant farmers in Paraguay, is now engaged in studies for the dissemination of no-tillage cultivation system of soybean in the fertile area covered with Terras Roxas soils in Paraguay and neighboring countries for sustainable production.

The JIRCAS's new research project entitled "Soybean Improvement, Production and Utilization in South America" places emphasis on the following characteristics,

- (1) Multidisciplinary studies on soybean production and utilization in South America through the collaboration of researchers from Japan and South American countries.
- (2) Promotion of collaboration with JICA, and selection of CETAPAR as one of the research sites of the project.

Research areas for implementation include,

1. Genetics and breeding,
2. Soil management and pest control,
3. Crop management and production,

4. Postharvest technology,
5. Socioeconomic aspects.

Research organizations expected to participate in the project are institutes affiliated to EMBRAPA (Empresa Brasileira de Pesquisa Agropecuaria, Brazil) and to INTA (Instituto Nacional de Tecnologia Agropecuaria, Argentina), and CETAPAR. The project will be implemented during the period 1997-2006.

Table 1. Cultivated acreage, yield and production of major crops in the 1962-1992 period

Cryopreservation of Germplasm of Tropical Crops

Hiroko Takagi, Nguyen Tien Thinh and Pius M. Kyesmu

Conservation of plant genetic resources has become an issue of common global concern. With increasing numbers of accessions requiring *ex situ* conservation through recent intensive collecting activities, it is important to develop reliable techniques for long-term conservation, especially for vegetatively propagated species that are mainly preserved in field gene banks.

Cryopreservation, storage in liquid nitrogen (LN₂) at a temperature of (-196°), is the only current method that could provide ideal conditions for base collection of vegetatively propagated plant germplasm. In recent years, remarkable progress was made in the field of cryopreservation techniques and different plant materials (cells, protoplasts, meristems, embryos, etc.) from more than 110 plant species were reported to be adequately stored in LN₂. Consequently, cryopreservation was recognized as a practical, efficient and economical tool for long-term storage of vegetatively propagated plant germplasm. There is a growing interest in cryopreservation of crop germplasm in the tropics where species that require clonal maintenance are prevalent. Since tropical species are known to be more sensitive to chilling, low temperature and desiccation than cold hardy or temperate species, cryopreservation of tropical species has not been studied extensively.

In view of the significance of cryopreservation for plant genetic resources activities, a project on the development of techniques for the long-term conservation of vegetatively propagated tropical crops was set up at the Japan International Research Center for Agricultural Sciences (JIRCAS). This project aims to develop simple techniques for the efficient and stable cryopreservation of shoot tips of several tropical crops i.e. taro, yams and banana.

Recent progress in cryopreservation has provided potentially valuable cryogenic procedures such as slow freezing, desiccation, encapsulation/dehydration, and vitrification. We focused on the vitrification method because the handling of explants by this method is relatively simple and the method has been reported to be successful with complex tissues such as meristems rather than cells. The principle of the vitrification method is as follows: dehydration of a specimen by exposure to a vitrification solution containing a high osmoticum and changes in the conditions of intracellular water as well as penetration of antifreeze substances (such as sucrose, ethylene glycol, dimethyl sulfoxide (DMSO), glycerol) in the vitrification solution to promote the vitrification of the specimen by rapid cooling in LN₂.

Through detailed investigations of the conditions of each procedure of the vitrification method, a protocol for shoot tips of taro (*Colocasia esculenta* (L.) Schott) was eventually optimized (Table 1). The keys for the success were as follows: 1) conditioning culture of shoot tip donor plants with high concentration of sucrose (120g/l), 2) selection of shoot tips with proper size and developmental stage, 3) preculture of dissected shoot tips with 0.3M sucrose prior to the cryogenic procedure, and 4) loading treatment by cryoprotectants at lower concentrations than vitrification solutions. Vitrified and warmed shoot tips obtained by this method resumed growth within 7days, developed shoots directly without intermediate callus formation and almost all the shoot tips that survived were easily transferred to soil in pots. No morphological abnormalities were detected in the plants developed from the cryopreserved shoot tips (Photo 1). The protocol developed was applied to various triploid and diploid taro cultivars and post-thaw survival rates of 67-100% were obtained for the different genotypes.

The protocol for taro was also successfully applied to tannia (*Xanthosoma* spp.), banana (*Musa* spp.), yams (*Dioscorea rotundata* and *alata*), pineapple (*Ananas comosus*), orchid (*Cymbidium*) with some modifications depending on the level of sensitivity of each species to sucrose and vitrification solution.

Our study demonstrated that cryopreservation of shoot tips by vitrification can be useful for the long-term conservation of vegetatively propagated tropical crops.

[Photo 1:](#)

[A\) Taro shoots formed from cryopreserved shoot tips by vitrification. Dead shoot tips turned white whereas those which survived showed a green color](#)

[B\) Taro plants developed from cryopreserved shoot tips by vitrification](#)

Table 1. Protocol developed for cryopreservation of shoot tips of taro by vitrification

- Step1:** Culture the shoot tip donor plants on Murashige and Skoog medium (MS) supplemented with 120g/l sucrose for three weeks (conditioning culture)
- Step2:** Dissect shoot tips (0.5-0.8mm in length, apical dome + 1-2 leaf primordia)
- Step3:** Preculture the shoot tips on MS containing 0.3M sucrose for 1 night at 25°C
- Step4:** Treat the precultured shoot tips with a loading solution [2M glycerol + 0.4M sucrose] for 20min at 25°C
- Step5:** Expose the loaded shoot tips to PVS2 [30%(w/v) glycerol + 15%(w/v) ethylene glycol +15%(w/v) DMSO + 0.4M sucrose] for 10min at 25°C
- Step6:** Directly immerse the shoot tips into LN₂ and store
- Step7:** Rapidly rewarm the cryopreserved shoot tips in a 40°C water bath
- Step8:** Soak the shoot tips into 1.2M sucrose for 10min at 25°C
- Step9:** Reculture the shoot tips on two layers of blotting paper over MS supplemented with 0.3M sucrose
- Step10:** Transfer the shoot tips to MS containing 0.1M sucrose for regrowth of plantlets

Entrepreneur Farmers in Peninsular Malaysia: Profile of *Peladang Jaya*

Kumi Yasunobu, Wong Foong Yee and Laily Paim

The new National Agricultural Policy (1992-2010) sealed a new era for the small-holder farmers in Malaysia. The emphasis of the new policy is on the commercialization of the small-holder and the small "unorganized farmers" sub-sector. To achieve the above objectives, the traditional farmers need to become entrepreneur farmers. In our study, we focus on a special exclusive group of farmers, who have won the annual title of "*Peladang Jaya*" or "Successful Farmers", awarded by the Ministry of Agriculture as respondents. They were chosen to become role model of modern, innovative, resourceful farmers, for others to emulate. They are outstanding individuals when compared to other farmers, nationwide. In our evaluation, they are one step nearer to the "entrepreneur farmer" types as envisioned by the policy makers, to transform the agricultural sector into a modern commercialized entity.

The main purpose of the study is to explore the characteristics of a group of leader farmers, who stood above the rest of their counterparts nationwide, for which they won the title of "*Peladang Jaya*" in annual competition. From the year 1987 to 1993, out of a total 88 farmers listed, 71 *peladang jaya* were selected; 40 male and 31 female farmers. They were purposely selected to represent all the states in Peninsular Malaysia. The respondents were personally interviewed by the researchers. The data collection lasted from November 1993 to July 1994.

In Malaysia, encouraged by the market demand, the enterprising farmers began to diversify their crops and farming activities, which include livestock raising and aquaculture. The survey found that the *peladang jaya* were mostly engaged in mixed cropping, except for 20% who were involved in mono-cropping paddy cultivation. In paddy cultivation, 14 people were mainly engaged in mono-cropping. Others combined the cultivation of paddy rice with other field crops-mostly a combination with industrial, and/or with short term cash crops, and fruit orchards.

The average income of the respondents in the sample was RM42,791 per year. The income was derived from earnings from farming and non-farming activities. The proportion earned from farming activities was high at 73%. Judging from the average annual income earned, this group of *peladang jaya* can be categorized as middle income group, and a few can be classified as upper middle income group.

As for the farm and household equipment, the standard of living of *peladang jaya* was higher than the Malaysian average in Agricultural Census. All the farmers owned houses, some of them being relatively large and comfortable, fully equipped with the basic necessities and utilities such as piped indoor water and toilets, when compared to the farmers in their respective villages. Almost all the respondents owned basic electric appliances such as fan (98.6%), refrigerator (97.1%), television set (100%) and radio (95.7%). All except 2 of the respondents used a LPG stove for cooking and 88.6% owned sewing machines. Seventy nine percent of the farmers•Ehouseholds owned washing machines while slightly more than two-thirds had telephones. It is noteworthy to observe that almost one-third (32.9%) owned Kubota/2 wheel tractors, while another 10% big tractors.

By applying principal component analysis, seven factors that represent the attitude of the *peladang jaya* were identified as follows:

Factor 1: "work eagerness"

The respondents were diligent in conducting farming job. Once they faced a problem, they attempted to solve it.

Factor 2: "good planning"

They recognized the importance of planning and realized that their effort leads to success. In other words, they attributed their success mainly to proper planning.

Factor 3: "challenging"

They realized the importance of recording and they showed challenging spirits. They knew what action should be taken to resolve a difficulty without other people's help. **Factor 4: "self-confidence"**

They considered that the ability to manage is much more important than physical involvement. They also carried out the project because they had a great deal of knowledge and experience.

Factor 5: "cautiousness"

The respondents were able to consider risk.

Factor 6: "resourcefulness"

The respondents knew where and how to seize the opportunities required to improve their farming.

Factor 7: "information seeker"

In summary, they were not only eager to collect information but also did not hesitate to ask people to get more information. These 7 factors accounted for approximately 75% of the variance.

Based on the analysis and interview observations, following three major characteristics can be pointed out for the leading farmers:

- 1) They made utmost efforts to increase their income. Besides farming they held various side-jobs in small industry or were engaged in large scale business.
- 2) They were interested in the new technologies including machinery, chemicals and new varieties. They planted the crops which other farmers in the area did not use. They easily adopted new projects.
- 3) They had acquired a knowledge and/or experience of farm management practices. Almost all the respondents participated in courses and seminars.

It is noteworthy that even though their educational background was not high, they were eager to gain useful information pertaining to farm management as much as possible. Their formal educational attainment varied from none to 6 years (elementary school level). Some of the respondents who did not have formal education attended "*pondok*" (religious school) in the village.

Besides being actively involved in farm and non-farm activities, the respondents were also engaged in social activities, such as group farming projects, agricultural associations, religious groups, village committees, etc. They joined not only as members, but held important positions like head, deputy and committee member, implying that they are playing an important role as leaders in their community.

“Sugarcane Stalk* Can Be a Good Roughage for Dairy Cattle in the Dry Season

Tomoyuki Kawashima

Dairy production has been developed in the temperate and cool zone. The feeding system adopted in this area is generally based on preserved roughage such as hay and silage. This system requires large machinery with a large scale of operation. On the other hand, dairy production has been newly introduced into monsoon and savanna zones in the tropics. Generally speaking, dairy production in this region is characterized by a small scale of operation and manpower system. In this system, hay or silage making has not yet been practically implemented. Farmers are very much relying on rice straw as a roughage in the dry season (Photo 1). Low nutritive value of rice straw limits further improvement of production. And collection of rice straw is a labor/time-consuming work, which is another constraint. On the other hand, sugarcane has unique characteristics. It can produce a large amount of biomass and stand until the end of the dry season without withering, which allows farmers to cut it when necessary without the need for preservation. The use of sugarcane stalks (Photo 2 and 3) as a roughage for cattle has been examined in Northeast Thailand.

A metabolic trial by using Brahman cattle was carried out in order to determine the content of metabolizable energy in sugarcane stalks, which amounted to 9.05 MJ/kg. It was estimated that sugarcane can supply nearly 3 times the level of metabolizable energy per ha than that that by ruzi grass which is the major grass produced in the region.

Sugarcane stalk can be divided into an easily soluble fraction, i.e. sugar, and hardly degradable fraction, i.e. bagasses. The turnover rate of digesta from the rumen was compared between the cattle given either ruzi grass hay or sugarcane stalks. While the liquid phase outflow was faster in the cattle given sugarcane stalks than in those given ruzi grass hay, the solid phase outflow was slower in the cattle given sugarcane stalks (Table 1). It was considered that bagasses remained in the rumen for a long period of time without degradation, which would suppress feed intake. Although sugarcane stalks have a relatively high metabolizable energy content, cattle can not consume a sufficient amount of sugarcane stalks to satisfy their energy requirement. Therefore, cattle must be given concentrate feed to fulfill not only the protein but also the energy requirement.

Feeding trial was carried out using milking cows owned by a private dairy farmer in order to examine the use of sugarcane as a roughage for milking cows. Milking cows were given either only rice straw *ad libitum* or chopped sugarcane stalks plus rice straw *ad libitum*. Both groups were also given commercial concentrate feed whose amount was determined by the farmer based on the cow's body condition as well as milk yield. Milk production tended to be higher in the cows given sugarcane stalks than those given only rice straw in spite of the lower total DM consumption. Protein content in the milk of the cows which received sugarcane stalks was significantly higher than that in the milk of cows given rice straw. It was considered that the energy supply was increased by supplying sugarcane stalks, which affects the improvement of the protein content in the milk, while energy supply was not sufficient when only rice straw was given to cows.

Sugarcane stalks can be a good roughage for milking cows in the dry season provided that they are

Sugarcane as a roughage for cattle feeding

supplemented with proper protein and energy sources.

[Table 1. Turnover rate of liquid and solid phase in rumen, and liquid volume of cattle given ruzi grass hay and sugarcane stalks](#)

Response of Lowland Rice to Inoculation with Plant Growth-Promoting Rhizobacteria (PGPR) and Their Culture Supernatants

Dr. Hussein M. El-Khawas

*Department of Microbiology, Faculty
of Agriculture, Cairo University, Giza, Egypt*

Cereal crops are the most important sources of food. In particular, rice is the major food for more than one-third of the world population. Many plant growth-promoting rhizobacteria (PGPR) have been isolated from cereal crops and demonstrate the ability to promote plant growth under different growth conditions. Various free-living nitrogen-fixing bacteria are considered to be PGPR, including *Azospirillum* and *Klebsiella* species. These nitrogen-fixing microorganisms also produce growth regulators such as auxins, several gibberellins and cytokinins. Therefore, the aim of my study at the JIRCAS International Collaboration Research Section (ICRS) is to identify and quantify auxins, gibberellins, and cytokinins in culture medium of *Azospirillum* and *Klebsiella* strains and to determine their effect on the development of rice roots. In addition, the study will also focus on the response of rice seedlings to inoculation with different PGPR strains. The practical use of such PGPR bacteria may enable to save chemical fertilizers.

Physiological, Biochemical and Genetic Characterization of Salinity Tolerance in Rice

*Dr. Safdar Hussain Shah
Agricultural Research Station
Dhodial Mansehra, NWFP, Pakistan*

Generally plants experience some kind of stress during the various stages of growth. Salinity is a widespread stress occurring worldwide which limits the yield on 30% of the total land. The ever-increasing salinity-affected area coupled with the decreasing soil resources, dwindling fresh water availability and increasing demand for food requires that plant scientists develop a biological strategy (breeding crops for saline areas) to complement the technological strategy (reclamation and drainage, etc.) for intensive and extensive agriculture. Salinity exerts diverse effects (osmotic, toxic and ionic imbalance) on plants/cells and tolerant genotypes are expected to have more than a single adaptation simultaneously.

My collaboration at JIRCAS Okinawa Subtropical Station aims to identify and characterize the salinity markers in rice that are associated with the osmotic component (cytosolute accumulation) and toxic component (modifications of membranes) of salt tolerance by studying the cation co-tolerance phenomenon through the selection of cell lines tolerant to LiCl (toxic effect), PEG (osmotic effect) and NaCl (osmotic+toxic effects). This may lead to the elucidation of the components of salinity tolerance in rice that could contribute to the characterization of salt tolerance and development of salt-resistant plants by biotechnological techniques in conjunction with classical breeding methodology.

JIRCAS Fellows in Okinawa

Studies on the Relationship between Salinity Tolerance and Cold Tolerance at the Booting Stage of Rice (*Oryza sativa* L.)

Li Chengyun

Yunnan Academy of Agricultural Sciences, People's Republic of China

Drought, cold, heat and salt stress all induce dehydration in plants and it is well known that the panicle initiation stage is a very sensitive stage both to cold and salt stress in rice. It has been reported in the literature that a number of genes respond to dehydration as well as to low temperature and high salt stress at the transcriptional level. These results indicate that there may be some common physiological characteristics between salinity and cold tolerance, especially at the booting stage. Although tolerance of rice varieties to salinity and cold has been studied by many researchers, salt tolerance was mainly studied at the seedling stage and cold tolerance at the booting stage. Therefore, 30 rice varieties showing a wider variation in cold tolerance will be utilized in this study for the development of salinity tolerance. The effect of salinity on the percentage of seed setting, mean grain weight, grain yield, protein and amylase content in brown rice, *in vitro* pollen germination, Na⁺ accumulation in roots, old leaves and flag leaves will be investigated. The results may enable to clarify the mechanism of cold and salt tolerance in rice plant.

Workshop on Heat Tolerance of Crops

- October 7&8, 1997 JIRCAS Okinawa Subtropical Station -

Takaharu Hayashi

JIRCAS is expected to contribute to the development of agricultural technology for developing countries. One of the divisions of JIRCAS, Okinawa Subtropical Station (OSS) was established to promote agricultural research under a subtropical environment. Thus, heat tolerance of crops is a major research activity at OSS. The Workshop on Heat Tolerance of Crops held at OSS aimed at two objectives. One was to review previous research output from OSS and the other was to devise new strategies for developing techniques for improving heat tolerance of crops including mitigation of heat stress and heat tolerance.

The workshop was held for two days from Oct. 7 to Oct. 8, 1997 at OSS under the sponsorship of JIRCAS. Prof. Anthony Hall from the Department of Botany & Plant Science, University of California and Dr. George Kuo from the Asian Vegetable Research and Development Center were invited as keynote speakers. Dr. Ishige from JIRCAS Headquarters was also invited as commentator and chairman of the general discussion. A total of 28 researchers including OSS staff members participated in the workshop.

On the day first, Dr. Kuo, Director of Crop Improvement Program, gave a presentation on “Vegetable improvement of heat tolerance under tropical conditions” and Prof. Hall gave a presentation on “Positive and potential negative effects on crop of Heat Tolerance Genes”. Following the keynote speeches, six researchers from OSS including three visiting scientists from JIRCAS Visiting Research Fellowship Program '97 presented their research outcome. On the second day, five researchers outlined future strategies for studies of heat tolerance of crops at OSS. Participants exchanged views on the progress of heat tolerance studies and confirmed the importance of such studies. In the last part of the workshop, Dr. Ishige, chaired the general discussion. During the workshop, questions, were raised and discussions and comments took place. The workshop may enable OSS to devise new strategies for developing techniques for improving heat tolerance of crops in the future.

Preliminary Notice for The 5th JIRCAS International Symposium

“Postharvest Technology in Asia – For a Stable Supply of Food Products – ”

The symposium on “Postharvest technology in Asia – For a stable supply of food products –” organized by the Japan International Research Center for Agricultural Sciences (JIRCAS) will be held in Tsukuba, Japan during the period of September 9-11, 1998.

In Asia, agricultural research so far has been mainly centered on the improvement of crop production itself to achieve self-sufficiency in food in order to support the growing population of the respective countries. It is anticipated that, in the near future, the food supply problems will become more complex as patterns of food consumption become more diversified in the region along with the increase of income and societal development.

“Postharvest technology”, which encompasses issues ranging from harvesting methods in farmers’ fields to food processing, should be more emphasized to prevent crop losses, to utilize agricultural products efficiently and to meet the changes in the food demand.

Recognizing the importance of “Postharvest technology”, this symposium will attempt to highlight the main priorities, constraints and perspectives in the field of postharvest technology. Three sessions with invited speakers will cover the following themes:

Session 1: Main priorities and constraints relating to postharvest technology in Asia

Session 2: Perspective of technology for grain storage and preservation in the tropics

Session 3: Development and orientation of technology for food industries in Asia

Latest Research Topics in the Crop Production and Postharvest Technology Division

-With Emphasis Placed on Crop Protection-

Dr. Koji Kawashima

Director, Crop Production and Postharvest Technology Division

The Crop Production and Postharvest Technology Division is expected to cover various agricultural research fields such as the production of paddy rice, upland crops and fruit trees, plant protection, weed control, cultivation of cash crops, irrigation and drainage, agricultural engineering, postharvest technology, agricultural economics, etc.

At present there are 17 researchers in the Division including nine in the field of plant protection, two each in the fields of paddy production, irrigation, and postharvest technology, one each in the fields of upland crop production and agricultural economics. Out of 17 researchers, ten were dispatched abroad for collaborative research and seven are carrying out research in Japan.

Some of the collaborative research studies conducted abroad in this Division will be described, with emphasis placed on plant protection.

1. Study on the Biology and Control of Leaf Cutting Ants (collaborative research with Universidade Estadual Paulista, Campus de Botucatu, Brazil)

In the tropical and subtropical areas of the North and South American continent, leaf cutting ants attack almost every crop including pasture crops. Especially in Brazil, along with deforestation, the area of leaf cutting ants has expanded recently, including species that didn't used to be serious so far. Leaf cutting ants mow a large volume of plants that are stored in the nest underground to produce their food, a special kind of mushroom. In order to eradicate the ants, poisonous feeds are scattered or strong pesticides are applied into the underground nest. However, since these methods are not as effective as expected and furthermore they bring about environmental pollution, alternative methods of control are being studied.

A JIRCAS researcher has succeeded in raising ants for more than six months for the first time under artificial conditions in the laboratory. Then he selected the leaves which the insects prefer and sprayed them with pesticides so that the insects would take them into their nest. It was interesting to note that after the leaves were heated at 120°C and that some components were removed, the ants consumed such leaves, suggesting that preference for a kind of leaves depends on the presence or absence of a repellent.

2. Biorational Control of Desert Locust (collaborative research with ICIPE, Kenya)

Even since the prehistorical era until now in North Africa, mainly in Sudan and Ethiopia, large swarms of locusts have occurred with occasional migration to eastern and western areas, resulting in serious damage to agricultural products and pastures in these areas.

To eradicate the desert locust, large amounts of various chemicals have been sprayed by airplane but due to the adverse impact on the environment alternative ways that are environmentally friendly are being sought.

A JIRCAS researcher is studying the effects of insect hormones and pheromones on the behavior of the locusts. These substances disturb the insect physiological behavior-oviposition, aggregation, sexual

attraction, resulting in the decrease of locust survival. It was observed that when a hormone (NC-184) was applied to young (3rd to 4th instars) or adult locusts, the body color became darker and the duration of the 5th instar was prolonged. Induction of abnormal sexual behavior of young locusts by the hormone may enable to control the desert locust.

3. Ecological Studies on Long Distance Migrating Planthoppers

(collaborative research with Chinese Rice Research Institute, China)

Planthoppers are among the most serious insects for paddy rice in the monsoon area in East Asia. Since in Japan and in most of China planthoppers can not survive during the winter season, it is considered that outbreaks are due to the migration of a large number of insects from other areas. Ecological studies are essential to develop an accurate method for the forecasting and the control of planthoppers.

A JIRCAS researcher is staying in Hang Zhou, South China. He is investigating the immigration, multiplication and emigration of planthoppers in the paddy area of the southern Yangzi Jiang river and also the relation between the weather conditions and the behavior of the insect for migration. It has been reported recently that the population of the white-backed planthoppers has drastically increased. The reason for the increase is being investigated. Ecological studies on planthoppers during the winter season are also being carried out in the coastal area of South China. Genetic diversity of planthoppers is being traced geographically to clarify the center of origin of this insect.

4. Integrated Research on the Control of Biotic Agents in Rice Production (collaborative research with MADA and MARDI , Malaysia)

Alor Setar area in North Malaysia is the major rice granary in Malaysia. In the 1980s direct seeding of rice rapidly spread to this area due to labor shortage and it was gradually observed that direct seeding was associated with the growth of biotic agents, i.e. weeds especially during the first dry direct seeding season. Two JIRCAS researchers are carrying out studies on rice cultivation and weed control. In order to avoid weed hazard, it is recommended to sow an early variety of rice just before the onset of the rainy season. For this purpose some rice varieties have already been selected.

For some of the main weeds, seed production, survival rate of seeds in soil and chemical tolerance are investigated. Recently it has been observed that weedy rice was a serious weed. Morphological and ecological studies are being conducted to develop methods of control of this weed.

[Photo1:Leaf cutting ant](#)

Production of Urea Molasses Blocks for Ruminant Animals in Malaysia

Akinori Oshibe, M. Wan Zahari and M. S. Nor Ismail

Despite the abundance of various agricultural by-products, Malaysia is still a net importer of feed ingredients with an estimated value of more than M\$ 500 million annually. By using molasses, urea and other ingredients as supplements, these materials can be made into urea molasses block (UMB), a promising and practical feed supplement for ruminants. Recently, a suitable UMB formula using efficient processing technology has been developed at the Malaysian Agricultural Research and Development Institute (MARDI) for semi-commercial UMB production through the collaborative work between MARDI and JIRCAS. This paper reports on the method of UMB processing and its effects on the performance of ruminants.

We designed a UMB processing line that consists of an ingredient conveyance system, weighing system, a cutter mixer, a vertical twin shaft mixer and a single horizontal shaft mixer. A procedure that could be handled by a small number of operators and required a short time was developed. More than fifty formulae were examined based on the mixing efficiency, speed of solidification and palatability for animals. The composition of the formulae associated with a good palatability is shown in Fig. 1. Performance of the lambs was used as a criterion for the evaluation of the UMB. Fifteen lambs (mean live-weight 17.3 kg) were randomly divided into three groups. The first group which acted as a control was fed oil palm frond silage (containing 6% crude protein) *ad libitum*. The second and third groups received a similar type of diet supplementation with either imported UMB or locally made UMB (WZ42D), respectively. Changes in live weight and UMB intake were recorded weekly over the 6-week period of the experiment. At the end of the experiment, the total intake of WZ42D was approximately five times higher than that of imported UMB (Fig. 2), which may be due to the higher palatability. On the other hand, body weight of the control group decreased markedly during the trial (Fig. 3). It was evident that low UMB intake was a limiting factor in the use of imported UMB. Intake and live-weight gain of the animals supplemented with WZ42D were significantly higher ($P < 0.05$) than those in the other groups. Within the conditions of the trial, it can be concluded that the performance of the animals which received WZ42D was higher than that of the animals fed imported UMB.

Statistical Database System for World Agriculture, Forestry and Fisheries

JIRCAS-STAT

Osamu Koyama

In order to facilitate analytical work for the planning of research projects and to conduct research related to world food demand / supply projections, the Division has constructed a statistical database system which enables to handle a large variety of socio-economic time series data in an integrated manner.

With the database system, the user can look up the data needed by simply selecting the regions, items and years. The user can arrange the data in various types of tables. In addition, using the combined software, graphical display of the data and statistical / econometric analyses can also be easily carried out.

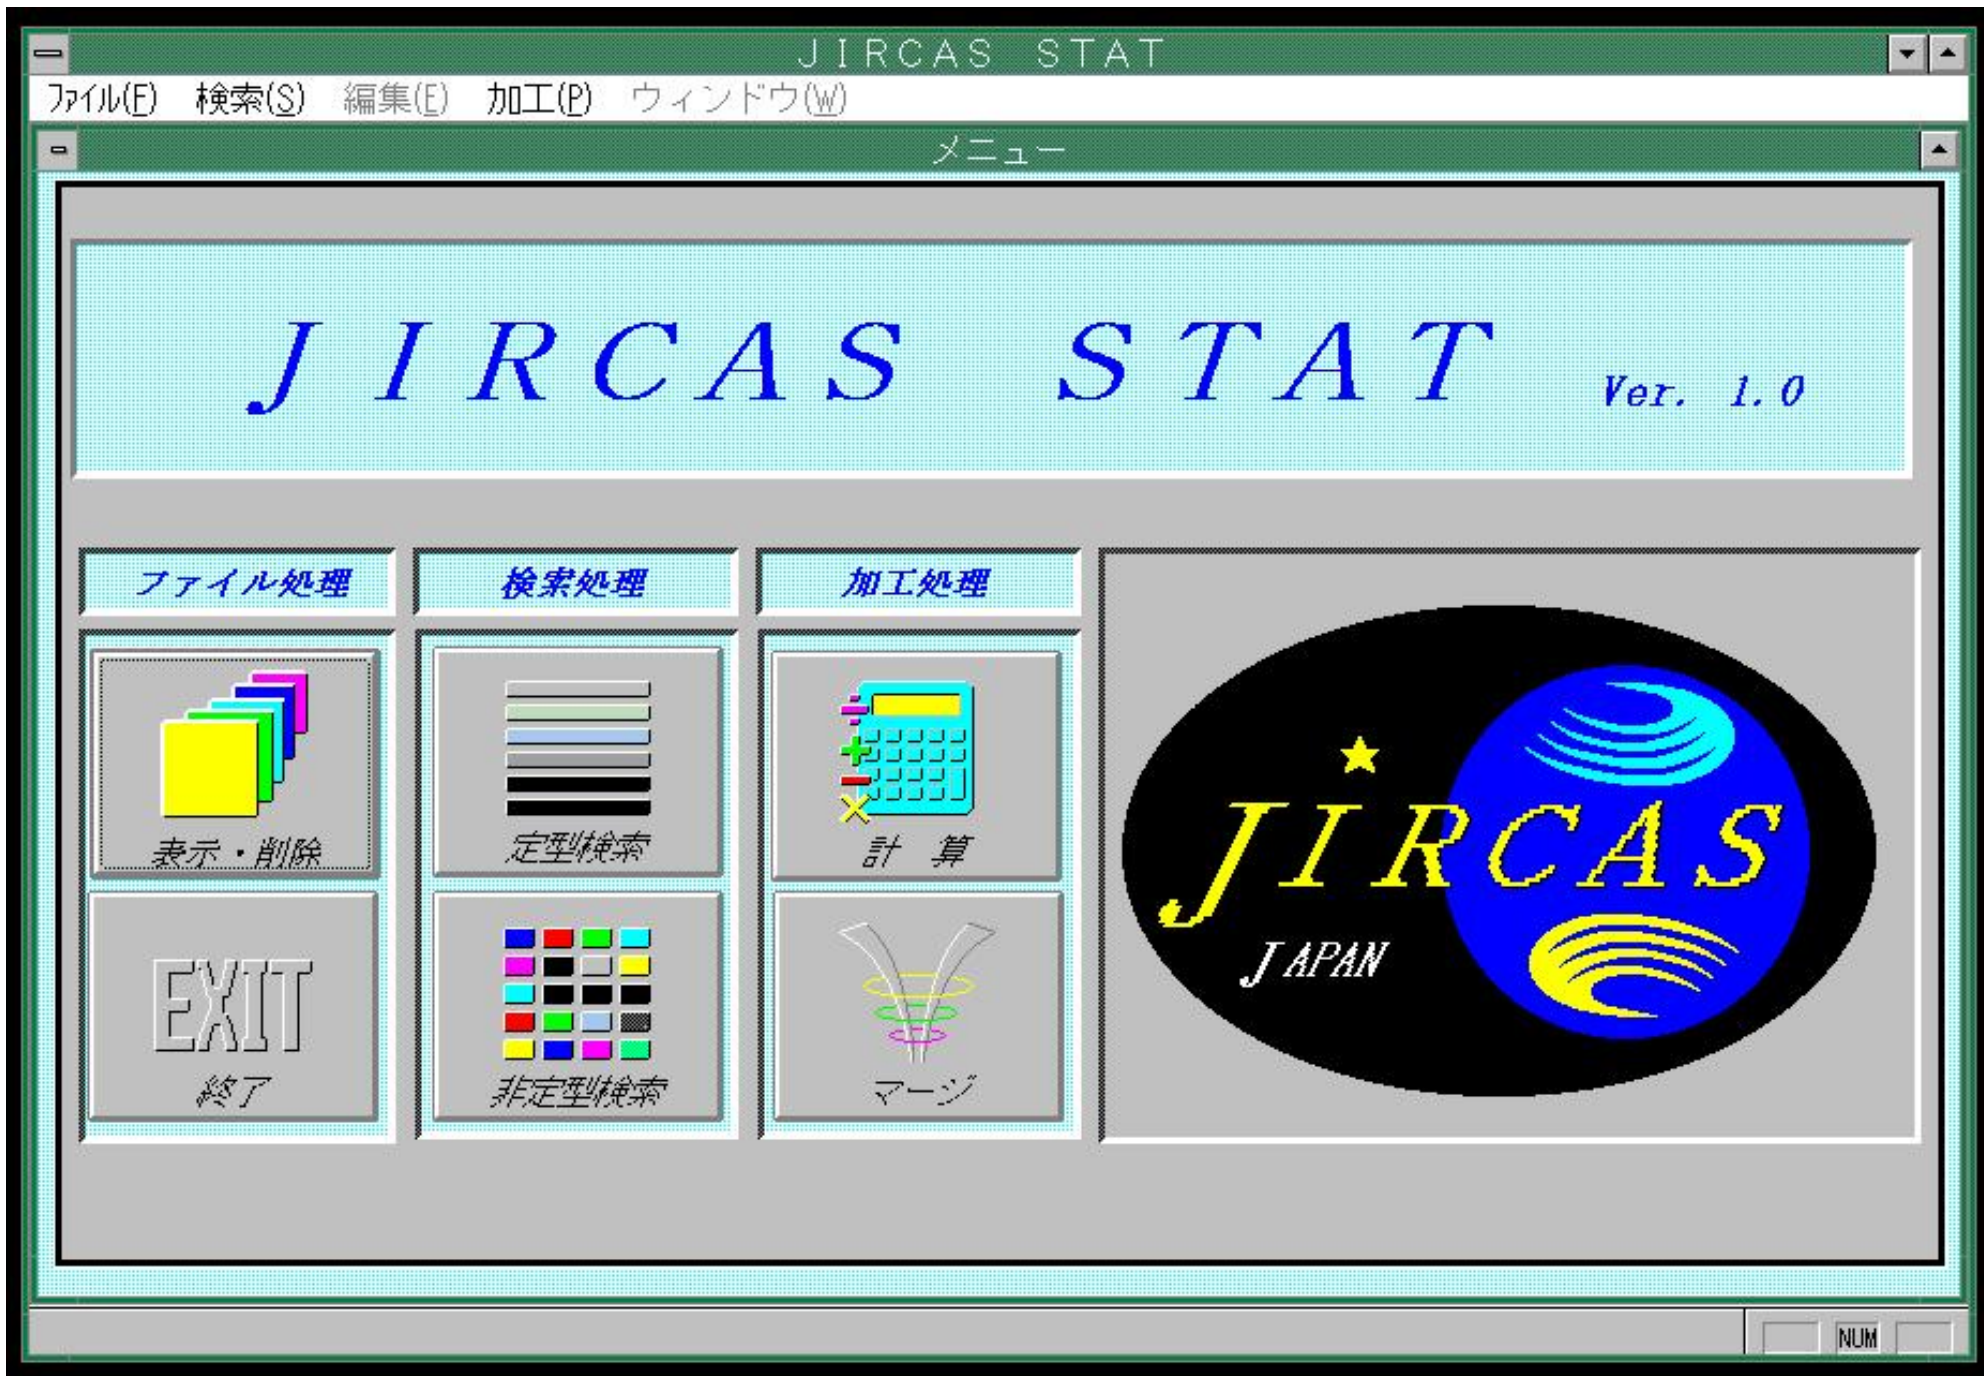

Until now, most of the relevant data published by the international organizations had been stored in a database with a common format. The database covers yearly statistics related to agriculture, forestry and fisheries fields. It also includes general indicators such as population, GDP, land use in addition to the data classified by products, e.g. production, trade, food balance sheets, food aid, etc.

The advantage of this system is that it is user-friendly. As it is based on the Windows operating system, the most popular system for personal computers, users do not need to learn any special commands. Due to the original approach of transforming a modern relational database structure into a structure suitable for the statistical time series data, the system affords a great efficiency in terms of both processing speed and data storage space.

The system is being used for the preparatory work of the econometric model analysis of the world food market carried out by the Division. It has been installed in several locations of the Headquarters of the Ministry. Within a year it will also be available through information networks to the remote users in the Ministry. In addition, a database system for documents and pictures is being constructed in the Division.

Research Collaboration in Kazakhstan Has Started

JIRCAS initiated a collaboration with the Kazakh Institute of Agriculture (KIA) for a 5-yr (1996-2000) research project entitled: "Development of Sustainable Systems of Grassland Management and Animal Production in Central Asia". On this occasion, Dr. Keiji Kainuma, Director General of JIRCAS visited Kazakhstan at the beginning of July and signed the Memorandum of Understanding between the Kazakh Institute of Agriculture (KIA) and JIRCAS, as the last mission during his tenure at JIRCAS. Under the MOU, Dr. Kenji Sato, a pasture agronomist of JIRCAS, will be engaged in the new collaborative project at the Institute. The research project is the first to be implemented by JIRCAS in Central Asia.

International Symposium on the Biosafety Results of Field Tests of Genetically Modified Plants and Microorganisms

Shigeo Matsui

From 29 countries all over the world, 220 scientists and administrators, including 90 from abroad, in the field of biotechnology met together on July 14-17 at Tsukuba Dai-ichi Hotel. It was the "4th International Symposium on the Biosafety Results of the Field Tests of Genetically Modified Plants and Microorganisms" which was held as the 3rd JIRCAS International Symposium at the same time. The participants were molecular biologists, plant breeders, food engineers, medical scientists, bacteriologists, virologists, geneticists, etc. Some of them are in charge of public acceptance or safety assessment in their governments or companies.

Recently, progress in biotechnology, especially in recombinant DNA technologies, has made the use of artificially gene-modified plants or microorganisms common and familiar to us. First gene-modified and commercially produced commodity "Flavr Savr" tomato which was released only two years ago is now followed for example, by cotton and potato plants with *B.t.* genes which produce insect-killing proteins, herbicide-resistant rapeseed, soybean and corn plants, virus coat protein-transferred tobacco and sugar beet plants which are tolerant to virus diseases, low ethylene-emitting carnations with long vase life, etc., as introduced by researchers from Monsanto, AgrEvo, PGS and Florigene, private companies. Moreover, gene-modified bacteria and viruses are being tested for use for bioremediation or to substitute chemicals conventionally applied to protect and stimulate crops. The papers presented at the symposium indicated that we are reaching a historical point in the era of new agriculture, indeed.

The effects of these transformed organisms on the eco-systems or on human health require that exhaustive field tests be performed. To discuss the results from such tests, the Symposium has brought together scientists with a wide range of expertise every other year since 1990, and this year, the conference coincided with the rapid increase of releases of genetically modified organisms (GMOs).

This Symposium was also significant in that it was held in Asia for the first time and leading scientists from developing countries were invited to introduce the present situation of the biosafety issues in each country. Developing countries really need to develop those new crops to feed rapidly growing populations and to minimize environmental stresses and actually they are very eager to use transgenic crops, as typically reported by Dr. Chen from China.

In order to evaluate biosafety, the development of new methods was presented. Allergen proteins from MGOs could be detected using IgE antibody-binding assay and immortalized cells, as reported by Dr. Lehrer from USA and Dr. Shinmoto from Japan, respectively. Dr. Ramos from Spain showed that the containment of recombinant microbes to the site of application was possible by using "suicide genes". Environmentally applied microorganisms can be detected by CCD camera if they are bioluminescent, as reported by Dr. Dane from USA. Regarding the risk assessment, commercial use of genetically modified virus insecticides was discussed by Dr. Wood from USA, and the possibility of natural gene transfer from transgenic plants to wild viruses aggravating the disease in crops was discussed by Dr. Tepfer from France.

Most of the speakers admitted that there is little possibility that the genetically modified plants or microorganisms will be dangerous to us and our environment. However, it is still essential that proper

guidelines should be established and relevant field tests should be performed to confirm the biosafety before such organisms are released to the environment.

At the end of the Symposium, Dr. K. Kainuma, Director General of JIRCAS emphasized in his closing remarks that international collaboration is essential to promote the harmonization of biosafety guidelines for the development of transformed crops, in particular in the developing regions. He also indicated that he was much pleased to transfer his duties to Dr. Willy De Greef, who is accepting the responsibility to host the 5th Symposium in 1998 in Belgium.

Participants obviously enjoyed the opportunity to see each other after an interval of two years and to obtain up-to-date information. They also enjoyed the nice foods and beautiful sounds of the *koto* strings during the dinner held on the third evening of the Symposium.

<<Project Report>>

Sustainable Agricultural Systems in Northeast Thailand

Makie Kokubun

1. Constraints on agricultural development in Northeast Thailand

As a result of the rapid economic growth in the past decade, the relative economic importance of agriculture has remarkably decreased in Thailand. In Northeast Thailand, where the economy largely depends on agriculture, income per capita is only one ninth compared to that of Bangkok. Due to the low profitability of agriculture in the region, a large outflow of labor force from the region to urban areas has occurred, which has led to the shortage of workforce in agriculture, particularly young people.

Since the 1960s, a large acreage of forest has been cleared to make room for upland fields in Northeast Thailand, leading to a reduction of the water-holding capacity and to salt accumulation due to the elevation of the groundwater table. In addition, the deforestation of sloping land has made the land highly vulnerable to soil erosion by wind and rainfall. Soil fertility of the reclaimed fields, which was originally low, has further deteriorated after several years of cultivation, because of the inadequate application of fertilizers and organic materials. Moreover, precipitation is erratic and the dry season lasts for more than half a year in the region. These environmental constraints as well as the social problems facing Northeast Thailand have restricted agricultural development in the region.

2. Comprehensive project based on past JIRCAS (formerly TARC) and JICA achievements

To address these constraints and problems, JIRCAS initiated in 1995 a 7-year research project, "Comprehensive studies on sustainable agricultural systems in Northeast Thailand". This multidisciplinary research project includes soil, crop and livestock sciences as well as economic and social studies. The contents of the project are based on the knowledge and experience gained in previous collaborative research activities undertaken by JIRCAS (formerly TARC) and JICA in Northeast Thailand for the past few decades. Research activities are currently being carried out at the Agricultural Development Research Center in Northeast Thailand (ADRC) and other Thai research institutes affiliated to the Department of Agriculture (DOA), Department of Land Development (LDD), Department of Livestock Development (DLD), Khon Kaen University (KKU) and Asian Institute of Technology (AIT).

Biological regulation of methane emission in paddy fields

Methane is an important greenhouse gas which contributes to global warming. As an important source of CH₄, rice fields account for approximately 10 % of the global anthropogenic methane emission and it is considered that 80 % is derived through the methane-generating bacteria (MGB).

CH₄ emission from rice fields is the net effect of CH₄ production and CH₄ oxidation. CH₄ oxidation by methane-oxidizing bacteria (MOB) consumes 1 to 10 % of the total global emission and MOB are considered to be important biological regulators of methane fluxes in nature.

My collaboration with Dr. Adachi aims to characterize the dominant MOB in Ishigaki paddy fields and to establish a model ecosystem *in vitro* to elucidate the mechanism of methane production and oxidation in paddy fields. I do hope that these studies will result in technological development for environmental control of methane emission and sustainable crop production in rice-growing countries.

***Azospirillum* study in lowland rice**

It is well known that soil microorganisms are the driving force behind nutrient transformation in soils and thus contribute significantly to soil fertility. Especially for the availability of nitrogen, the involvement of soil microorganisms is indispensable.

Azospirillum are associative N₂-fixing bacteria. Inoculation of these bacteria to lowland rice may enable to increase the efficiency of N fertilization at a low cost. They also produce growth hormone for plant root growth and promote nutrient absorption by plant. Indigenous strains of *Azospirillum* have been successfully isolated from Ishigaki Island, Japan and two indigenous strains (V.S.2.2. and VIII.P1.2) and one type culture (AZ 92-2) were selected as promising strains for the promotion of growth of lowland rice. Present study focuses on the mechanisms of enhancement of the growth of lowland rice by *Azospirillum* .

Heat tolerance in grain legumes

Groundnut and chickpea are the two major grains in the semi-arid tropics (SAT) as an important source of dietary protein and fat. The average yield is around 0.8 t ha^{-1} which is far below their yield potential. High temperature is one of the major abiotic constraints on the adaptation of these two crops in tropical and subtropical areas.

High temperature affects primarily membrane-related processes and heat tolerance appears to be determined by the thermal sensitivity of primary photochemical reactions occurring in the thylakoid membrane system. Tolerance limits vary among genotypes but are also subjected to acclimation. These legumes are more sensitive during their reproductive stages than vegetative ones. Therefore, the objectives of the current research work are as follows:

1. To analyse the effects of high temperature on photosynthesis, flowering and pod setting processes.
2. To examine the genotypic variations in heat acclimation potential.
3. To determine the biochemical changes in leaf and floral parts of these crops.

Physiological and biochemical mechanisms of heat tolerance in Brassicaceae and Legumes

Cabbage and Chinese cabbage form heads in a temperature range of 15-22C. Therefore their production in the tropical region is largely restricted to the cool highland areas. My research under the JIRCAS Visiting Research Fellowship Program 1995 aimed at elucidating the physiological and biochemical mechanisms of heat tolerance in the Brassicaceae.

Our results showed that the period of plant growth most sensitive to the temperature changes in cabbage and Chinese cabbage generally corresponds to 40-56 DAS (Days After Sowing) and 32-45 DAS, respectively in terms of heading failure. We then concentrated our attention on protein regulation during the heading process. At present we are interested in the purification and characterization of low molecular weight heat shock proteins (smHSP) in terms of identification of a 19.2 KD protein, confirmation of the inducible nature of the protein, investigations on cell water potential and component of solutes from various treated plants, etc.

Cloning and characterization of heat tolerance genes in *Brassica* (Cabbage)

The productivity of plants is markedly affected by abiotic stresses and the genetic improvement of stress tolerance is an urgent need for sustainable agriculture. The effects of an increased incidence of heat shock, as a result of global warming for example, would be quite considerable, particularly with the occurrence of high temperatures on a number of consecutive days. Investigations into the molecular mechanisms of survival under high temperature stress could provide valuable information both on how plants survive and what genes are involved.

The Brassicas are subjected to a variety of stresses such as cold, heat and others. Stress is often associated with complex physiological changes and is mediated by alterations in the messenger RNAs (mRNAs) and proteins. My study aims to elucidate the regulatory mechanisms through cloning and characterization of heat tolerance genes in *Brassica oleracea* var. *capitata* by constructing cDNA libraries using mRNA and further to identify the heat-regulated transcripts by differential screening. The isolation and characterization of heat-regulated transcripts would lead to the identification of the molecular regulatory elements responsible for gene expression in response to heat tolerance.

Physiological and biochemical mechanisms of genotypic variability in response to salinity in rice

Soil salinity restricts rice production in arid and semi-arid regions of the world. In irrigated agricultural lands without adequate drainage system, soil salinity will also pose a major threat to rice cultivation. Breeding of high-yielding salt-tolerant cultivars that can adapt to a saline environment is more practical than costly adjustments of stressed environments through engineering and chemical treatment. However, information regarding the mechanisms that affect rice growth and adaptation to salinity is scanty.

In my research, physiological and biochemical mechanisms of genotypic variability in response to salt stress in cultures of rice cells and tissues *in vitro* are studied based on the notion that metabolites that maintain homeostasis and growth are important criteria in the selection of salt-tolerant rice varieties. In addition, spontaneous genetic mutations that can be induced in tissue culture are exploited for introgression of salinity tolerance in rice. Changes in the activities of the enzyme system that minimize tissue and seedling damage under saline environment are also investigated.

Mapping of QTLs for salt tolerance of rice (*Oryza sativa* L.) using molecular markers

Accumulation of salt in soil causes deleterious effects and leads to a reduction in rice production.

•@Saline soils cover about 950 million hectares of the earth surface. Improving the salt tolerance in rice is one of the major objectives of rice breeding programs.

Since 1985, rice germplasm for salinity tolerance has been evaluated and utilized from a large number of rice germplasm accessions in China. Significant progress has been made.

At the JIRCAS Okinawa Subtropical Station, I am identifying QTLs (quantitative trait loci) for salt tolerance in rice by using molecular markers. I hope that we will be able to identify marker loci linked to salt tolerance, evaluate the contribution of those genes to genetic variation, determine gene interaction, and understand the genetics and inheritance of salt tolerance as a basis for investigating the possible mechanisms involved in salt tolerance of rice in this program. I believe, that our research may be useful in improving salt tolerance in rice.

Physiological and biochemical studies on genotypic variability in rice (*Oryza sativa* L.) in response to salt stress

Salinity is one of the substantial stress factors affecting crop production in many countries. In Thailand, saline soils are widely distributed along the coastal areas and cover approximately 5.9 million hectares in the Northeast region. Basic principles of stress injury and resistance in plants should be elucidated in order to breed salt-tolerant genotypes and to ensure better agricultural development in these areas.

My study at JIRCAS focuses on the responses of rice seedlings to salinization and induced mutation for salt tolerance in rice. The research outcome of this study will be relevant to my responsibility in Thailand for breeding plants resistant to various environmental stresses, such as mungbean and some other crops suitable for rice-based cropping systems, in order to achieve sustainable agricultural production in the country.

Cryopreservation of germplasm of vegetatively propagated tropical monocotyledonous plant species

A large number of plant genetic resources in the tropics consist of vegetatively propagated monocotyledonous species. •@These genetic resources are non-renewable and are among the most essential among the world's natural resources. •@For the use of present and future generations, it is necessary to preserve them.

Recently, **cryopreservation** has become an ideal tool for the long-term preservation of plant germplasm since it is a safe, economical and compact way of storage in comparison with *ex situ* conservation through field genebanks and *in vitro* tissue culture conservation. At JIRCAS Okinawa Subtropical Station, I am studying the development of cryopreservation techniques for the germplasm of several tropical monocotyledonous species. The research has successfully proceeded and several efficient cryoprotocols have been developed for the preservation of shoot meristems of taro, tannia, banana, rice and orchid.

Developing protocols for the cryoconservation of the West African tuber crop 'Rizga' (*Plectranthus esculentus* N. E. Br. syn. *Coleus dazo* A. Chev. and Perrot.).

P. esculentus, a minor tuber crop that belongs to the mint family-Lamiaceae, is cultivated vegetatively within the semi-arid regions of Sub-Saharan Africa. Its germplasm is continually being eroded as a result of the decline in its cultivation and preference for exotic tuber crops. Hence the need to develop conservation protocols in order to conserve its genetic base since it provides the raw materials for development either through traditional plant breeding or the use of biotechnological tools. Cryoconservation is one of such protocols which is being developed at the JIRCAS International Collaboration Research Section (ICRS). This technological development which is currently rudimentary in developing countries such as Nigeria should contribute to the conservation and storage of genetic resources of economically and biologically important crop plants leading to the improvement of agricultural activities in these countries.

People

Nobuyoshi Maeno became Director General of JIRCAS on August 1, 1996, succeeding Dr. Keiji Kainuma who retired after serving as the first DG of JIRCAS since 1993. Dr. Maeno, a pasture agronomist with extensive experience in collaborative research on tropical pastures, was until recently Director of JIRCAS's Research Planning and Coordination Division. As for the profile of Dr. N. Maeno, please see pg 3 of the JIRCAS Newsletter Vol. 2, No. 2, December 1994.

Keiji Ohga, an agricultural economist and former Director of JIRCAS's Research Information Division, succeeded Dr. Maeno as Director of JIRCAS's Research Planning and Coordination Division. As for the profile of Mr. K. Ohga, please see pg 8 of the JIRCAS Newsletter Vol.2, No.1, June 1994.

Kunio Tsubota, an agricultural economist, succeeded Mr. Ohga as Director of JIRCAS's Research Information Division. Mr. Tsubota was until recently Deputy Director of Asian and African Division, National Research Institute of Agricultural Economics. He served as an agricultural economist at OECD in Paris (1982-1986) and project economist at the Asian Development Bank in Manila (1990-1993) along with working at the Headquarters of the Ministry of Agriculture, Forestry and Fisheries (MAFF).

Message from Dr. Kainuma, former DG, to the Editor of the Newsletter: "At the time of leaving JIRCAS, I would like to express my deep gratitude to the members of the organizations with which JIRCAS collaborated, for their continuing support and friendship during my tenure."

Toward Global Partnership in Agriculture Research

Nobuyoshi Maeno

Director general

•@On August 1, 1996, I became the second Director General of Japan International Research Center for Agricultural Sciences (JIRCAS) after succeeding Dr. Keiji Kainuma who retired from the Ministry .

Under the dynamic leadership of Dr. Kainuma, the former Tropical Agriculture Research Center was reorganized into JIRCAS and the difficult task of setting up a new structure was eventually accomplished.

•@During the three-year tenure of Dr. Kainuma, the new orientation of the JIRCAS activities was defined, for example new research facilities were constructed, comprehensive research projects were implemented, research activities in various countries that hitherto had not been targeted for research collaboration, such as Kazakhstan in Central Asia were initiated, the JIRCAS Visiting Research Fellowship Program at Tsukuba was inaugurated, research activities in Japan were further promoted while the relations between JIRCAS and the Japan International Cooperation Agency (JICA) became much closer.

•@Therefore, presently, the research activities of JIRCAS are being expanded and promoted along the basic strategy built-up during the past three years as follows:

1. Expansion of the areas targeted for research collaboration

•@When TARC was reorganized into JIRCAS, the areas targeted for research collaboration expanded to cover all the developing regions, in addition to the tropical and subtropical regions. However, due to the constraints on the budget earmarked and on the research capability, it became necessary to set up priorities. Presently, research collaboration with the countries located in the Asian region accounts for 80% of the total, mainly due to geographical considerations and a certain similarity in culture. Although in the case of Africa and Latin America, research is implemented mainly in collaboration with the CGIAR centers, etc., in future, the relations with the countries located in these regions may gradually expand. In addition, since the research themes taken up vary mainly with the countries and regions, the strategy adopted must be adjusted accordingly.

2. Importance of research dealing with information systems and socio-economic aspects

•@For the selection of research themes relevant to the needs of the countries and for the effective implementation of the projects, it is necessary to collect, process and analyse in a comprehensive manner, information pertaining to agriculture, forestry and fisheries fields in various regions. In addition, it is essential to develop appropriate technology compatible with the socio-economic conditions of the respective regions. To achieve these objectives, it is important to promote information activities aimed at integrating social and natural sciences.

3. Multidisciplinary versus unidisciplinary approach

•@Due to the complexity of the agricultural ecosystems and of the social systems, in order to develop techniques for the promotion of sustainable development of agriculture, forestry and fisheries activities in harmony with the environment, it is more than ever necessary to adopt a systematic and integrated strategy instead of an isolated and fragmentary approach. Therefore efforts should be made to promote the implementation of comprehensive projects on a multidisciplinary basis in addition to specific studies. Research covering information sciences and socio-economic aspects, as mentioned previously (2), should place emphasis on the drafting and implementation of integrated projects.

4. Development of collaboration on a multinational basis

•@Hitherto, research collaboration with the NARS had been implemented on a bilateral basis with the respective countries and organizations. However, for large scale problems common to several countries or regions, the implementation of research collaboration on a multilateral basis would be more effective and efficient. Therefore, in future, in order to promote collaboration on a multinational basis, it will be necessary to gain the understanding and cooperation of the related NARS.

5. Link between research carried out overseas and in Japan

•@The research strategy adopted since the establishment of TARC consisted of dispatching researchers to various countries to carry out collaborative research in the respective regions. In future, this system will be essentially maintained. However, in the case of basic advanced research fields requiring the use of sophisticated equipment and instruments, it is preferable to use the facilities available in Japan. Therefore, JIRCAS has set up its own research facilities in addition to utilizing the equipment and facilities available in other research institutes located in the Tsukuba Research Complex. As a result, in future, since the links between research carried out overseas and in Japan may become closer, a system whereby research carried out in Japan could alleviate the difficulties in the execution of research projects overseas could eventually evolve.

6. Development of human resources (training programs and fellowships)

•@To contribute to the development of sustainable agriculture, forestry and fisheries activities, it is essential to promote research as a resource base, hence the need to train researchers who can fulfill such requirements. To achieve this objective, JIRCAS currently sponsors two types of fellowships in making the best use of advanced facilities and of an environment conducive to research. These activities aim at enhancing the capability of the invited researchers while promoting research collaboration with the JIRCAS researchers. In addition, it is anticipated that when the recipients of the fellowship return to their respective countries, they will become the core partners for

research collaboration with JIRCAS.

- @**For the past three years, the activities of JIRCAS have become widely recognized within the agricultural research community worldwide and JIRCAS has received requests from a large number of countries for the initiation of research collaboration.**
- @**Therefore, the collaboration on a partnership basis between JIRCAS, NARS, CGIAR centers, etc. should pave the way for a global partnership for the development of techniques aimed at the preservation of the global environment and the promotion of sustainable agriculture, forestry and fisheries activities.**
- @**However, due to the limitation in the number of researchers and research funds, it will be essential for JIRCAS to fully utilize its comparative advantage and to identify research priorities best suited to its capability and to the needs of the respective countries and regions.**

-JIRCAS RESEARCH HIGHLIGHTS-

Use of Stored Pearl Millet Pollen in Wheat Haploid Production

•@~@Masanori
Inagaki

•@The use of wheat haploids in breeding programs is of great interest to breeders, since the production of haploid plants followed by chromosome doubling enables the breeders to obtain genetically homozygous lines. The successful production of doubled haploids provides the most rapid means for developing recombinant inbred lines with favorable uniformity in selection procedures.

•@The method for producing wheat haploids from cultured pollen which has been referred to as anther culture technique, is still limited by the differences in the responses of wheat genotypes. On the other hand, the method using wide crosses followed by embryo rescue has recently been developed. Significant technical advances have been attributed to pollen selection from subfamily species and application of plant growth regulators. However, since this type of methodology always requires the presence of viable pollen at the time of pollination and restricts haploid production duration, the development of an adequate pollen storage technique could enable to alleviate this shortcoming.

•@The effects of drying and freezing on the viability of maize and pearl millet pollen and the crossabilities of wheat with stored pollen were examined in this study. Pearl millet pollen is relatively more tolerant to drying and freezing than maize pollen. As a result, pollen storage at ultra-low temperatures for one year did not affect the haploid production frequency in wheat•~pearl millet crosses, but markedly reduced the frequency in wheat•~maize crosses. Stored pearl millet pollen can be used as an alternative donor for producing wheat haploids when fresh pollen is not available (Photos 1 and 2).

•@Efficient production of wheat haploids complements conventional breeding programs, and accelerates the release of new varieties in developing countries where rapid varietal development is critical for sustainable wheat production systems.

Options for Mitigating Methane Emissions from Tropical Rice Fields

•@~Kazuyuki Yagi

•@ Atmospheric concentration of methane (CH_4) has been increasing rapidly in recent years. Because CH_4 is a radiative trace gas (greenhouse gas) and takes part in atmospheric chemistry, the rapid increase could be of significant environmental consequence. The scientific report of the Intergovernmental Panel on Climate Change (IPCC) concluded that a 10 to 15% reduction in the CH_4 emissions from individual sources would stabilize the concentration in the atmosphere. Of the wide variety of sources, wetland rice fields are considered to be an important source of atmospheric CH_4 , because the harvested area of rice increased by about 70% during the last 50 years, and it is likely that CH_4 emissions increased proportionally. Recent estimates suggest that global emission rates of CH_4 from rice fields account for about 4-19% of the emission from all sources.

•@ Due to the large amount of global emission, the reduction in CH_4 emission from rice cultivation is very important to stabilize the atmospheric concentration. In addition, since it is possible to control the emissions by agronomic practices, rice cultivation must be one of the most hopeful sources for mitigating CH_4 emission. In particular, tropical rice fields are important because more than 70% of the world rice acreage is located in this region. The current studies which aimed at measuring the CH_4 flux from rice fields and at developing options for mitigating CH_4 emissions from tropical rice fields were carried out within the framework of a collaborative project among the National Institute of Agro-Environmental Sciences (NIAES), Japan International Research Center for Agricultural Sciences (JIRCAS) (formerly Tropical Agriculture Research Center), Department of Agriculture, Thailand (DOA), and Malaysian Agricultural Research and Development Institute (MARDI) from 1991 to 1996.

•@ Field measurements of CH_4 flux were conducted at 9 sites in Thailand (5 sites in the central plain and 2 sites each in North and Northeast Thailand). The CH_4 flux from rice paddy fields to the atmosphere was measured by using the closed chamber method (Photo 1). The measurements were performed during the rice cultivation periods. The results showed a large variation in CH_4 emission rates among the sites. The average emission rates during the rice cultivation periods ranged from 1.1 to 23.0 $\text{mg m}^{-2} \text{hr}^{-1}$. A relatively large flux was observed in the northern and northeastern sites, whereas a small flux was observed in rice fields with acid sulfate soils and soils with a low content of labile organic matter and high content of free oxides. The results indicated that the soil properties and agronomic practices including water and organic matter management affected the CH_4 emission rates from rice fields.

•@ Effect of organic matter application on the CH_4 flux was also investigated. Application of rice straw to paddy soils prior to flooding increased the total CH_4 emission 3.8- to 10.4-fold. The largest CH_4 flux was observed in the early stage of cultivation in the plot with rice straw application plot, whereas in the latter stage in the plot without rice straw application (Fig. 1). Green manure application also increased CH_4 emission significantly. On the other hand, some organic amendments such as palm oil wrung residues and complehumus did not affect the CH_4 emission rates significantly. These results indicate that fresh organic matter containing a large amount of labile fractions significantly enhances CH_4 emission from rice fields. For mitigating CH_4 emission from tropical rice fields, aerobic degradation of organic matter by composting or incorporation into soil during the off-season drainage period could also be proposed.

Photo 1: Closed chamber method for CH_4 flux measurements

Biotype of *Fimbristylis miliacea* (L.) Vahl. to 2,4-D in the Muda Area

•@*Hiroaki Watanabe, Md. Zuki Ismail and Nai-Kin Ho**

•@In the Muda area, chemical weed control began with the use of 2,4-D dimethylamine in the early 1960s and wettable powder formulation of 2,4-D iso-butylester became popular among farmers from the early 1970s because of its superior effectiveness for the control of broadleaved weeds and sedges. *Fimbristylis miliacea* (L.) Vahl. is the most common annual sedge in direct-seeded rice fields in Malaysia. The weed could be controlled easily by the application of 2,4-D at the rate of 0.8 to 1.0 kg a.i./ha. However, a 2,4-D-resistant biotype of *F. miliacea* was observed in the off-season of 1989 in a farmer's field in Kampung (Kpg.=village) Gulau, locality D-III in the Muda Irrigation Area, where 2,4-D had been seasonally applied since 1975.

Differences in the susceptibility to 2,4-D dimethylamine between biotypes were investigated in a pot experiment. R-type recovered after the application of 2,4-D dimethylamine at doses up to 1.39 g a.i./m² (equivalent to 16 times the recommended dose), whereas the susceptible biotype (S-type) from Kpg. Titi Batu, locality G-IV, MADA, was strongly affected at all rates higher than 0.022 g a.i./m² (equivalent to one-quarter of the recommended dose). The R-type was not distinguishable from the S-type based on taxonomic characters such as panicle form, shape of spikelets, glume and nut (seed). There were no statistical differences in the size of panicles and spikelets between the biotypes.

R-type showed a cross-resistance to other phenoxy-compounds such as 2,4-D iso-butylester, 2,4-D ethylester, 2,4-D sodium salt and MCPA. However, no distinct differences were observed between the biotypes in the reaction toward propanil, paraquat and glufosinate ammonium.

Distribution of the R-type was investigated using soil samples from 100 rice fields in the Muda area in 1993. R-type plants were detected in five rice fields at different locations including Kpg. Gulau, while only S-type plants were found in the other 95 rice fields, indicating that most of the rice fields in the Muda area were infested with the S-type. Infestation with *F. miliacea* and percentage of R-type plants were investigated in Kpg. Gulau. No relationship was observed between the degree of *F. miliacea* infestation and R-type percentages. R-type percentage decreased from 1993 to 1995 in the rice fields where 2,4-D compound herbicides had not been applied since 1992.

In Malaysia, the use of sulfonyleurea compounds such as bensulfuron-methyl and metsulfuron-methyl is increasing steadily and tends to replace 2,4-D herbicides. Herbicide-resistant biotype often evolved by repeated use of the same herbicide. Continuous monitoring of the herbicide-resistant weeds is imperative in the Muda area.

PEOPLE

Katsuyuki Minami, Director of the Environmental Resources Division, JIRCAS, was selected by the International Union of Air Pollution Prevention and Environmental Protection Associations (IUAPPA) in cooperation with the International Academy of Sciences (IAS) as the first recipient of the award "Hopes for the Future for a Sustainable World" for his work on "The Effect of Agricultural Practices on Methane Emissions from Rice Fields".

Kiyoshi Tanaka, a forest pathologist, became Director of JIRCAS's Forestry Division on October 1, succeeding Dr. Yasuo Osumi. Dr. Tanaka was until recently Research Coordinator at the Forestry Agency, Ministry of Agriculture, Forestry and Fisheries (MAFF). He carried out most of his research work at Hokkaido Research Center and Kansai Research Center, Forestry and Forest Products Research Institute, MAFF. He also spent one year as Visiting Scientist at the Pacific Southwest Forest Experiment Station (USDA) in California, USA from 1978 to 1979.

•âProject Report•â

Comprehensive Studies on the Development of Sustainable Agro-pastoral Systems in the Subtropical Area of Brazil

Kozo Fujisaki

•@JIRCAS is committed to contributing to a more effective implementation of collaborative research programs to promote sustainable development of agriculture, forestry and fisheries in harmony with the local conditions and environment in the developing regions through the establishment of closer relations with both overseas and Japanese research organizations. Based on the strategy of JIRCAS, the research project entitled "Comprehensive Studies on the Development of Sustainable Agro-pastoral Systems in the Subtropical Area of Brazil" will be implemented during the period 1996-2002.

The subtropical area of Brazil

•@The subtropical area of Brazil has been considered to be one of the areas where modern agriculture originated in South America. This area, where continuous cultivation of field crops has been carried out on a large scale as the major agriculture system with extensive cattle grazing, is extremely important to the food supply and economy of Brazil at present. This area which covers about 400 thousands km² (approximately equal to the Japan land area) has a triangular shape, straddling the cities of Londrina, Botucatu, Ribeirao Preto and Campo Grande. Also, the area is characterized by the settlement of hundreds of thousands of Japanese-Brazilian farmers who are mainly providing essential food commodities for the Sao Paulo and Rio de Janeiro megalopolises.

•@In the subtropical area of Brazil, the increase of agricultural production has been achieved by continuous expansion of arable land and high dependence on the net primary productivity of fertile land with minimum input. As a result, in most of this area the land has become environmentally vulnerable and the efficiency of production has remained low without improvement of agricultural technologies. Plant growth retardation associated with continuous cropping, the occurrence of diseases, outbreaks of pests, and soil erosion threaten agriculture in this area and are the main constraints on sustainability and productivity.

New project on agro-pastoral systems in the subtropical area of Brazil

•@This research project is focused on the development of sustainable farming systems with high productivity in environmentally degraded areas in the subtropical zone of Brazil, with emphasis placed on land utilization through the adoption of crop-pasture rotation systems. For this purpose, the following research themes will be taken up:

- 1) Analysis and evaluation of indigenous and traditional land utilization systems for agriculture
- 2) Multidisciplinary studies for the adoption as sustainable crop-pasture rotation systems

‡@ Mixed and multiple cropping agricultural systems employing soybean as a main crop for field crop diversification

‡@ Introduction and management of forage crops in mixed, multiple-cropping systems for soil improvement and erosion control

‡B Dynamics of soil fertility and plant nutrition in crop-pasture rotation

‡C Control of biotic agents, e.g., pathogens, pests and weeds

‡D Management of grazing cattle in crop-pasture rotation

3) Socio-economic evaluation of crop-pasture rotation from the standpoint of farming systems

4) On-farm participatory research on newly developed "agro-pastoral systems"

Project sites

The studies will be mainly carried out in collaboration with research centers affiliated to EMBRAPA, namely National Research Center for Beef Cattle (CNPGC) and National Research Center for Soybean (CNPSo). The expertise of CIAT in crop-pasture system development in South American countries will be sought. Also, collaboration with the JATAK International Center of Agriculture Technology, which is one of the Japanese nongovernmental organizations for Japanese-Brazilian farmers, will be promoted.

Mr. Matsumoto, Chairman of AFFRC, and Dr. Maeno, DG of JIRCAS, Visited Indonesia

Masahito Sato

•@Mr. Sakuei Matsumoto, Chairman of the Agriculture, Forestry and Fisheries Research Council (AFFRC), Ministry of Agriculture, Forestry and Fisheries (MAFF), and Dr. Nobuyoshi Maeno, Director General of JIRCAS visited Indonesia in August 1996. They had the opportunity of meeting with his Excellency Sjarifudin Baharsjah, Minister of Agriculture of Indonesia, Dr. Faisal Kasryno, Director General of the Agency for Agricultural Research and Development (AARD), Ministry of Agriculture (MOA) and the Directors of the Institutes affiliated to AARD.

•@They exchanged views about the future orientation of research collaboration between the Institutes affiliated to Indonesian organizations, namely AARD and the Institutes affiliated to MAFF, namely JIRCAS.

•@It was eventually agreed: 1) that research collaboration implemented by JIRCAS for the development of technology in the field of agricultural production should also include socio-economic aspects to promote rural development in taking account of the conditions prevailing in the respective regions of Indonesia, 2) that it is essential that research collaboration deal with the expansion of agricultural production compatible with the preservation of the natural environment on a global scale in order to achieve sustainable development of agriculture and 3) that for the effective implementation of the research projects it is desirable that JIRCAS promotes research collaboration with the Indonesian organizations in paying a close attention to the technical cooperation activities sponsored by JICA.

•@Mr. Matsumoto and Dr. Maeno visited several research institutes affiliated to AARD, such as the Central Research Institute for Food Crops and Research Institute for Food Crop Biotechnology in Bogor, as well as The Research Institute for Coastal Fisheries in Ujungpandang. They also met with JICA administrators and experts in Jakarta and visited the ESCAP/CGPRT Center in Bogor and JICA Mangrove Forest Conservation Project in Bali.

Recent Advances in Nutrition and Feeding Standard of Farm Animals in Asian-Australasian Countries:

Satellite Symposium of the 8th Animal Science Congress of Asian-Australasian Association of Animal Production Societies (AAAP)

Hirofumi Hayakawa

•@International symposium on the above theme was held in Tsukuba Science City during the period October 20-21, 1996 under the joint auspices of the National Institute of Animal Industry (NIAI), Japan International Research Center for Agricultural Sciences (JIRCAS) and Japan Livestock Technology Association (JLTA). From 12 countries, 105 scientists, including 34 from abroad, in the field of animal nutrition and animal production participated in the symposium.

•@Livestock play a vital role in the rural economies of the Asian-Australasian region. Recent advances in animal nutrition are making great strides in many countries. However, there are still many problems to address technically to achieve an optimum level of animal production under practical conditions. Development of feeding standard for farm animals together with feed information on nutritive values, both being the outcome of research activities in the field of animal nutrition, is originally expected to require the collaboration of both researchers and animal farmers.

•@Keynote addresses, were as follows: "Nutrient requirements for ruminants in the tropics" by Dr. B.A. Young from the University of Queensland, Australia, "Development of feeding technologies and contribution of nutrition research to dairy farming in Japan" by Dr. S. Oshio from National Grassland Research Institute (NGRI), and "Concept of the Asia-Pacific regional feed composition information network" by Mr. K. Kosaka from JIRCAS. In the country reports, scientists from Malaysia, Thailand, Indonesia, Vietnam, Nepal, Korea, China and Japan made presentations on related topics.

•@The symposium provided a new opportunity to discuss these important issues and search for the solutions through the promotion of collaborative networks in this region.

Artificial Propagation of Giant Freshwater Prawn

Muharijadi Atmomarsono

Research Institute for Coastal Fisheries, South Sulawesi, Indonesia 90511

•@The giant freshwater prawn, *Macrobrachium rosenbergii*, is one of the important crustaceans mainly cultured in the countries of the Asia-Pacific region, and North and South America. However, the production of prawn larvae in the hatchery is still insufficient due to the dependence on the use of natural spawners, and therefore, the prawn larvae must be partly supplied by using wild forms. Many methods have been applied to increase the production rates, but information about reproductive mechanisms and means of controlling larval diseases in the early stages is still lacking.

•@It is well known that eyestalk ablation in prawns can stimulate the molting cycle and vitellogenesis based on species, age, and stage of the ovary. Part of my current work involves the examination of the structure and processing of vitellogenin (yolk protein) in female *Macrobrachium rosenbergii* by sampling the hemolymph of eyestalk-ablated prawns and analysing samples using sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) followed by western blotting. In subsequent experiments the role of the ovary will be examined to determine whether the ovary itself functions as an endocrine organ to promote yolk protein production and/or serves as a source of endogenous vitellogenin.

•@*Macrobrachium rosenbergii* prawns migrate naturally to brackish water areas during the time of spawning, when the female broods an egg mass attached to the abdominally located setae. Prawns may be prone to diseases at any stage of their life cycle. Since diseased breeders which are infected with pathogenic fungi can contaminate their larvae, it is necessary to separate the eggs from the breeders for disease prevention. If eggs are put into freshwater, the larvae die soon after hatching. In order to determine the optimal conditions of salinity or osmolarity of the water media for hatching and survival of giant freshwater prawn embryos, I am analysing osmoregulatory mechanisms and testing the use of sea water at various percentages. Results thus far suggest that water media with an osmolarity between 500-600 mOsm (about 50% sea water) are most satisfactory. Identification and evaluation of fungi isolated from giant freshwater prawns will also be carried out in the near future.

[Photo 1: M. Atmomarsono \(right\) and M. N. Wildew are monitoring the conditions of culture of the giant freshwater prawn](#)

Evaporation and Formation of Secondary Salts

-Challenge to Desertification-

[Chang Qing](#)

Xinjiang Institute of Biology, Soil and Desert Research, Chinese Academy of Sciences, People's Republic of China

•@It is estimated that about 10% of the land on our planet is being affected by salinization which is now recognized as an increasing cause of land and stream degradation in arid and semi-arid lands. Arid and semiarid areas account for almost half of the land area of China. Salinization and resulting desertification are the most serious challenges to agriculture and the environment in these regions.

•@Relevant studies in the field of agriculture, geochemistry and environmental sciences have been carried out. During the past 5 years, I studied the occurrence and mineralogy of salt-affected soils in the desert area of northwestern China. The soil salts are derived from weathering products of rocks, while the redistribution of salts mainly depends on the water movement and evaporation rate. We were able to elucidate the mechanism of salt accumulation and identify mineralogical species on a relatively large geographic scale.

•@Now, my research theme is focused on the mechanism of formation of evaporative secondary salt minerals under simulated arid conditions. Under climatic conditions characterized by high temperature and scarce precipitation, evaporation is the dominant link between rock weathering and salinization from weathering products. Our recent experiments suggest that surface properties and porosity of solid phase (soil matrix) and, density and adhesion of liquid phase (soil solution) are important factors determining the processes of evaporation-precipitation.

Information Activities at JIRCAS and Role of Research Information Division

•@Mr. Keiji Ohga

Director, Research Information Division

•@Obviously the word information has various connotations. Most of the people including myself who deal with information systems tend to use the word information in relation to computer technology. But here I will define information as the •gknowledge acquired or derived for decision-making or taking a specific action.•h In this sense everybody at JIRCAS is engaged in some kind of information activity. Researchers collect and process data in the course of their research work. Staff members of the Research Planning & Coordination Division and of the Administration Division use and coordinate collected information to formulate research plans and draft administrative regulations, respectively.

•@What is the role of the Research Information Division? the Research Information Division of JIRCAS fulfills three functions. The first function is to carry out surveys to analyse activities relating to agriculture, forestry and fisheries mainly in countries located in developing regions. The second is to formulate and coordinate international collaborative research projects. The third is to develop and maintain computer-based information systems at JIRCAS.

•@During the surveys conducted overseas on activities relating to agriculture, forestry and fisheries in developing regions, information on agricultural sciences and related socio-economic conditions in these regions is collected and subsequently analysed. Surveys are conducted by two groups of research coordinators with a wide expertise in related research fields and international cooperation. The first group adopts a region-oriented approach covering five zones; monsoon Asia, arid and semi-arid Asia, Africa, Latin America, developed countries. They place emphasis on countries for which JIRCAS had limited information hitherto, such as Central Asia or Africa. The second group of research coordinators adopts a problem-oriented approach by conducting surveys on three topics; environment, food problems and rural development. Both comprehensive regional surveys and problem-oriented surveys are conducted on an interdisciplinary basis combining natural sciences and socio-economic fields.

•@Research coordinators also formulate and coordinate collaborative research projects based on the surveys and analyses of regional agriculture or agriculture-related problems. JIRCAS is currently implementing three integrated research projects in Vietnam (Mekong Delta), Malaysia and Northeast Thailand. For the comprehensive or multidisciplinary projects the research coordinators work in close collaboration with the directors of the research divisions and researchers concerned.

•@The Research Information Division is responsible for developing and maintaining research information systems based on computer networks at JIRCAS. Information scientists combine research on information processing with the operation of the computer system at JIRCAS. As applied information science is now an essential component of agricultural sciences, the Division is developing comprehensive information systems, including statistical data, documents such as reports on surveys and image data based on PC windows and UNIX workstation since JIRCAS is involved in research related to socio-economic fields in connection with research on agricultural technology development in LDCs.

•@The Division is also in charge of a specific project dealing with projections of the supply and demand of major food commodities including cereals, animal products and oil seeds, based on econometric analyses in collaboration with organizations concerned in China, Indonesia, Malaysia and Thailand.

•@The three functions of the Research Information Division are all based on information activities and are closely interrelated. The Division plans to combine in future activities relating to interdisciplinary research with planning and supportive activities.

1994 Annual Meeting for Review and Promotion of Research for International Collaboration

Dr. Nobuyoshi Maeno

Director, Research Planning and Coordination Division

•@

1. Report on the meeting held at the new JIRCAS Headquarters

•@The 1994 Annual Meeting for the Review and Promotion of Research for International Collaboration was held on February 7, 1995 in the International Conference Room of the new JIRCAS Headquarters constructed in conjunction with the establishment of JIRCAS (the official inauguration of the facilities took place on April 18, 1995).

•@A total of 51 participants attended the meeting, including representatives from various institutes affiliated to the Ministry of Agriculture, Forestry and Fisheries along with delegates from the Ministry as well as the Director General, Directors of Research Divisions and several staff members of JIRCAS.

•@At first the collaborative activities pursued by JIRCAS during the fiscal year 1994 were reviewed and discussed, including information, research projects, international symposium, workshops, seminars, various meeting, Visiting Research Fellowship Program at the Okinawa Subtropical Station of JIRCAS, in addition to the orientation of JICA activities, etc.

•@During the present meeting, emphasis was placed on the Visiting Research Fellowship Program at Tsukuba which will be initiated on October 1, 1995. Under the program, a total of 6 researchers will be invited, of which 4 will undertake long-term projects for a period of 2 years at JIRCAS and 2 researchers will be engaged in short-term projects for a period of 5 months mainly at the National Institute of Agrobiological Resources. In addition, the report on the proceedings of the meeting organized on the previous day for reviewing TARC/JIRCAS collaborative research activities with Thai agricultural research organizations for the past 25 years and discussing the future orientation of research collaboration attracted a great deal of attention (see related article).

•@Thereafter discussions were held on an important topic, namely the possibility of undertaking research in the field of agriculture, forestry and fisheries in areas that hitherto had not been targetted by TARC, including cold areas located in Central Asia, South America as well as Mongolia, in addition to the programs currently implemented in the tropical and subtropical zones. The results of short-term surveys

conducted in this newly targetted region were analysed for further orientation of research. It was eventually concluded that although there is a definite potential for the development of agriculture, forestry and fisheries in these areas and there is a strong demand for research collaboration with JIRCAS to enhance this potential, it is still essential to collect more basic information about this region. In future, based on further information, it may be possible to promote collaborative research mainly centered on animal production and grassland management in such areas. Plans are currently being formulated for the implementation in the fiscal year 1996 of two research projects as follows: 1. Comprehensive studies on the development of sustainable agro-pastoral systems in the subtropical zone of Brazil and 2. Development of technology for grassland management and animal production systems. Short-term surveys will be conducted along with preliminary arrangements for the implementation of these projects.

•@The general discussion was centered on the strategy that should be adopted to promote integrated research as a challenge to the expansion of both research fields and areas targetted for research as well as on the Visiting Research Fellowship Program at Tsukuba.

•@

2. JIRCAS Visiting Research Fellowship Program at Tsukuba

•@On October 1,1993, the Tropical Agriculture Research Center (TARC) was reorganized into the Japan International Research Center for Agricultural Sciences (JIRCAS).

•@Since its establishment in 1970, TARC has been engaged in collaborative research activities consisting of the dispatching of researchers to various institutes located in the tropics and subtropics to promote the development of agriculture, animal husbandry and forestry in these regions and substantial results were obtained.

•@However, recently there has been a growing awareness of the importance of conducting collaborative research in making use of the high level of research opportunities available in Japan, including advanced research fields of biotechnology to alleviate various constraints such as environmental problems occurring on a global scale. To achieve this objective, in addition to the dispatching of researchers to conduct collaborative research , since 1992 the Visiting Research Fellowship Program has been implemented to enable 10 outstanding researchers holding a doctorate degree from institutes located in tropical and subtropical countries to carry out collaborative research for a period of one year at the Okinawa Subtropical Station of the Center (Okinawa was selected in view of the similarity of the research priorities and climatic conditions to those in the tropical and subtropical regions).

•@To respond more adequately to the rapid and recent changes in the situation of agriculture and food supply worldwide, JIRCAS added fisheries to the research fields already covered and included temperate and cold regions into the areas targetted for research to address in a comprehensive manner the problems of food production and conservation of natural and environmental resources confronting the developing regions. Therefore, starting from this year, JIRCAS will implement the Visiting Research Fellowship Program at Tsukuba in taking advantage of the research environment of Tsukuba Science City, namely the strong base for research and development in the field of advanced science and technology, by inviting young promising researchers from counterpart institutes in the developing regions to carry out collaborative research in order to address the problems facing these areas.

•@

The outline of the program is as follows:

•@Under the Fellowship Program, a total of 6 researchers will be invited, to carry out research pertaining to one of the themes listed below. Four researchers will undertake long-term projects for a period of 2 years and 2 researchers will be engaged in short-term projects for a period of 5 months. The former 4 will carry out collaborative research at JIRCAS, while the latter 2 will conduct research at the National Institute of Agrobiological Resources (NIAR) at Tsukuba.

Research Themes

I Long-term Projects

1. Methods for optimum utilization of biological resources

1) Analysis of plant responses to environmental stresses and gene expression

2) Development of DNA-based assay for indexing plant diseases

3) Development of practical methods for the evaluation of the quality of indigenous crops and for the analysis of components and functionality of foods

4) Methods for the development of livestock breeds with high productivity through crossing with indigenous species

5) Development of methods for the diagnosis and prevention of diseases affecting aquatic animals for fresh water and marine aquaculture

2 Analysis and evaluation of the impact of climatic and anthropogenic factors on environmental resources

1) Relation between climatic changes and biomass in agro-ecosystems

2) Investigations of the process of rock-weathering through the analysis of the rock surface by electron spectroscopy

II Short-term Projects

1) Methods for the analysis and preservation of biodiversity

2) Production of new biological resources through the application of biotechnological procedures

3) Methods for the analysis and control of biological functions

Fellowship Qualifications

(1) Applicants should be outstanding researchers who will play a major role in the activities of the counterpart institutes in future. After the completion of the Fellowship, they should continue to carry out research at the same institute.

(2) Hold a Master's degree in a field relating to natural sciences and technology or equivalent qualifications in related fields. Be preferably less than 35 years of age.

- (3) Carry out research related to one of the themes listed under •gResearch Themes•g.
- (4) Should enjoy good health.
- (5) Have an adequate command of English or Japanese language.

Tenure

In principle, the long-term projects will cover a period of 2 years and the short-term projects will cover a period of 5 months.

Fellowship Conditions

- (1) A round-trip airline ticket (economy class) will be available.
- (2) Living allowance: ¥260,000.- per month.
(including housing allowance)
- (3) Housing: International Guesthouse
1-2, Kannondai, Tsukuba
- (4) Fixed-rate insurance package (for injury, sickness and damage, etc.) will be covered under the JIRCAS Fellowship Program.

Application Procedure

Applicants are required to submit the following documents to the Director-General of JIRCAS.

- (1) Application form (Form I)
- (2) Two recommendation letters (Form II) from the official representative or appropriate authority of the research organization in the respective research field
- (3) Medical certificate (Form III)
- (4) Copy of University Diploma

Deadline for Application

June 30, 1995

Notification

The Director General of JIRCAS will examine the application documents and notify the results of the selection to the successful applicants and their recommending authorities about two months after the deadline date for application.

Further information about the Visiting Research Fellowship Program can be obtained from the International Relation Section, Japan International Research Center for Agricultural Sciences, 1-2, Ohwashi, Tsukuba, Ibaraki, 305 Japan.

Review on Thai-JIRCAS Collaborative Research for 25 years

Koji Kawashima

•@The meeting organized for reviewing TARC/JIRCAS's collaborative research activities in Thailand during the past 25 years was held in Tsukuba, at JIRCAS Headquarters on February 6th, 1995. Two delegates from the Department of Agriculture (DOA), Thailand joined the discussions. It was the first meeting held at JIRCAS International Conference Room after the opening of the new building in December 1994. The review of JIRCAS-Thai collaborative research was particularly timely because in September 1994, a ceremony marking the 25th anniversary of the collaboration between the agricultural research organizations of Thailand and the research institutes affiliated to the Ministry of Agriculture, Forestry and Fisheries of Japan was held in Bangkok (JIRCAS Newsletter Vol. 2, No. 2).

[Photo : Thai-JIRCAS collaborative research](#)

•@The meeting chaired by Dr. K. Kawashima started with an opening address given by the Director General of JIRCAS, Dr. K. Kainuma, followed by an overview of the collaborative research activities (Dr. T. Murakami) and review of research in the field of soils and fertilizers (Dr. N. Nakaya) and plant protection (Dr. C. Noda), impact of research cooperation on the development of agricultural technology in Thailand (Dr. C. Wisit), review of research in the fields of postharvest technology (Dr. H. Nakakita), livestock and animal diseases (Dr. H. Hayakawa), future research priorities (Mr. C. Charus) with final comments from nine resource speakers covering various research fields including forestry and fisheries.

•@JIRCAS is currently sending abroad approximately 40 researchers on long-term•@assignment every year and Thailand remains one of the most important counterpart countries.

•@During the past 25 years, nearly one hundred researchers with long term assignments stayed in Thailand (26 for research in the fields of plant protection, 23 for soil and fertilizers, 14 for upland field crops , 13 for wetland rice , 12 for research on livestock and animal diseases, 5 for postharvest technology, etc. About 580 researchers with short term assignments visited Thailand and from Thailand 108 researchers and administrators were invited to Japan.

•@The counterpart-institutes of JIRCAS in Thailand include DOA, Department of Livestock Development (DLD), Kasetsart University (KU) and Khon Kaen University (KKU). In addition, research is scheduled to be carried out at the Agricultural Development Research Center for Northeast Thailand (ADRC), Asian Institute of Technology (AIT) and Department of Land Development (LDD) in future.

•@During the meeting, Dr. C. Wisit highly evaluated the past collaborative research and as an example of successful research in the soil science area, he indicated studies on soil productivity which demonstrated that a low phosphorus content in paddy soil was associated with a low rice yield. Although the DOA plans to pay more attention to the preservation of the environment , Dr. Wisit stated that the improvement of crop productivity still remained one of the major objectives. Mr. C. Charus mentioned that the DOA plans to further promote collaborative research in the fields of postharvest technology, integrated pest management and environmental protection in future.

•@During the past 25 years, a total of two to three hundred Thai researchers were engaged in

collaborative investigations with TARC/JIRCAS members on a long term basis. In addition, it was emphasized that more attention should be paid to postharvest problems. In this regard, the DOA will be reorganized and a new institute for research on postharvest technology will be established. The utilization and development of livestock resources will be one of the future research subjects. In the fields of fisheries research collaboration which was initiated in 1994 at KU will be further promoted.

- @ Also a comprehensive research project for the development of sustainable agricultural systems in Northeast Thailand for a duration of seven years will start in 1996, with the participation of seven Thai organizations.

- @

- @

New Buildings for JIRCAS

Taiichiro Maekawa

•@On April 18, 1995, a ceremony was held to mark the official inauguration of the new JIRCAS buildings (JIRCAS Main Building, Fisheries Science and Earth Science Laboratories and Biotechnology Unit). These buildings are located within a short walk from the Central Building where most of the research divisions remain. The new buildings with their simple and functional design and walls made of pale moss green ceramic tiles are well integrated within the surrounding landscape.

1. JIRCAS Main Building

•@This building where the headquarters of JIRCAS are located consists of three parts: Center, East Wing and West Wing.

1. Center: On the first floor there is a large entrance hall (567 m²),•gJIRCAS Hall•h with an area for informal meetings and an information corner for the public. The walls are decorated with photographs illustrating various aspects of agriculture, forestry and fisheries worldwide taken by JIRCAS researchers during surveys or long-term assignments. The International Conference Room with a booth for simultaneous interpretation and a sophisticated projector is on the second floor.
2. East Wing: The first floor houses the Research Information Division, including an information •@processing room containing various types of computers. On the second floor the facilities of the Research Planning and Coordination Division as well as a lecture room are located.
3. West Wing: The facilities of the Administration Division are located on the first floor. The second floor houses the office of the Director General in addition to several other offices and meeting rooms.

2. Fisheries Science and Earth Science Laboratories

These facilities that are housed in a separate building contain advanced equipment for various analyses and experiments. The ESCA (Electron Spectroscopy for Chemical Analysis) apparatus enables to analyse the surface of materials at the molecular level. With the Aquatron studies on the optimum conditions for aquaculture of freshwater, marine and brackish water fishes can be carried out. The Wind Tunnel enables to analyse the effects of climatic factors on crop cultivation, including changes in the atmospheric air stream, temperature and humidity levels. Among the apparatus, ESCA is of major interest as there are only five instruments of this kind in Japan. These facilities will be used to promote basic research related to fisheries science and earth science for application to various fields of agriculture, forestry and fisheries both in Japan and overseas.

•@

3. Biotechnology Unit

•@This two-storied unit is equipped with the most advanced facilities to carry out research on gene transformation and regulation of expression in plants to develop transgenic plants tolerant to various adverse environmental conditions, including drought tolerance. There are also three P2-level laboratories and greenhouses where gene engineering studies can be conducted with maximum safety.

•@It should be emphasized that the facilities described above which will be used by researchers from both JIRCAS and various countries were built to contribute to the development of sustainable production in the field of agriculture, forestry and fisheries worldwide.

JIRCAS RESEARCH HIGHLIGHT

Analysis of Land Degradation Phenomena Using Remote Sensing Techniques - Extraction of Geomorphological Characteristics and Land Coverage in Eroded Areas -

Satoshi Uchida, Shahid Ahmad and Rakhshan Roohi**

•@Studies on the geomorphological patterns which describe the specific characteristics of gullies caused by severe soil erosion were carried out in the Pothwar plateau area located in the northern part of the Punjab province, Pakistan. Various types of sensors loaded on remote sensing platforms in the upper atmosphere enabled to observe these patterns.

•@Examination of the spatial characteristics of satellite imagery of SPOT data showed that the variation in brightness of pixels within a distance of about fifty meters was considerably larger in severely eroded areas compared with other areas. The two-dimensional distribution of gully areas assumed a shape corresponding to the dissection of the valleys. Based on these observations, a model was constructed for automatically identifying eroded areas by image processing of remote sensing data. In some cases, it was possible to distinguish eroded areas from others although additional geographic information, such as the topography or location of settlements, may be necessary to improve the performance of the method.

•@Another attempt was made to analyze the relation between erodibility and ground surface conditions which could be estimated by the calculation of multispectral band data of LANDSAT-TM. It was observed that the erodibility was negatively correlated with the coverage index deduced from band 2 (green) and band 3 (red) data at the time of Rabi cultivation .

•@Soil erosion shows a dynamic behavior with temporal changes depending on environmental conditions. One of the advantages of remote sensing is that the same area can be observed repeatedly within a certain interval of time. This thus suggested that a model describing the dynamic behavior of soil erosion based on the results of this study can be constructed by analysis of multi-temporal data.

Structure and Function of Dehydration - Inducible Genes in Higher Plants

Kazuko Yamaguchi-Shinozaki and Tomio Terao

•@The genetic improvement of drought tolerance is an important problem for the future of agriculture in desert and savanna areas of developing countries. Biotechnology has the potential to improve the drought tolerance of crops using transgenic plant technology. The limiting factor for developing this technology are the isolation of genes that function in drought tolerance and the precise understanding of the molecular process of drought tolerance. As higher plants are immobile they must adapt to conditions of severe environmental changes in order to survive. Plants respond to these environmental changes with a number of physiological and developmental changes to tolerate these stresses. Drought, one of these stresses, severely affects plant growth. Plant hormone, abscisic acid (ABA) is produced under water deficit conditions and plays an important role in drought tolerance. A number of genes respond to dehydration as well as exogenous ABA treatment at the transcriptional level. However, there are few reports on the dehydration stress-induced expression of genes prior to the accumulation of endogenous ABA.

•@We used *Arabidopsis thaliana* as a plant material for the analysis of molecular processes of drought tolerance. In order to analyze the early response of plants to dehydration stress at the molecular level, we isolated cDNA clones for drought-inducible genes expressed prior to the accumulation of endogenous ABA. When *Arabidopsis* plants were subjected to dehydration stress, they lost water gradually, reaching a plateau of 90% water loss after 10 hr of dehydration stress. Accumulation of ABA began to increase after dehydration-stress for 2hr and reached a maximum level at 10 hr. We constructed a cDNA library from polyA RNA prepared from 1-hr dehydrated *Arabidopsis* plants. We isolated 26 cDNA clones from the cDNA library by applying the differential screening method. The cDNA clones were classified into 16 groups based on Southern blot hybridization, and named ERD (Early Responsive to Dehydration). All the genes, named *erd*, corresponding to ERD cDNAs were induced by 1hr-dehydration. Nucleotide sequences of the DNA inserts of the 16 ERDs have been determined and homologies to these 16 sequences were examined in a protein sequence data base. These analyses of the cDNAs revealed that genes induced by dehydration encode proteins that may play a role in the protection of cells from dehydration as shown in Figure 1. For instance, they encode putative proteinases that may degrade denatured or unnecessary proteins, chaperonins that probably renature proteins, water channel proteins that function in controlling the osmotic potential of stressed cells, LEA proteins that may protect plant cells against dehydration, and so on. These genes could be used as useful sources for the construction of transgenes to transform crop plants in order to produce drought tolerant transgenic crops in the near future.

JIRCAS RESEARCH HIGHLIGHT

Micro-climatic improvement associated with the use of windbreaks made of a combination of various tree species

Taichi MAKI

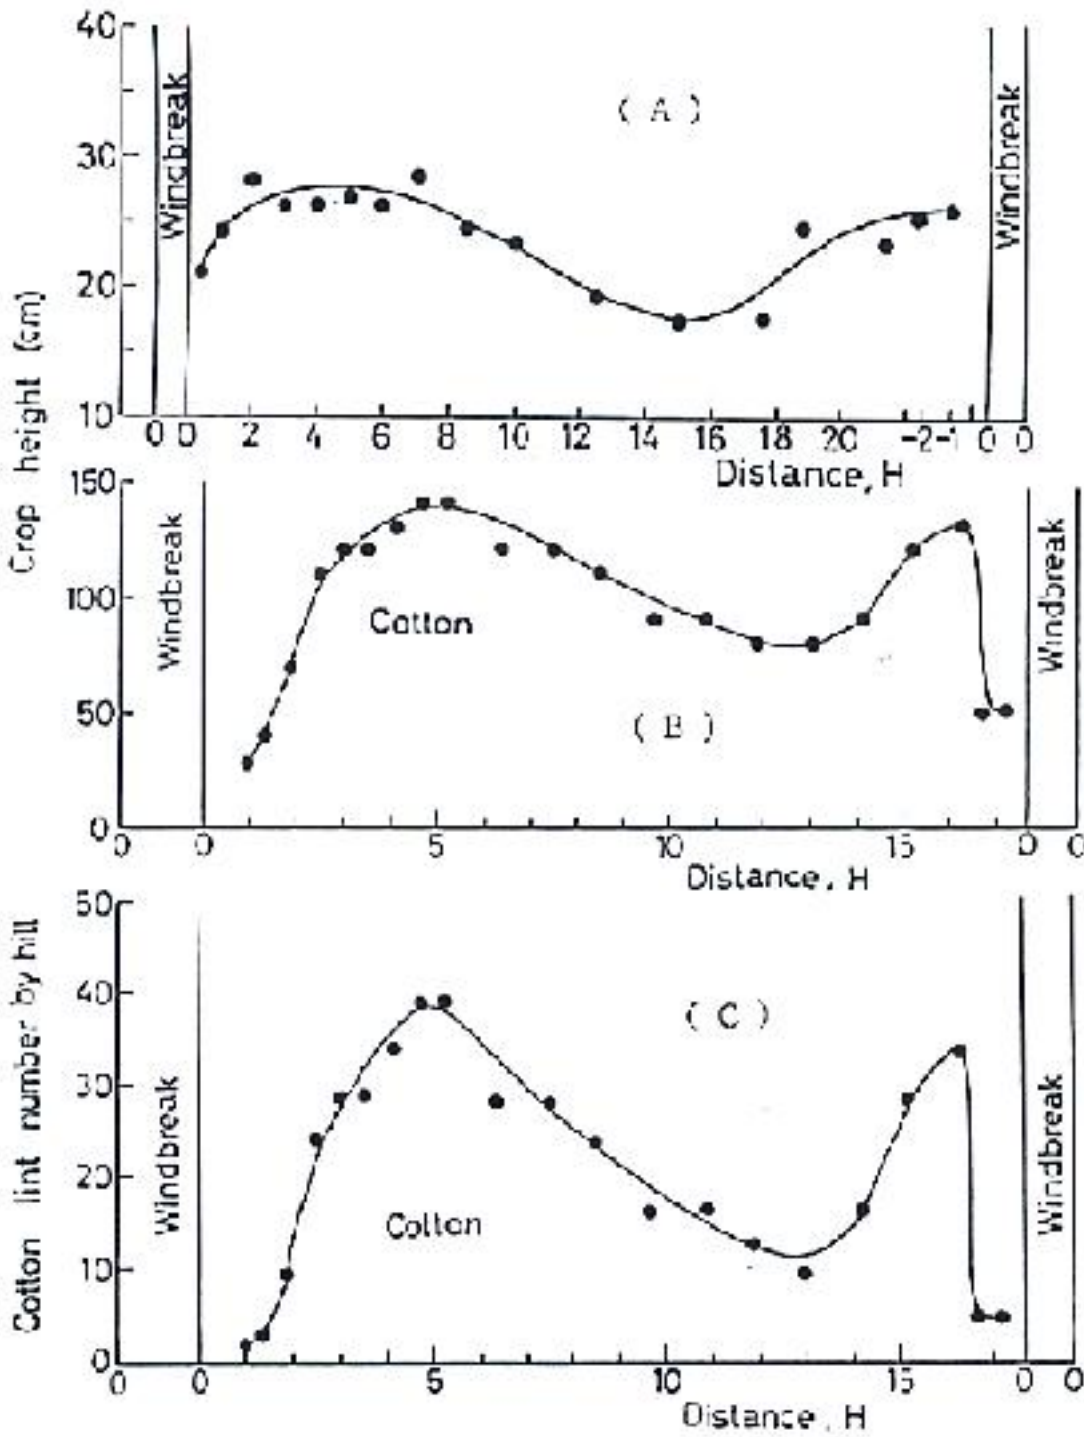

•@It is important to improve the micro-climate in marginal areas of arid lands where desertification is expanding. It was shown that the micro-climatic conditions improved or could be alleviated by the construction of multiple rows of windbreaks made of a combination of various tree species in an agricultural field, and that crop growth and development were promoted and the yield increased under high temperature conditions of dry and strong wind at Turpan, China. The height of the windbreaks made of *Ulmus pumila* L., *Elaeagnus angustifolia* L. and *Populus euphratica* Oliv. was 8.0 m and the tree density was 70%.

•@The wind speed decreased by 40% on the windward side of the first windbreak, then it increased by 80% gradually near the windward side of the second windbreak. However, the wind speed decreased with the increase of the number of windbreak rows. The negative effect of the decrease of the wind speed on the increase of the air-soil temperatures was considerable during the day. However the humidity which is important in arid lands increased and its effect became more pronounced with the increase of the number of windbreak rows.

•@The decreasing pattern of the wind speed during the night was similar to that during the day. The air and soil temperatures increased near the windbreaks, but decreased by radiation cooling between the 1st and 2nd windbreaks. The effect of humidity during the night was more pronounced than that during the day in particular when the number of windbreak rows increased.

The height of cotton plants at the early stage of growth and development was large from 1 to 10 H (distance from the windbreak expressed as multiples of windbreak height, H) for the 1st windbreak and for the 2nd windbreak from 5 H on the windward side. At the maturation stage, crop height was large from 3 to 8 H on the leeward side from the 1st windbreak and at around 2 H on the windward side for the 2nd windbreak. The effect of the windbreak on cotton yield was more pronounced than that on crop height.

[Fig.1.Variation of crop height of cotton at\(A\)young stage and \(B\)mature stage, and \(C\)cotton lint number per hill at mature stage cased by the windbreaks made of a combination of tree species.](#)•@

JIRCAS RESEARCH HIGHLIGHT

Development of water balance model for Tank Cascade Irrigation Systems in Sri Lanka

Jun Itakura

•@In the dry zone of Sri Lanka, the construction of inter-connected tank (reservoir) irrigation systems used to be a traditional method of irrigation to alleviate water shortage. A series of tanks had been linked in a small watershed to facilitate the re-use of return flow. Such irrigation systems referred to as •g Tank Cascade Irrigation Systems (TCIS) •h enabled farmers to use small watersheds and were extensively developed in ancient times.

•@However, the use of TCIS declined during the colonial period. The over-exploitation of tanks and poor management had disturbed the water use within watersheds. At present, the rehabilitation of TCIS is one of the major agricultural policies in Sri Lanka. To achieve this objective, JIRCAS and IIMI initiated a joint research project in 1991, to develop a water balance model of TCIS in order to rehabilitate the TCIS.

•@One typical TCIS was selected as a study site. Based on a two-year analysis of the water balance seepage & percolation loss rate of the system was estimated at 4.7 mm/day. It was found that wasteful consumption of water (including seepage & percolation loss, evaporation loss) accounted for over 50% of the total water consumption in the watershed. These figures underline the ineffective aspect of TCIS.

•@Water balance analyses indicated that the return-flow (inflow from the upstream tank to the last downstream tank) ratio accounted for 20 - 40% of the total outflow consisting of seepage & percolation loss and water discharge from the upstream tank. These findings confirm that the re-use of return-flow is a very important factor for water use in TCIS.

•@In the basic design of the water balance model, three coefficients (runoff percentage, seepage & percolation loss rate, return flow ratio) essential for the construction of a water balance model were determined. To incorporate these coefficients into the model, fluctuations of tank water storage volume were simulated and compared with actual fluctuations. Although this model was very simple, the similarity of the two fluctuation curves was very close and it was considered that the model may enable to develop techniques for improving long-term water management and rehabilitation of TCIS.

Due to the deleterious effect of overcrowding of tanks such as increase of water use and water pollution, the possibility of streamlining tanks in TCIS was studied with the model. It was considered that the tank in the most upper-stream position could be eliminated and combined with the second upper-stream tank at the expense of water use. For the management of TCIS in future, streamlining of tanks should be examined.

JIRCAS RESEARCH HIGHLIGHT

Procedure for simultaneous analysis of productivity and adaptation traits in indigenous cattle in Africa

•@Kenji Togashi

•@Indigenous cattle in Africa, through natural selection, have developed characteristics which make them well-adapted to adverse environmental conditions such as diseases, parasite infestations, climatic and nutritional stress. Thus, indigenous breeds are valuable genetic resources which need to be maintained and improved to implement livestock breeding programs. There is a great potential for improving livestock productivity by utilizing genetic adaptation of African indigenous livestock. However, unless the structure of genetic variation in a livestock population in Africa is analyzed, future livestock development may be difficult due to the loss of the genetic diversity which evolved over millennia. In low input and highly variable environments such as those prevailing in the tropics, especially in smallholder systems, selection pressure on females for production traits such as milk yield is nearly zero. Thus, how long a cow remains in a herd is closely linked to her overall adaptation. Under such circumstances herd-life can be considered to be a measure of adaptation. At any point in time, the period during which a particular animal remained in the herd can be considered to correspond to herd-life. However, such animals still may stay in the herd beyond the period of measurement. Thus, herd -life is right-censored. If censoring is ignored in the analyses, information may be lost and bias may be introduced. Several methods have been developed for analysing survival data in cattle. However, none of these took into account censoring. A procedure for simultaneous analysis of productivity traits for example (milk yield) and adaptation traits (herd-life) was developed in which location parameters (sire or animal breeding value) for herd-life (right-censored) and milk yield (uncensored) were estimated. A subset of the data on Kenyan Friesian was used to illustrate this procedure. The estimates for heritability for milk yield, heritability for herd-life, genetic correlation and residual correlation were 0.172, 0.424, -0.452 and 0.210, respectively. Particularly genetic correlation was negative, suggesting that selection for the increase of milk yield may adversely affect adaptation. That is, we may lose the genetic adaptation which evolved over millennia in indigenous cattle in Africa if we keep selecting only for productivity trait, for example the increase in milk yield. The productivity of indigenous cattle in Africa could be improved without a concomitant loss of adaptability by using the simultaneous procedure developed in the cooperative studies between ILRI (International Livestock Research Institute) and JIRCAS.

***In vitro* selection and introduction of salt tolerance into cultivated rice varieties from their wild relatives.**

•@Salinity affects about 400 million hectares of land in the world. In Bangladesh approximately 1 million hectares of land are affected by salinity problems in the coastal regions, and not suitable for rice cultivation. This saline area is increasing day by day along with the expansion of shrimp culture. Over the past 25 years, with the active cooperation and financial support of the International Rice Research Institute (IRRI), the Bangladesh Rice Research Institute (BRRI) has so far developed more than 20 high-yielding rice varieties adapted to different agro-ecological regions of the country. However, none of the modern varieties developed by BRRI are salt -tolerant. Actually in the past, BRRI had attempted to develop or improve high-yielding rice varieties suitable for favourable environments only. Since the population of the country is increasing rapidly, the demand for an increase in rice production is also growing. It is therefore, essential to develop modern rice varieties adapted to stress environments along with favourable environments. Recently BRRI has undertaken research projects to develop modern rice varieties adapted to stress environments. Salinity is one of the problem areas that is targeted.

•@As a recipient of the JIRCAS-Visiting Research Fellowship Program 1994, I am carrying out some studies on *in vitro* selection of proline & hydroxyproline-resistant varieties of cultivated rice that could be utilized in the salt-tolerant rice variety development program. I am also trying to incorporate salinity tolerance gene(s) into cultivated rice varieties from their wild relatives using appropriate biotechnological procedures. I hope that the research experience and knowledge that I am acquiring through this fellowship will be useful for the development of salt-tolerant rice varieties in Bangladesh in future.

Crop Production in Hot and Dry Environments -

A Growing Challenge to Agricultural Sustainability

•@Hot weather and moisture deficits cause substantial reductions in crop productivity. Breeding of stress-tolerant crops is of considerable significance for two reasons. First, there is a growing need to use more marginal land for food production due to increasing pressures of rising human population and degradation of favorable land and natural resources. Secondly, the predictions on climate change indicate that in future carbon dioxide concentrations will increase, periods of hot weather may be more frequent and extreme, and that water limitation may be more severe than now. Progress in breeding cultivars adapted to these climates is, however, slow due to the limited knowledge on genetic diversity for tolerance, and the lack of simple and reliable screening techniques.

•@Legumes are important sources of protein and fat in many developing countries but their cultivation is being increasingly relegated to marginal lands. Improvement of stress tolerance in legumes can ensure sustainability. I have been carrying out studies on heat tolerance of legumes since October 1993. The results suggest that groundnut and soybean are more tolerant than pigeonpea and chickpea, and that each legume shows a wide genetic diversity. Refinement of screening methods, and analysis of the mechanisms of tolerance during pod set are in progress.

Knowing More About Bacteria Which

Filter out Methane in Rice Paddies

•@Methane is an important greenhouse gas that significantly contributes to global warming. It has been associated with past climatic changes in the world. Today, the concentration of methane in the atmosphere increases by about 1% every year. A significant proportion of methane global emissions is derived from rice paddies through the methane producing microorganisms. Much is known already about methane production but less on its regulation.

•@While there are bacteria which produce methane, there is another group that eats up methane. These are the methane-oxidizing bacteria (MOB) and they are considered to play a major role in regulating the fluxes of methane from important methane sources such as wetlands and rice paddies. The MOB are obligately aerobic bacteria that can utilize methane as the sole source of carbon and energy for growth. They are important biological regulators of methane in nature.

•@Very limited information is presently available on the levels of populations of MOB and their activities in different environments such as rice paddies. We are now conducting experiments on these aspects which may enable to improve management practices or to identify inputs to control methane emissions.

•@For this reason, I feel that we are really doing some pioneering studies here at JIRCAS. I am working on MOB with a Japanese co-researcher, Dr. K. Adachi, under the guidance of Dr. T. Senboku, our section head.

***Azospirillum* Inoculation to Lowland Rice:**

Enhancement of Plant Growth and Increase of Nitrogen Fertilization Efficiency

•@

•@Fertilizers are considered to be very important inputs leading to increased yields : they were responsible for approximately 55% of the increase in yields in developing countries. The expansion of fertilizer use is expected to be rapid during the next two decades, averaging 8.5% a year. Since the foreign exchange cost of fertilizer to importing countries is high, accounting for more than half of the total cost, and as its cost to the producer in relation to total monetized inputs is also high, priority should be given to research aimed at increasing the efficiency with which inputs are used.

•@Nitrogen is the most common nutrient whose deficiency affects the production of crops. Studies on the increase of N fertilization efficiency have been carried out mostly through the manipulation of the form and application of N fertilizer. The inoculation of *Azospirillum* to lowland rice may enable to increase the efficiency of N fertilization at a lower cost and in turn increase the benefit of the farmers. *Azospirillum* which are associative N₂-fixer bacteria are able to produce a growth hormone leading to the improvement of the growth of plant roots and to the enhancement of the ability of the plants to absorb nutrients.

•@Presently, I am trying to isolate endogenous *Azospirillum* from Ishigaki island, Japan and screen them to select a promising isolate that may enable to promote the growth of lowland rice. I am also trying to determine to what extent *Azospirillum* can minimize the rate of N fertilizer applied to lowland rice. These studies may contribute to a better understanding of the means to improve the technology for increasing N fertilization efficiency compatible with the preservation of the environment .

Mycorrhizas: Colonists of Plants and Soil and Their Role in Sustainable Agriculture

•@ World agriculture faces an unprecedented problem: that of achieving long term sustainability in the supply of food for domestic and international consumption. Sustainability of crop production depends on many factors including the maintenance of optimum soil physical structure and chemical and biological balances in the soils. Conventional agriculture has highlighted the problems of soil degradation arising from the excessive use of pesticides and chemical fertilizers, the removal of organic matter from the topsoil, erosion and compaction. This has led to a call for change from production-oriented agriculture to production and protection-oriented one. Such a call is very appropriate for many African countries where the cost of chemical fertilizers is prohibitive to a large number of small scale farmers, and where population pressure has led to markedly reduced fallow periods to enable adequate soil fertility recovery. There is increasing evidence showing that the integrity and resilience of the soil-plant system in the face of natural and cultural stresses depend on a myriad of microorganisms such as mycorrhizas.

•@ Mycorrhizal fungi penetrate living cells of plant roots without harming them and their hyphae utilize bulk soils, thereby linking plants and soils and act as mineral transport agents. The potential of the vesicular-arbuscular type of mycorrhizas to increase plant productivity is well recognized though insufficiently exploited. My studies in Ishigaki are aimed at selecting efficient indigenous strains of mycorrhizal fungi, establishing a germplasm bank and selecting optimum fungi/host plant combinations to enhance crop production.

Physiological Studies on the Mechanism of Heat Tolerance in Cabbage Varieties

•@

•@Cabbage is considered to be one of the most popular vegetables for human beings. Increase of productivity is essential to meet the demand of the population. In Egypt, cabbage plants are always grown in the winter season.

•@Investigations on the metabolic responses to temperature of different cabbage varieties have been carried out at different potassium and nitrogen levels, as well as plant hormonal concentrations (GA₃, IAA).

•@The process of acclimatization to high temperature involves the acceleration of the photosynthetic activity, sugar accumulation, increase in growth and cuticle layer accumulation rates and decrease in transpiration and evaporation rates.

•@I am thus analysing various physiological characteristics of cabbage varieties under high temperature conditions compared with the control temperature to develop positive correlations between heat stress, nutrient levels and plant hormonal concentrations to increase vegetable production.

•@

Use of Vesicular-Arbuscular Mycorrhizas as Biofertilizer to Improve Crop Production

•@

•@ Vesicular-arbuscular mycorrhizas (VAM) induce mutualistic symbiosis between plant and fungus. This symbiosis is found in most (over 90%) of the major plant families including agriculturally important plants such as maize, soybean, onion, upland rice, citrus and cacao. Numerous experiments have shown that a wide range of plant species benefit from infection with VAM fungi, primarily through enhanced phosphorus (P) uptake, especially in P-deficient soils. The fungus benefits from this association by obtaining its carbohydrate requirements.

•@ P deficiency is one of the common nutrient problems which limit plant growth particularly in acidic soils. The role of VA mycorrhizal fungi is important under such conditions because external hyphae in the soil can compensate for poor root growth by taking up nutrients particularly P, after which the fungi in the roots transfer the nutrient to the plant, which in turn enhances plant growth.

•@ The aim of the project is to isolate and evaluate VAM fungi which are efficient in taking up P from the soil and subsequently promoting the growth of the plant primarily in acidic soils on Ishigaki island. The project may contribute to the isolation and screening of acid-tolerant fungi which are efficient for enhancing plant growth, able to function with low inputs of P fertilizer and responsive to a wide range of crops.

•@ The results from the research outlined above will be further applied at Bogor Agricultural University (IPB), Bogor, Indonesia after the completion of the fellowship, to promote basic research on the mechanism of acid tolerance of VA mycorrhizal fungi and utilization of VA mycorrhizal fungi particularly in acidic tropical soils to enhance crop production in the field. The studies may contribute to the development of sustainable agriculture compatible with the preservation of the environment on a global scale.

Preservation of Plant Genetic Resources in VIETNAM

•@

•@ Although VietNam is a small country in South East Asia, the specific geographical and climatic conditions make it rich in plant genetic resources. This natural receptacle for a long time, however, has been subjected to various types of erosion, of which the VietNam War and the post-war poverty could be the two major factors. As a result, some valuable species have already become extinct and many others are disappearing. Recently, international programs of assistance in the collection and preservation of plant germplasm have been implemented in VietNam.

•@ Along these lines, I am fortunate to have the opportunity to carry out studies on the cryopreservation of plant genetic resources of one of the important tuber crop plants in VietNam -Taro (*Colocasia esculenta* Schott.) under the JIRCAS Fellowship Program.

•@ Such studies which are among the first in this field in VietNam should contribute to the development of a firm base for further undertakings in the preservation of natureal resources through biotechnology.

Collection, Evaluation and Conservation of Genetic Resources of

Vegetatively Propagated Crops

•@

•@Because of the large size and geological and climatic complexities, China is rich in plant genetic resources. A large number of germplasm accessions have not been collected, evaluated, conserved and used up to now. With the increase in the developmental activities of mankind, plant genetic resources especially those of vegetatively propagated crops, are being rapidly lost because they are mainly conserved in the field and are easily destroyed by human intervention and natural disasters.

•@Biodiversity has become one of the most important research topics in China since the signature of the World Treaty on Biodiversity in 1992. At the Institute of Botany, Academia Sinica in Beijing, more than 100 researchers are engaged in research on these subjects. Collection, evaluation and conservation of genetic resources are the main aspects of such research. I feel that the protection of plant genetic resources is essential for the survival of mankind.

•@At the JIRCAS Okinawa Subtropical Station, I am studying various aspects related to the conservation and evaluation of yam germplasm. I hope that I shall be able to apply the various new techniques learned in this program in my future studies on vegetatively propagated plants such as medicinal plants and fruit trees, which play an important role in China's agriculture, medicine and economy.

Evaluation of Rice Germplasm for Salinity Tolerance

•@

•@Salinity limits rice yields or prevents rice planting over large land areas around the world. Population pressure and loss of favorable land require research to develop varieties that can more effectively tolerate salinity. To achieve this objective, the evaluation and utilization of rice germplasm accessions are essential.

•@There are abundant rice germplasm resources in Yunnan province, China, which is considered to be one of the resources center of diversity of cultivated rice. Since 1982, Yunnan Academy of Agricultural Sciences has cooperated with TARC (Tropical Agricultural Research Center) and subsequently with JIRCAS, (Japan International Research Center for Agricultural Sciences) to evaluate and utilize rice germplasm and significant progress has been made.

•@As a researcher from the Yunnan Academy of Agricultural Sciences, I am evaluating the salt-tolerance of rice germplasm from Yunnan province. I have studied about 200 Yunnan varieties from the Gene Bank in Japan. I have detected salt-tolerant varieties, among which upland rice varieties. I plan to investigate various physiological characteristics. This information, I believe may enable us to analyse tolerance mechanisms that could contribute to the development of salt-tolerant varieties.

Tsukuba seminar on the occasion of Japan-IRRI day

Shoji Miyazaki

•@The seminar entitled •gRecent progress in Rice Research and Challenges toward the 21st Century•h, sponsored by the Japan International Research Center for Agricultural Sciences (JIRCAS) was held in cooperation with the International Rice Research Institute (IRRI) in the auditorium of the Tsukuba Office of the Secretariat of the Agriculture, Forestry and Fisheries Research Council, Tsukuba City, on November 24, 1994.

•@The Tsukuba seminar, one of the two important meetings organized on the occasion of Japan-IRRI day, focused on scientific aspects and was followed by the Tokyo meeting for public awareness which was held on the next day in Tokyo. Approximately 400 participants including ten scientists from IRRI were gathered together to review recent progress in rice research and also discuss future prospects at the seminar.

•@•gMore than one thousand children die every hour because of hunger and hunger-related diseases•h said Dr. Klaus Lampe, Director General of IRRI in his keynote address. •gFrom soil preparation to harvesting, what have been the standard practices over thousand of years will in all likelihood change drastically before the middle of the next century. Our ultimate goal is harmony between the need for doubling food production and our obligation to protect the resources on which this production is based.•h

•@After another keynote address entitled •gGenetic Restructuring of Rice Plants•h presented by Dr. Hiroshi Fujimaki, Director General of the National Institute of Agrobiological Resources, seven papers were presented by rice researchers as follows : G.S. Khush, Challenges in Rice Breeding and Biotechnology; M. Yano, Genome Research and Breeding Strategies in Rice Plants; M. Yamauchi, Direct Seeding Technology; R. Ikeda, Rice Breeding in Japan; P.S. Teng, Sustainability in Rice Growing; K. Ohtsubo, Grain Quality and Utilization in Rice; T.W. Mew, IRRI-Japan Shuttle Program Strengthens Rice Research.

•@During the seminar, the auditorium was full of participants including numerous young scientists as well as students who are involved in rice research. We hope that many of these young people will join our effort to fill up billions of empty rice bowls with rice, with emphasis placed on the sustainability•@of agricultural production.

•áNew Research Area•â

Research Collaboration with Mongolia

NAKANO H. and T. MIYASHIGE

•@Mongolia is a country of highlands surrounded by Russia and China. Although the land area of Mongolia is four times larger than that of Japan, its population is only about two millions which is equivalent to one fiftieth of Japan population. Recently Japanese mass media have given a wide coverage of the nature, people, culture and society of Mongolia after the opening of Mongolia to foreign countries. These programs reflect the deep interest of the Japanese people in Mongolia. Collaboration with the Japanese Government has also been initiated in many fields. However, it was the first mission of JIRCAS to determine whether a form of collaboration in the field of agriculture could be initiated with Mongolian organizations.

Country of grasslands

•@Mongolia is a country of grasslands and nomads. A Mongolian proverb says •gMongolians are born on the back of a horse and grown there•h. Sheep, goats, cattle and yaks, camels in addition to horses are also very important animals for nomadic people who account for about half of the population. Grasslands cover 80% of the land area. From on airplane, in summer Mongolia appears as a vast green grassland where many wheel tracks connect towns and camping sites of nomads. Ulan Bator was hidden in the grassland. In Mongolia, we were surprised to observe such a variety of traditional foods made of livestock products. Most of the nomads have lived only with these foods without consuming any cereals and vegetables.

•@After World War ‡U, mechanized farming for upland crops and large-scale livestock production were introduced in the country in order to increase the agricultural productivity and meet the demand of the consumers in newly built cities. Thereafter the production of cereals and vegetables was promoted. Currently people living in the cities consume a large amount of foods of plant origin as well as livestock products. However, along with the introduction of a market economy after the collapse of the socialist system, the productivity of modern agriculture in this country has experienced a decrease. The supply of agricultural chemicals such as fertilizers was discontinued and agricultural machines, irrigation facilities and plant equipment for food processing factories became obsolete.

Mongolian boy on a horse
nomad Family

Mongorian

•@

For future development in agriculture

•@Climatic conditions are very harsh in Mongolia. Since from October to April there is a long winter, the nomads must protect their animals from the intense cold. Heavy snow makes it difficult for the animals to graze on withered grass. In the cropping season from May to September, the productivity of cereals such as wheat and barley is low and very unstable due to cold stress and drought stress. Strong wind in spring and fall causes severe soil erosion of the cultivated fields. The soil fertility is gradually declining due to soil erosion and the insufficient application of organic materials. Scarce rainfall contributes to salt accumulation in soil, too.

•@Moreover, the changes in the eating habits of the Mongolian people mainly in cities are associated with an ever-increasing demand for vegetables, rice, sugar and vegetable oil as well as livestock products. The development of agricultural technology for producing the foods must be promoted to achieve self-sufficiency. In future, preservation of native grasslands will be an important subject for increasing livestock production. Mongolian researchers discussed prospects for the future and emphasized the role of agriculture in the economy of the new country. They hope that research collaboration with JIRCAS will be initiated to address these problems. •@Farewell and Meeting again

•@We remember with great pleasure a party held in the camp of nomadic families who invited us. We were served sheep meat cooked in the Mongolian style and kumiss, an alcoholic beverage made of mare's milk. After the party, we were taken to a small hill and drank together again. It is a ceremony whereby Mongolian nomads bid farewell, hoping to see their guests again.

•@The people in Mongolia, who lead a secluded life in vast grasslands, obviously enjoy meeting their friends. We do hope that it will be possible to initiate a form of collaboration between Mongolian and Japanese scientists .

•áResearch Collaboration•â

Collaborative Research Project with CIMMYT on Wheat•~Maize Crosses

Masanori Inagaki

Biological Resources Division

•@The International Maize and Wheat Improvement Center (CIMMYT) was established in 1966 in Mexico, following the implementation of a special research program sponsored by the Mexican Government and the Rockefeller Foundation. CIMMYT, with headquarters at E1 Batan, 45 km northeast of Mexico City, and with 15 regional offices in the developing countries, implements research and training programs related to the production of maize and wheat. Major activities include the development and worldwide distribution of improved varieties, the conservation of genetic resources, and the production of documentation related to new knowledge about these crops.

•@New wheat varieties developed by CIMMYT in the 1960s are characterized by a stable stem rust resistance, photoperiod insensitivity and semi-dwarfness. These characters allow adaptation of the wheat varieties far beyond Mexico to other developing countries. The resulting rapid growth in wheat production led to the term of •gGreen Revolution•h. In the Post-Green Revolution phase, various agroecological regions or mega-environments of the developing countries have been defined in order to develop effective breeding strategies. The methodology for wide adaptation and high yielding potential involves shuttle of breeding materials between alternate sites in Mexico. Rapid development of the varieties is another aspect to meet the demand for increasing production.

•@Use of haploids is of great interest to wheat breeders, since the production of haploid plants followed by chromosome doubling enables to obtain genetically homozygous lines. The successful production of doubled haploids provides the most rapid method for developing homozygous breeding lines with favorable uniformity in selection procedures, and complements conventional breeding programs. The Japan International Research Center for Agricultural Sciences (JIRCAS, formerly Tropical Agriculture Research Center) has been promoting technical development of wheat haploid production through wide crosses in collaboration with the International Center for Agricultural Research in the Dry Areas (ICARDA). It is possible to obtain wheat haploids from wide crosses using wheat as female parent and a perennial species, *Hordeum bulbosum* L. as pollen parent. After fertilization, the chromosomes of the pollen parent are eliminated from the hybrid zygote resulting in the production of wheat haploids. This method is limited since the success of haploid production strongly depends on the wheat genotypes used for crosses.

•@Recent reports have indicated that crosses of wheat with maize pollen resulted in the production of wheat haploids across diverse wheat genotypes. In addition to maize, selected species from the Panicoides subfamily, such as pearl millet and sorghum, also provide an alternative pollen source for wheat haploid production. A collaborative research project between CIMMYT and JIRCAS has been carried out since 1993 and has focused on the development of wheat •~ maize crosses for producing and utilizing wheat haploids for breeding purposes and genetical analyses. The current cooperative studies

related to wheat haploids include the development of method for long-term storage of maize pollen, genetic analysis of drought tolerance, and evaluation of various breeding schemes. Technical development for efficient production of wheat haploids should contribute to the promotion of basic research projects as well as conventional breeding programs.

JARQ

---- Japan Agricultural Research Quarterly ----

Purpose: Dissemination to overseas countries of up-to-date information on achievements and trends of research activities pertaining to agriculture, forestry and fisheries that are carried out in Japan but would also be relevant to the needs of the respective countries, particularly in the developing regions.

History: *Japan Agricultural Research Quarterly (JARQ)* was established in 1966 by the Agriculture, Forestry and Fisheries Research Council, the Ministry of Agricultural and Forestry. Through the editorial services of the Tropical Agricultural Research Office also established in 1966, such a publication which aimed at introducing the achievement and trends of agricultural research activities in Japan to overseas readers was expected to contribute to the development of agriculture in the countries of the tropical and subtropical regions. In June 1970, the Tropical Agriculture, Forestry and Fisheries Research Council. The publication of *JARQ* was thereafter undertaken by TARC. In October 1993, TRAC was reorganized into the Japan International Research Center for Agricultural Sciences (JIRCAS) with the creation of the Fisheries Division. As a result, *JARQ* also covers the field of fisheries research.

Publication Information: *Japan Agricultural Research Quarterly (JARQ)* is published four times a year, by the Japan International Research Center for Agricultural Sciences, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki, 305-8686 Japan. The present circulation of each issue numbers 2,100, of which nearly two thirds are sent to more than 90 countries mostly in developing regions. Subscription is limited to institutions only, free of charge, and subscription inquiry should be directed to the Editorial Secretary of *JARQ*.

Editorial Policy: The Editorial Board serves as a screening committee. The Board members nominate candidates for the submission of papers for the forthcoming issues, and the decision is finalized during the Board meeting. Contributed papers are divided into two categories: **research articles** which summarize the findings of recent research activities of the author which may have been published elsewhere (but include also original contributions), and **research reviews** which review the objectives, procedures, and achievements of research activities by Japanese researchers on a specified research topic.

Editorial Inquiries: Send questions on editorial policy and procedure to the Editorial Secretary. Advice and comments are also welcome.

Abstract

Cell culture techniques are necessary for the use of biotechnology including the production of transgenic rice plants. However, there are significant differences in *in vitro* culture responses among rice varieties. These differences limit the application of biotechnology to genetic improvement of rice. In this study, it was demonstrated that nitrite reductase activity is one of the physiological factors correlated with the differences among rice varieties in cell culture. It was indicated that the modification of the culture medium was effective in overcoming the differences in cell culture: the calluses of some Indica and Japonica type varieties showed a poor growth or did not grow under the initial conditions, whereas the calluses of all the varieties tested showed good growth when the nitrogen source, carbon source and medium pH were modified. As a result, in this study the culture conditions applicable to a wider range of varieties, including Indica type, Japonica type and Indica-Japonica crossed varieties as well as Japonica type were identified.

Discipline: Biotechnology

Additional key words: *Oryza sativa*, abscisic acid, amino acid, genotypic difference, nitrogen metabolism

References

Introduction

In rice, progress is being made in the application of biotechnology, including haploid method of breeding by anther culture, the use of somaclonal variation, the production of somatic hybrids by cell fusion, and the production of transformed plants. To use these techniques, plants must be regenerated from objective cells using cell culture techniques. However, significant differences in the efficiency of callus formation, somatic embryogenesis, and plant regeneration have been detected among the varieties of many plant species, including rice^{1,21}). These varietal differences limit the application of biotechnology to the genetic improvement of rice. For example, only a few Japonica varieties, such as Nipponbare and Taipei 309, can be readily cultured and maintained in the embryogenic state, and used to produce transformed rice plants^{9,19,23}). So far, no reports have dealt with the improvement of culture conditions that could be applied to a wide range of varieties and genotypes in rice.

In rice cell culture, immature and mature embryos are used as materials for callus induction, because the derived calluses have a high ability of plant regeneration^{19,23}). Embryogenic suspension culture can be established by continuously culturing the calluses in a liquid medium. A large amount of protoplasts, into

which foreign genes have been introduced by electroporation^{19,23)} and polyethylene glycol⁹⁾ methods, have been isolated from the suspension cultures. And also the cultures can be used as target materials for the transfer of foreign genes by biolistic⁴⁾ and *Agrobacterium* methods¹⁰⁾. Therefore, it is important to develop embryogenic suspension cultures for the application of biotechnological methods in rice.

In this study, the culture conditions for rice were improved in order to overcome the varietal differences in the culture response and to obtain embryogenic cultures from all types of rice varieties. Furthermore, the physiological factors related to varietal differences in rice cell culture using calluses cultured under the improved conditions were identified.

Materials and methods

1) Callus induction and culture

Fifty rice varieties used in this study are shown in [Figs. 2 and 3](#). Rice seeds were provided by the Genebank and the Rice Breeding Laboratory, Chugoku National Agricultural Experimental Station, Ministry of Agriculture, Forestry and Fisheries of Japan (MAFF). Seeds were sterilized in 70% ethanol for 30 s and in a sodium hypochlorite solution containing an available chlorine concentration of 1 % for 30 min, followed by rinsing with sterile water 3 times. After rinsing, the sterilized seeds were immersed in sterilized water for 6 to 7 h. Embryos were cut off from the imbibed seeds and were placed with the scutellum pointing upwards on induction media. The induction media contained constituents of Medium C (shown in [Table 1](#)) except for proline and were solidified by 0.8% agar. The pH of the medium was adjusted to 5.8. Seven-day-old calluses derived from the scutella were transferred to 20 mL of Medium A and Medium C in 100 mL-flasks on a gyratory shaker at 100 rpm by subculturing every 7 days. For subculturing, about 0.4 mL cell volume of calluses were transferred to 20 mL of a fresh medium with the same composition in 100 mL-flasks. The calluses were used as materials after subculture for more than 2 months. The following experiments were carried out with 3 replications.

For the measurement of the callus growth rate during the seven-day-culture period, about 250 mg fresh weight of the subcultured calluses were transferred to a fresh medium. Fresh weight of the calluses was measured after removing excess medium around calluses with pieces of sterile filter paper at 0 and 7 days after transfer, and growth rates were calculated.

2) Enzyme assays

Ten Japonica type varieties used for the enzyme assays are shown in [Fig. 4](#). The calluses were subcultured in Medium C for more than 2 months. About 250 mg of the subcultured calluses were transferred to Medium B or C. The 2 media contained potassium nitrate at the same concentration of 20 mM. The calluses were homogenized in three-fold volumes of the extraction buffer 3 days after transfer according to the method of Ida et al.¹¹). The extraction buffer contained 50 mM Tris-HCl (pH 7.9), 5 mM cysteine and 2 mM EDTA. The homogenate was centrifuged at 10,000 x g for 20 min and the supernatant (500 \hat{I} /₄L) was concentrated with Microcon 10 (Amicon Inc. , USA) for reducing the amounts of nitrate ions. The concentrated supernatant was diluted by the addition of 500 \hat{I} /₄L of the buffer containing 50 mM Tris-HCl (pH 7.5), 1 mM cysteine and 2 mM EDTA and was assayed for nitrate reductase (NR) and nitrite reductase (NiR) activities. The operations described above were carried out at 4 \hat{a} .,f Protein content of the extract was determined by a Bio-rad protein assay kit using bovine serum albumin as standard protein.

Enzyme activity was assayed by *in vitro* method. The assay mixture for NR contained 25 mM potassium phosphate buffer (pH 7.5), 10 mM KNO₃, 0.2 mM NADH, 5 mM NaHCO₃ and 5 \hat{I} /₄L of extract in a final volume of 0.5 mL. The assays were conducted at 30 \hat{a} .,f for 15 min. The reaction was terminated by the addition of 50 \hat{I} /₄L of 0.5 M Zn(CH₃COO)₂ and excess NADH was oxidized by the addition of 50 \hat{I} /₄L of 0.15 mM phenazine methosulfate¹⁷). The amount of NO₂ⁱ/₄* produced was determined colorimetrically²).

NiR activity was assayed following the reduction of $\text{NO}_2^{i/4\bullet}$ from the assay mixture¹²⁾. The assay mixture contained 50 mM Tris-HCl (pH 7.5), 0.5 mM NaNO_2 , 1 mM methyl viologen and 50 $\hat{\text{I}}/4\text{L}$ of extract in a final volume of 0.9 mL. The reaction was started by the addition of 100 $\hat{\text{I}}/4\text{L}$ of 0.12 M $\text{Na}_2\text{S}_2\text{O}_4$ dissolved in 0.2 M NaHCO_3 and incubated at 30 $\hat{\text{a}},,f$ for 60 min. The reaction was terminated by vigorous mixing on a tube mixer until the color of methyl viologen fully disappeared. After the addition of 100 $\hat{\text{I}}/4\text{L}$ of 1 M $\text{Zn}(\text{CH}_3\text{COO})_2$, the mixture was centrifuged at 10,000 x g for 10 min. The amount of residual $\text{NO}_2^{i/4\bullet}$ in the supernatant was determined colorimetrically as in the NR activity assay.

For the measurement of the $\text{NO}_2^{i/4\bullet}$ content, the supernatant of the callus homogenate was prepared as described above 3 or 7 days after transfer. $\text{NO}_2^{i/4\bullet}$ content of the supernatant was colorimetrically determined by the method of Aslam and Huffaker²⁾.

3) Measurement of abscisic acid content in calluses

The calluses of Nipponbare, Koshihikari and IR24 which were subcultured in Medium C were used for the measurement of abscisic acid. About 1 g of the calluses were collected at the end of the seven-day-culture period. The calluses were homogenized with 3 mL of the 100% methanol on ice. The homogenizer blade was washed with 16 mL of 80% methanol and the washed solution was added to the homogenate. The homogenate was kept overnight at 4 $\hat{\text{a}},,f$ in the dark. Polyvinylpyrrolidone (0.5 g) was added to the homogenate, mixed and kept for more than 10 min. The mixture was filtered and evaporated *in vacuo*. After evaporation, the residue was dissolved in 1.5 mL of 0.5 M potassium buffer (pH 8.3). The sample solution was partitioned against hexane 3 times and then against ethyl acetate 3 times. The pH of the aqueous phase was adjusted to around 2.5 and the solution was partitioned against ethyl acetate 3 times. The ethyl acetate phase was collected and evaporated *in vacuo*. The residue was dissolved in 100% methanol and loaded onto a Bondesil DEA column (Varian Associates. Inc., U.S.A.). After absorption, the column was washed with 100% methanol and eluted with methanol containing 0.5% acetic acid. The eluate was evaporated *in vacuo* and the residue was used for the determination of the ABA content by an immunoassay. The culture medium was also collected and evaporated *in vacuo* at the end of the seven-day-culture period and purified for the determination of the ABA content in the same way as for calluses except for hexan partitioning and first ethyl acetate partitioning. Butylated hydroxytoluene, an antioxidant, was added to all the solvents for homogenization and purification at the concentration of 20 mg/L. ABA content in the purified sample was determined using an abscisic acid immunoassay detection kit (Sigma-Aldrich Japan K. K., Japan).

Physiological factors related to differences between Nipponbare and Koshihikari in culture response

Ammonium sulfate is most commonly used as a reduced nitrogen source for preparing a basal medium in tissue and cell culture, because the addition of ammonium ion in combination with nitrate generally enhances the growth rate of cultured cells^{8,15}). However, as described above, this compound was considered to be the factor that inhibited the growth of the calluses of Koshihikari type varieties. Attempts were made to investigate the metabolism of nitrogen sources in order to determine the physiological basis of the differences in callus growth between Koshihikari and Nipponbare type varieties¹⁴). The calluses cultured in the modified medium were considered to be suitable materials in this analysis, because no differences were observed in the growth rates and appearance of the calluses between Koshihikari and Nipponbare type varieties.

The nitrite ion content and activity of nitrate reductase and nitrite reductase were examined in the calluses of 10 varieties using the liquid medium (Medium B) with the same composition as that of the initial medium (Medium A), except that the concentration of potassium nitrate was 20 mM ([Fig. 4](#)). The calluses of the Koshihikari type varieties (No. 6-10) accumulated significantly more nitrite ions during the culture period than those of the Nipponbare type varieties (No. 1-5). The callus growth rate was negatively correlated with the nitrite ion content ($r=-0.9525$, $p < 0.001$), indicating that the calluses of the Koshihikari type varieties were injured by toxic nitrite ions, which led to browning and poor growth of the calluses.

The reduction of nitrate to ammonia is catalyzed by 2 enzymes, nitrate reductase (NR) and nitrite reductase (NiR), and nitrite ion is considered to be an intermediate in the pathway. The accumulation of nitrite ions may be attributed to either excessive production of nitrite ion by NR or slow reduction of nitrite by NiR reductase. In this study the second assumption was verified. The calluses of the Koshihikari type varieties showed significantly lower levels of NiR activity than those of the Nipponbare type varieties. On the other hand, no differences were observed in the NR activity in either group. The results suggested that the higher ion levels observed in the Koshihikari type varieties were due to a lower ability to reduce nitrite ions and that NiR activity is one of the physiological factors correlated with the differences between varieties in rice cell culture.

As shown in [Fig. 5](#), the calluses of the Koshihikari type varieties displayed the same growth rate as those of the Nipponbare type varieties in the modified medium (Medium C), but also contained significantly lower levels of NiR. NR activity was inhibited in the calluses of both varieties in the improved medium compared to Medium B. The results suggested that the inhibition of the NR activity resulted in the accumulation of trace amounts of nitrite ions in the calluses of the Koshihikari type varieties in spite of the lower NiR activity and, as a result, callus growth improved in the modified medium.

NR activity is known to be regulated by $\text{NO}_3^{i/4}$, light, reduced nitrogen sources, sugar, etc.^{3,19}). It was reported that ammonium ions and casein hydrolysates decreased the NR activity of rice cultured cells when the nitrogen sources were added in combination with $\text{NO}_3^{i/4}$ ¹⁶). However, it remained to be determined whether the effect on the inhibition of the NR activity was different among the amino acids added in rice cultured cells. Filner⁷) reported that the effect on the NR activity depended on the amino

acids added in cultured tobacco cells: NR activity was inhibited by one group of amino acids, i. e. alanine, arginine, etc. and depressed by a second group of amino acids, i. e. asparagine, lysine. In a further study, differences in the effect of reduced nitrogen sources including alanine and proline in rice calluses will be examined. The calluses of Nipponbare type varieties showed a slightly lower growth rate in Medium C (Fig. 5) than in Medium B (Fig. 4). This decrease may be associated with the decrease in both NR and NiR activities observed in the Nipponbare type varieties. Although we replaced 30 g/L sucrose in Medium B with 3.75 g/L maltose in Medium C, differences in sugar types and concentrations may also be responsible for the decrease in the growth rate of Nipponbare type varieties in Medium C. However, it was reported that when the sucrose concentration increased, the NR activity was enhanced at least in pea seedlings¹⁹). Further improvement of the sugar composition for rice cell culture should be examined by monitoring the balance between NR and NiR activities to avoid the toxicity of NO₂^{i/4}•.

Differences in endogenous abscisic acid content among varieties

IR24 type varieties could be cultured in the modified medium (Medium C). However, the calluses of this type showed a lower growth rate than those of Nipponbare and Koshihikari type varieties even in the modified medium: 6 varieties of IR24 type were found in the lower rank as shown in Fig. 3. In the following experiment, the regeneration ability of the calluses which were cultured in the modified medium was examined. The results showed that the calluses of IR24 type varieties exhibited a higher ability of plant regeneration than those of other types of varieties (data not shown). Based on these results, it was assumed that the IR24 varieties were characterized by both a lower ability of callus growth and high ability of plant regeneration from calluses. Although abscisic acid is a phytohormone which exerts various effects on plant growth²²), one of the effects consists of the inhibition of plant growth. In studies on plant tissue culture, the addition of abscisic acid to the medium enhanced the frequency of plant regeneration from cells²⁰). The content of abscisic acid in the calluses cultured in the modified media was compared among 3 varieties, Nipponbare, Koshihikari and IR24. As shown in [Table 2](#), in the calluses of IR24 the level of abscisic acid was 12.0 and 8.6 times higher than that in Nipponbare and Koshihikari, respectively. Similar results were obtained when the ABA content in the culture medium was compared among the three varieties. These results suggested that the higher content of endogenous ABA was responsible for the lower growth rate and higher regeneration ability of the IR24 calluses cultured in the modified medium.

It is assumed that the IR24 type varieties can naturally accumulate a higher level of ABA in the cells than other types of varieties. Because the initial medium contained unsuitable factors for callus growth, such as amounts of sucrose, ammonium sulfate and pH values, a high level of ABA could inhibit more strongly callus growth of the IR24 type varieties in the initial medium than in the modified medium. As a result, the calluses of IR24 type varieties may not be able to grow or display limited growth. To confirm this hypothesis, the relationships between the endogenous ABA content and differences in the culture response are being currently analyzed.

Discussion

Although varietal differences are widely observed in rice cell culture, there are few reports on the culture conditions required to overcome the differences. Daigen and Abe⁶) modified a culture medium by

one-fifth dilution of all of inorganic salts and obtained the conditions suitable for the culture of calluses of the Japonica type variety Koshihikari. In this study the range of tested varieties was expanded and the conditions applicable to a wider range of varieties including Indica type, Javanica type and Indica-Japonica crossed varieties as well as Japonica type were defined. For further improvement, such as enhancing the growth rate, the modified conditions developed in this study could be used as basal conditions.

For the application of biotechnology in rice, varieties and genotypes are selected based on the ability of their response to culture. The selected varieties may not necessarily belong to elite ones in rice. It is possible to transfer the traits which are genetically modified through biotechnological procedures from the manipulated plant to an elite variety by the backcrossing method. On the other hand, the backcrossing process to fix the genetic traits is time-consuming and an undesirable trait might be introduced into the derived plants if genes are closely linked to the gene for the trait. The modified culture conditions developed in this study should facilitate the application of biotechnology to rice breeding, so that elite varieties can be used directly.

There are few reports on the physiological processes related to the differences in the culture response. In most cases, no detailed analysis has been conducted to clarify the physiological aspects of varietal differences in cell culture. In this study, the nitrite ion content was found to be one of the physiological factors related to the differences in rice cell culture. It was also observed that when there is a high concentration of these ions in cells with poor growth, inhibition of the NR activity may enable to improve the growth. Physiological information related to the varietal differences in the culture response should be useful to simplify the process of improving the culture conditions as described above in rice and in other plants.

Abstract

Sixty-eight indigenous rice cultivars collected in deepwater areas in Bangladesh were examined in terms of heading behavior and allozyme variation. Seasonal ecotypes differed in the heading behavior for adaptation to their respective cropping seasons. Isozyme analysis revealed that cultivars grown in deepwater areas in Bangladesh consisted of a Japonica-like group and an unclassified unique group in addition to a major Indica group. Classification by isozyme variation was not necessarily consistent with the differentiation into seasonal ecotypes. Cultivars collected in a restricted area in Khulna District consisting of various seasonal ecotypes showed a genetic similarity to each other, suggesting that geographical differentiation preceded seasonal differentiation. Based on a case study conducted in 2 villages in Khulna, it was pointed out that diverse landraces which are adapted to different local and seasonal conditions have evolved by interacting with traditional planting systems.

Discipline: Genetic resources

Additional key words: heading behavior, isozyme, varietal differentiation

Introduction

Bangladesh is situated in the wide delta of the Ganges, Brahmaputra and Meghna rivers. Average annual rainfall is about 2,000 mm, with 95% being concentrated from May to September. In addition to rainfall, melting of snow in the Himalayas leads to the rise of the river water level during the monsoon period and more than half of the total land of the country is flooded. In the flood-prone low-lying areas, rice is the major or sometimes the only crop that can be cultivated.

Three cropping seasons of rice have been identified in Bengal (Bangladesh and West Bengal State of India), namely, Boro (winter), Aus (summer) and Aman (autumn)^{10,12}. Varietal groups which are used for different seasons, are designated by the name of the respective cropping seasons. In the dry winter season, Boro is grown mainly in the irrigated fields. In the rainy summer season, short duration Aus is grown in lowland as well as in upland areas. From summer to autumn, long-duration Aman is grown by

transplanting (T. Aman) or by broadcasting (B. Aman). B. Aman rice is almost synonymous to deepwater rice that can elongate the internodes markedly in response to the rising water level. Furthermore, 2 minor groups of deepwater rice, Rayada and Ashina, occur in Bangladesh. Rayada shows a very long growth duration, and is cultivated in a restricted area along the river Madhumaty, a tributary of the Ganges. Ashina belongs to a small varietal group characterized by early heading.

Nearly 10,000 landraces are considered to exist in Bangladesh. These varieties have been generally considered to belong to the Indica type in the same way as those grown in other low-lying areas in tropical Asia. Isozyme studies, however, revealed that Bangladesh deepwater rice contains some varieties that did not fall under either the Indica or Japonica type^{5,13}). The objective of the present study was to analyze the pattern of genetic variation among rice cultivars distributed in flood-prone areas in Bangladesh with special reference to varietal differentiation corresponding to the cropping seasons. A case study in Rayada-growing villages was conducted to analyze the diversity of rice cultivars in relation to the traditional cropping systems.

Materials and methods

The present study was mainly based on the samples and information obtained during a study-trip to deepwater areas in Bangladesh in which the second author participated. The trip was organized in December 1989 through the financial support of a grant from Monbuscho International Scientific Research (No. 0104110) and with the cooperation of the Bangladesh Rice Research Institute (BRRI). The details of the field observations were described in the trip report¹⁵). Sixty-eight rice cultivars dealt with in the present paper consisted mostly of landraces collected from farmers' fields or their seed stocks in the Districts of Dhaka, Habiganj, Sylhet, Mymensingh, Tangail and Khulna. Twenty landraces provided by BRRI were also analyzed.

Collected seed samples were sown in mid-April in 1990 and grown in the automatic short-day (12.5 h) apparatus at the National Institute of Genetics, Mishima. The same set of samples was planted in paddy fields under natural daylength (not all the accessions were examined because of the shortage of plants). Heading date of each variety was recorded under short and long (natural) day conditions. Isozyme assay was conducted using plumules or germinated seeds derived from multiplied seeds. Eight loci (*Est2*, *Est5*, *Est10*, *Est11*, *Est12*, *Mal1*, *Mal2* and *Amp5*) were assayed by polyacrylamide gel electrophoresis (PAGE) and 12 loci (*Acp1*, *Amp1*, *Amp2*, *Amp3*, *Cat1*, *Est2*, *Est9*, *Pgd1*, *Pgd2*, *Pgi1*, *Pgi2* and *Sdh1*) by starch gel system. In PAGE, 22 landraces from Asian countries other than Bangladesh were analyzed together as check varieties. The details of the methods of isozyme analysis were described in the reports of Ishikawa et al.¹⁴) and Cai et al.⁴). In the 2 villages of Surigati and Katadula (Khulna District), we tried to collect not only seed samples but also information about each variety through interviews with local people.

Abstract

Precision farming is bringing about a new revolution in agricultural farming systems with its high potential of reducing the environmental impact and increasing the productivity, based on the high efficiency of advanced technology. Variability management is the key approach in precision farming, using field maps and real-time sensing for temporal and spatial variation in soils, plant growth and yield, and other parameters related to cultivation. Site specific field management can be implemented based on accurate information. Scale-free precision farming approaches are suitable for small-scale Japanese agriculture. Prospects and strategies for Japanese precision farming are introduced, followed by the results derived from investigations on soil mapping and the use of soil sensors.

Discipline: Agricultural engineering

Additional key words: small-sized farm, variability soil map, soil sensor

1...10): [References](#)

Introduction

Precision farming, which aims at reducing the environmental impact and increasing the productivity, has been rapidly developed in the world during the current decade. In the United States, for example, the National Research Council⁶⁾ suggested that the federal government should encourage research and development related to precision farming as a national strategy. European countries have also promoted the development of precision farming. In Japan, the Ministry of Agriculture, Forestry and Fisheries started an R&D project on Japanese precision farming in 1998, while several universities and companies have already studied specific issues.

Promotion of precision farming should affect related industries as well as agriculture due to technology innovation.

In this paper, the concept of precision farming is outlined and studies related to Japanese precision farming (soil mapping and soil sensors) are introduced.

Concept of precision farming

Precision farming is characterized by a systems approach to orient the total system of agriculture toward sustainability, as shown in [Fig. 1](#)⁷⁾. Regulations for environmental conservation have become increasingly stricter worldwide. Specific problems such as pollution by chemicals, organic agriculture or agriculture without the use of pesticides have attracted a wide interest. However, such an agricultural system had focused on the improvement of only one or several aspects of agriculture, which sometimes resulted in reduced productivity, and did not enable to modify the whole system of agriculture supported by farmers. Precision farming aims at solving such trade-off problems on environmental conservation and productivity, using variability management and a systems approach²⁾.

Three fundamental techniques must be considered for integrating the components of precision farming systems.

- 1) Analysis of variability is the key concept of precision farming, in particular to analyze within-field variability, in order to adjust agricultural inputs to site-specific requirements. Variability should involve at least 3 aspects: spatial variability, temporal variability and predictive variability^{2,8)}.
- 2) Variable-rate technology (VRT) is used for adjusting the agricultural inputs to site-specific requirements at each location in the field, which requires variable-rate working machinery while manual application can be used in a small-scale farm. Variable-rate application allows: (1) accurate position in the field, (2) accurate information at the position, and (3) precise operations at the position.
- 3) Decision support system (DSS) offers some choices to a farmer in terms of trade-off problems such as productivity and environment. This component is characterized by a systems approach to optimize a complex system.

How to integrate the technology components to meet the conditions peculiar to Japan agriculture, is a major issue for researchers, engineers and politicians as well as farmers.

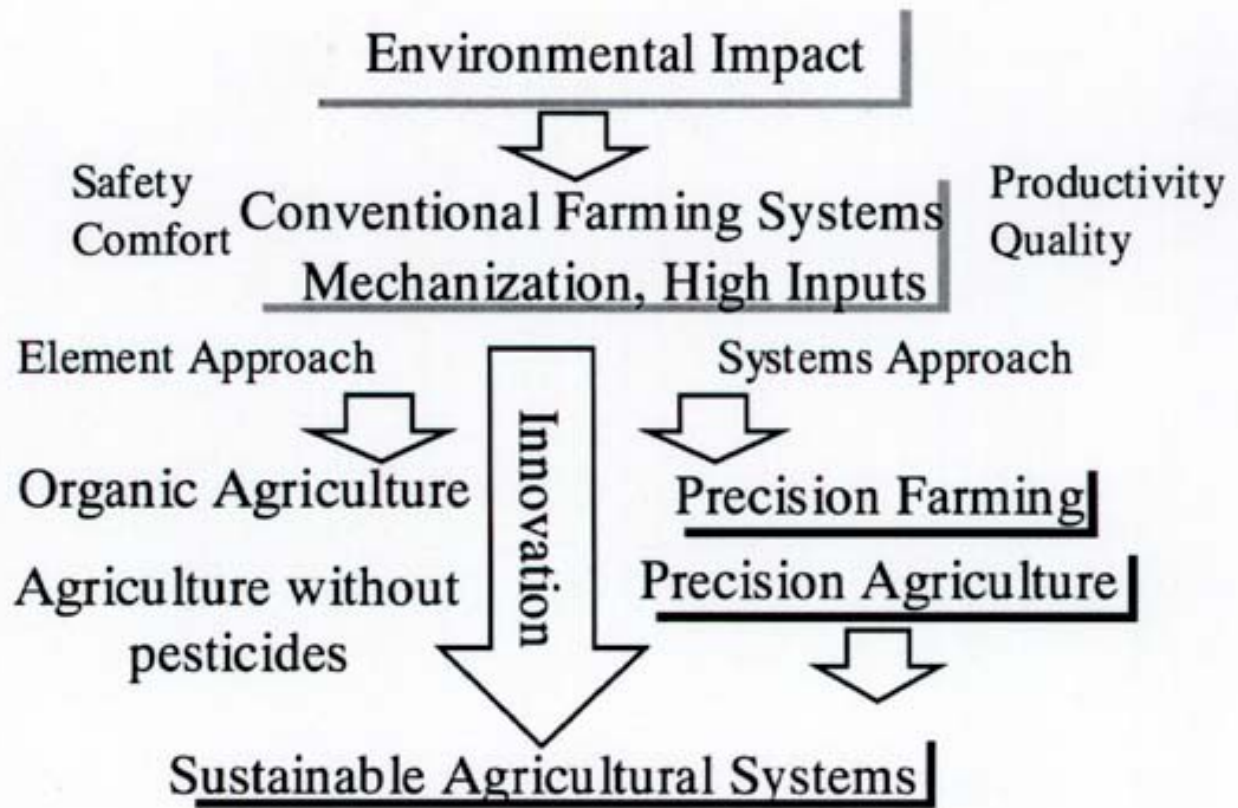

Fig.1. Trends of agriculture and implications for precision farming

BACK

Scale-free precision farming

Japanese agriculture is characterized by a small-scale and labor-intensive operations based on individual plant management involving variability. Considering the variability of management in precision farming, the precision farming approaches can be adopted for any scale of farming as shown in [Table 1](#).

In the case of small farms, farmers should concentrate their activities on fields based on empirical knowledge. Information on each field on an average and use of simple monitoring techniques for mechanical applications, enable to conduct variable-rate controls for site-specific management based on farmers' skills. The variability management system deals with only averaged data per field. For the management of a farm of several hectares, it becomes difficult for the farmers to evaluate the variability within each cultivation field. This is more evident for farming on a much larger scale. Positioning by using GPS techniques, automatically sensing systems, etc. may enable to generate field maps to analyze the spatial and temporal variability. Sensor-based variable-rate control machines can be used for managing such large-scale farms because of the requirement of high-speed operations.

Consequently precision farming approach can be designed and re-arranged to fit any scale of farms, which is an important aspect for Japanese agriculture due to the diversity in field size, crop variety, field elevation, water management for paddy fields, climatic and soil conditions, etc.

Prospects and strategies

1) *Paddy field precision farming*

The concept of paddy field precision farming will be outlined here ([Fig. 2](#)). In general, a paddy field is a small-sized and flattened field with a well-organized irrigation and drainage system. The paddy fields located in a region are interdependent at least due to water management. In Japan, intensive farm works are implemented to achieve uniformity in the soil conditions, transplanting, crop management, etc. within a field with full mechanization. It was generally considered that there was less variability within such a paddy field, although variability within the field had been reported⁵⁾.

Regarding between-field variability, many variations can be found in terms of crop varieties cultivated, productivity and yield, water permeability of soil and working time. Large facilities for grain drying and processing have already been operated as "rice centers" throughout the rice production areas in Japan, in addition to the compact grain dryers owned by individual farmers. Moreover there are well-organized farmers' associations and cooperatives everywhere. If a yield monitor could be attached to a combine harvester and use of the cooperative facilities could be recorded accurately, it would be easy to observe the variability between fields. This could be the first step of paddy field precision farming, putting one field as a unit for observing the variability, followed by determinations on how to manage the variability. Global monitoring system can be used for observing and managing such regional variability.

On the other hand, environmental pollution associated with paddy farming has become a cause for concern. How to reduce the environmental impact requires the development of a monitoring system and

measures for environmental conservation in the respective fields or locations in the field. As a result, management of within-field variability, aiming at reducing the environmental impact and at maintaining the productivity should be promoted. Sensor-based precision farming in paddy fields is thus required.

Sensing for within/between-variability, VRT machines and DSS algorithms that are the main technology components for precision farming should be developed as early as possible. These tools can also be used for evaluating the variability and for identifying the distinctive characteristics of precision farming in the respective countries.

2) Variability within a field

Temporal and spatial variability of $\text{NO}_3\text{-N}$ in a corn field in a 30.5 m grid sampling was reported by Everett et al. ³⁾, and soil nutrient mapping for short-range variability was also reported by Birrell et al. ¹⁾, but the minimum grid spacing was still 25 m. Grids with a narrower spacing with cells 6.1 m wide and 15.2 m long were used for investigating the temporal and spatial variability of soil parameters, and N recommendation maps were generated ⁴⁾. These grid spacings are still too wide for the small Japanese fields. Sampling using 1 m grids for $\text{NO}_3\text{-N}$ mapping was conducted over a 10 m² area in a small Japanese field and temporal and spatial variability was confirmed ⁵⁾, although the whole field was not observed. Japanese farming is sometimes characterized by crop-stubble management with intensive farm works in a small field, and it is generally considered that there is less variability within a field.

Analysis of the variability is the first step for precision farming. Our studies have focused on within-field variability of nitrate nitrogen ($\text{NO}_3\text{-N}$) in a 0.3 ha field, a typical size in Japan, because $\text{NO}_3\text{-N}$ is water-soluble and infiltrates groundwater easily, and it is also an important parameter of soil fertility.

Figs. 3 to 5 show $\text{NO}_3\text{-N}$ contour maps for 3 study areas within the field⁹⁾. Value levels were classified for every 2 mg/100 g. The whole field at the top 5-15 cm depth, as shown in [Fig. 3](#), showed 4 levels of $\text{NO}_3\text{-N}$ with the predominance of the middle 2 levels. The 1 $\tilde{\text{A}}$ —1 m² area at the top 5-15 cm depth, located in the southern part of the field, exhibited a fairly uniform distribution, as shown in [Fig. 4](#). The 8 $\tilde{\text{A}}$ —8 m² area at the 25-35 cm depth showed 7 levels of the $\text{NO}_3\text{-N}$ and a complicated pattern, as shown in [Fig. 5](#). It was therefore confirmed that the $\text{NO}_3\text{-N}$ distribution varied with the observation scale as well as depth. Implications of the variability for agricultural practices should be further investigated.

3) Spectrophotometer¹⁰⁾

On-line real-time sensing of soil parameters *in situ* has been an important issue for scientists and engineers engaged in precision farming research. Spectroscopic approach is one of the issues for real-time soil sensing because multiple parameters could be evaluated at the same time, since the photometric properties of many soil parameters can be included in a wide range of spectral absorption/reflectance records.

(1) Prototype spectrophotometer

A diagrammatic representation of the spectrophotometer is presented in [Fig. 6](#). It was composed of 3 main parts as follows.

A soil penetration chisel equipped with micro-optical devices operated as a tunnel for continuous space measurement in soil and to collect the light reflected at the same time, as shown in [Fig. 7](#). The optical units consisted of 2 optical fiber probes from a 150 W illumination halogen lamp, visible and NIR optical fiber probes, and CCD camera. The case for the sensor probes, about 600 mm long, 200 mm high and 50 mm thick, was equipped with a shank 700 mm deep, 100 mm wide and 25 mm thick. A micro-NIR thermometer was also installed for the calibration of temperature variations.

A spectrometer with linearly arrayed photo-diodes to detect the spectra of reflected light was used. It can simultaneously measure 256 channel spectra in a range of 400 to 900 nm by using the visible device and 128 channels in 900 to 1,700 nm by using the NIR device.

A control and data logging device of personal computer (233MHz, RAM 128 MB), liquid crystal display and a pulse generator with a free rotating wheel and rotary encoder to trigger timing signals were used. The soil penetrator was attached to a 4WD 18kW tractor with a three-point hitch. All the components were also placed on the tractor.

Fig.8. Soil surface image

through the CCD camera

(2) Field test

Test runs were conducted in a clay paddy field after harvesting and in an upland loam field. The paddy field test is briefly introduced below. The instrument for measuring the soil surface was flattened by the blade, as shown in [Fig. 8](#).

A distinct photo-spectrum reflectance was obtained from the underground soil at a 28 cm depth and at a spacing of about 1 m, as shown in [Fig. 9](#). It was confirmed that the correlation coefficients between soil parameters and spectrum reflectance were 0.83 (1,462 nm) for the soil moisture level, 0.78 (1,488 nm) for the pH, 0.80 (1,462 nm) for the electric conductivity (EC), 0.93 (1,538 nm) for the content of soil organic matter (SOM), and 0.44 (1,462 nm) for the content of nitrate nitrogen. Other information can be obtained from the soil spectrum reflectance collected.

Conclusion

In this paper, the concept of precision farming was outlined and studies related to Japanese precision farming (soil mapping and soil sensors) were introduced as follows.

1. Precision farming is characterized by a systems approach and variability management for farming on any scale, aiming at the maintenance of both productivity and environmental conservation. Analysis of the variability is the first step for promoting precision farming.

2. Paddy field precision farming could be initiated for between-field variable management, while technology components should be developed as early as possible.

3. The variability of the soil parameters was demonstrated in a small field in Japan.

4. A real-time on-line portable spectrophotometer was developed for collecting data on underground soil reflectance, which enabled to determine the moisture level, pH, EC and SOM content.

Abstract

In Japan, most of the farm operations in orchards on sloping land in the past had been carried out manually, since no suitable machinery was available. However presently, the problem of aging farmers and shortage of young successors, especially for citrus orchards on steep hillsides must be solved. Therefore, a mechanized production system (MPS) for orchards on sloping land was developed involving the construction of farm paths and the use of machines behind which the operator walks, such as air-blast sprayer, raised bed transporter, and fertilizer spreader. The benefits of MPS were confirmed by comparison with a conventional production system (CPS) in an actual farmer's orchard at Yoshida town, Ehime prefecture, which is one of the leading citrus-production districts in Japan. The use of this system enabled to reduce the total working hours by 35% as well as improve the working conditions without yield decrease and decline of the quality of fruits.

Discipline: Agricultural machinery

Additional key words: Farm path, pest control, transportation, fertilizer application

1...5): [References](#)

Introduction

As in most Asian countries, the area of arable land in Japan is very small. Therefore, hilly areas have been cultivated since ancient times. After World War II, many orchards on sloping land in Southwest Japan were brought under cultivation for satsuma mandarin, the most popular citrus variety with the highest fruit production. Since orchards on sloping land are well-drained, exposed to sunshine and well ventilated, farmers can grow sweet citrus fruits that fetch a high price.

However, the mechanization of such orchards has been lagging behind that of lowlands in Japan because the use of machinery is difficult, and sometimes even dangerous due to the steep gradients and high-density planting. As a result, farmers have tended their orchards by hand, spending long hours stooped over their trees. Statistics showed that the yearly labor requirement for citrus crops per unit area was 4 times higher than that for rice production using a tractor, a rice transplanter, and a head-feeding combine. Moreover, farming in Japan is facing growing problems due to the shortage of efficient farmers associated with the increase of the average age of the farmers and decrease of the number of young

people. Therefore the number of abandoned orchards is increasing.

To address these problems, a mechanized production system (MPS) was developed to reduce hours as well as improve the working conditions in citrus orchards on steep slope. This system involves the construction of farm paths and the use of small walking-type machinery behind which the operator walks.

Construction of farm paths⁵⁾

The mechanization of orchards on sloping land with steep gradients depends on the construction of paths for agricultural machinery. The construction of wide farm roads or paths to allow the passage of large machines is not suitable on steep slopes because the construction costs are high and there is a risk of landslide. Furthermore, the total yield from the orchard decreases because many trees must be cut to make room for the machinery. Instead, a new farm path system was developed for MPS.

The layout of the farm path system is shown in Fig. 1. It includes 2 kinds of paths, a working path which is 1.0 m wide, and a connecting road more than 1.3 m wide. The connecting road acts as a backbone, while working paths are located laterally to the road. To ensure that the machines can travel safely along the paths, the gradient of the connecting road should be less than 15°. The path should have a turning circle where the machines can turn around, with a diameter of 2 m.

The working paths also function as hillside ditches, intercepting run-off water. It is important to pave them, to prevent erosion and to allow machines to travel smoothly. We have developed a low-cost cement aggregate pavement, using soil from the orchards rather than gravel and sand brought in from outside. The cement is mixed with a coagulant powder and water, and hardens into smooth, durable pavement. Such a pavement is easy to construct, and the total cost is comparatively low.

Paved farm path

Construction process of farm paths is carried out as follows (*Fig. 2*):*(1) The path is dug out using a small back hoe. (2) Cement is mixed together with the coagulant and spread over the soil surface. (3) It is mixed together with soil, using a rotary-tiller. (4) Water is sprinkled onto the mixture, using a power sprayer. (5) A rotary-tiller is used to mix all the ingredients thoroughly together, and level out the surface.*

The ratio of soil, cement, and coagulant in the in the pavement materials is 100:13:0.3, respectively. The water is sprinkled at a rate of 20

L/m². Pavement depth is 7 - 10 cm. The farm path is constructed at a rate of 100 m²/h with a team of 5 workers.

It is also important to install a water supply system. Usually a water storage tank is constructed at the lower end of the connecting road, for collecting the water running down the farm paths. The water is used for irrigation, or for mixing pesticide sprays.

Development of small machines^{1,2)}

Because the farm paths in orchards on sloping land are steep and narrow, large farm machinery cannot be used. Instead, we designed specialized small machines with the following basic specifications; (1) Use of crawler treads, rather than wheels. (2) The operator does not ride on the machine, but walks behind it. (3) The machine has a very small turning circle.

1) Mechanization of pest control

In fruit culture, chemical sprays are necessary for pest control. In Japan, they need to be applied about 10 times per year. At present, power sprayers with long hoses are widely used, but they require a long amount of labor. Farmers need a kind of sprayer with a lower labor requirement and higher efficiency.

Therefore, we designed an air-blast sprayer ([Fig. 3](#)). The operator walks behind the sprayer along a farm path. The sprayer is equipped with an axial fan, and emits a fine and dense chemical mist. The operator can direct the spray precisely onto the target by controlling the direction of a fan drum, that can be adjusted freely between 35° upward and 20° downward. Air turbulence associated with the fan drum swinging automatically shakes the leaves of trees, so that chemical spray adheres to both sides of the leaves.

This sprayer is equipped with a liquid chemical tank with a capacity of 300 L. It can apply pesticides at a rate of 3,000 to 5,000 L/ha with a working efficiency of 0.15 ha/h. Since the machine is operated by only one operator without any co-workers, the application can be conducted at suitable times for fruit trees.

2) Mechanized transportation

At present, the transportation of loads involving a container for harvested fruits and a bag of fertilizer weighing 20 kg has been conducted manually with a high labor intensity. However, a transporter with crawler treads could be used to carry heavy loads. With a good network of farm paths, the use of such a transporter may lead to a significant improvement in efficiency and comfort of farm work.

The transporter we developed has an adjustable elevated bed measuring 45 to 118 cm, with outriggers to give stability ([Fig. 4](#)). Its loading capacity is suitable for 10 containers (a 20kg load). By raising the bed, it is possible to reduce the labor required for loading harvested fruits from the transporter to a truck. In addition, the raised bed can be used as a platform for the farmer who carries out operations in the tree canopy, such as pruning, thinning and harvesting.

3) Mechanized fertilizer application

The application of fertilizer 3 times each year (in spring, summer, autumn) does not require many working hours for fruit production in Japan, but the work of spreading fertilizer over an orchard is rather hard.

We developed a fertilizer unit mounted on the bed of the transporter ([Fig. 5](#)). The capacity of the hopper of the fertilizer is about 100 L. Granular or pellet type fertilizer metered through an auger attached to the bottom of the hopper is led to a discharge pipe, and blown out with air from a centrifugal fan. Mounting and unmounting the unit on the bed of the transporter are easy operations, because of the transporter's hydraulic lift system.

Fertilizer can be applied in a band up to 4.6 m wide, at a rate of 14 - 25 kg/min. Fertilizer can be applied at a rate of 1.0 to 1.5 t/ha with a working efficiency of 0.45 ha/h.

Advantages of mechanized production system^{3,4)}

1) Methods

To confirm the advantages of MPS, we set up a model orchard in an actual farmer's orchard with a mean slope gradient of 25° at Yoshida town, Ehime Prefecture. The model orchard was improved by adopting the developed farm path system from 1994 to 1995. The working path was placed at an interval of every 2 tree rows, with a path density of 1.2 km/ha. The rate of removed trees for the construction of the farm path was only 8%.

Field experiments were conducted to determine the labor intensity of each operation and the yearly working hours by comparison with a conventional production system (CPS) for 2 years. The labor intensity level of each operation was classified based on the increase of worker's heart rate. [Fig. 6](#) shows the difference between MPS and CPS for pest control, transportation of harvested fruits, and methods of fertilizer application. The other operations such as pruning, thinning, and mowing were also improved. Investigations of yield and selling price for the model orchard were performed to evaluate the productivity compared with the area average.

2) Labor intensity and working hours

[Table 1](#) shows the labor intensity and yearly working hours for MPS and CPS. The labor intensity required for pest control, fertilizer application, harvesting in the case of MPS was obviously reduced by the use of small machines. In addition, the labor intensity for mowing weeds using a bush cutter was also reduced because the worker could perform the operation on the working path and not on a slope. As a result, the labor intensity of the operations was reduced to less than the average level.

The working hours of each operation in the case of MPS were also reduced, and the application of fertilizer using the fertilizer spreader was more uniform than that with the hand-spreader. Especially the transporter in the case of MPS led to a significant reduction of the labor required for the transport of fruits during harvest so that the output of harvested fruits per worker could be increased. Tests showed a 38% reduction in the working hours required for harvesting. As a result, the yearly working hours were reduced by 35%.

3) Effect of introduction of MPS on citrus production

[Table 2](#) shows the yield and selling price of fruits in the model orchard where farm paths were constructed from 1994 to 1995. The yield and selling price of citrus fruits varied with the years because fruit-bearing occurred in alternate years. Compared to the area average, the yield in 1994 and 1995 was slightly higher than in case of thinning of citrus trees. The yield after the introduction of MPS was more than 150% higher, indicating that the improvement of orchards by this system did not cause a yield reduction in spite of some thinning of citrus trees.

The selling price also was higher than that of the area average. Considering that this district is one of the leading citrus production centers in Japan, MPS enabled to produce high-quality citrus fruits. In addition, the owner who introduced MPS stated that this system enabled to reduce the labor intensity and working hours and also to enhance the quality of fruits due to the improvement of the light conditions in lower and inner portions of the tree canopy.

Conclusion

In citrus orchards on sloping land, the shortage of labor has become a serious problem in Japan. Therefore, we developed a mechanized production system (MPS) involving the construction of farm paths, and the use of small machines behind which the operator walks, including an air-blast sprayer, raised bed transporter, and fertilizer spreader.

The advantages of MPS were tested in an actual farmer's orchard by comparing it with the conventional production system (CPS). The tests showed that the MPS enabled to reduce yearly working hours by 35% as well as improve the working conditions without a decline of the quality of fruits and yield. These results indicate that the introduction of this system enabled farmers to avoid hard manual labor required for the maintenance of orchards on sloping land and extended the scale of farm operations. Consequently, the MPS for orchards on sloping land should contribute to the development of stable orchard management.

Abstract

Natural ventilation system modifications were evaluated using a computational fluid dynamics (CFD) numerical model (code: Fluent Version 4.5). Wind speed and direction, side vent opening size and location, roof vent opening type, and number of spans were examined in terms of ventilation rates and airflow distribution. For the side vent located at 2.5 m above the floor with a west wind of 2.5 m/s, 59 % of the incoming air through the side vent was predicted to move out through the first roof vent opening without reaching distant areas in the greenhouse, resulting in high inside air temperatures. The air mainly moved in through the side vent and fourth roof vent openings for an east wind of 0.5 m/s while the third and fourth roof openings were the only predicted inlets of airflow for an east wind of 2.5 m/s. The hinged open roof multi-span greenhouses were predicted to have significantly higher natural ventilation rates than the double polyethylene-covered multi-span greenhouses for all the spans in the absence of side vent.

Discipline: Agricultural facilities

1...10): [References](#)

Introduction

While mechanical ventilation systems are still widely used throughout the industry presently, high energy costs associated with market-driven production methods have forced growers to consider alternative means of ventilating their greenhouses in order to remain competitive. While natural ventilation systems can be very difficult to design properly, increased emphasis is being placed on such systems for greenhouses as they generally require less electrical energy, less equipment operation and maintenance, and are much quieter than fan ventilation systems.

A common goal of ventilation system designs for greenhouses during hot summer weather is to keep the inside air temperature as close as possible to the outside air temperature. For natural ventilation, this objective is generally achieved by using high air exchange rates, evaporative cooling systems such as

fogging, evaporative cooling from plants, and some forms of shading systems. Natural ventilation is achieved by air exchanges through multiple openings due to natural pressure variations inside and outside the greenhouse. Wind is the primary driving force making natural ventilation systems very difficult to design properly because of variations in the wind velocity and direction. The optimization of these systems for suitable climate control requires a thorough knowledge of the airflow rates and patterns in relation to weather conditions and greenhouse structural characteristics⁶⁾.

A successful numerical model was assumed to be an ideal tool to analyze the complex phenomena of natural airflow and help designers choose optimum designs. There was a particular interest in computational fluid dynamics (CFD) numerical techniques to analyze the air distribution in agricultural structures as well as air quality and thermal conditions⁶⁾.

The objective of this study was to evaluate the consequences of various modifications of natural ventilation systems by using a computational fluid dynamics (CFD) numerical model (code: Fluent Version 4.5)²⁾. The studies focused on the effects of wind speed and direction, side vent opening size and location, roof vent opening type, and number of spans on ventilation rates and airflow distribution inside and outside multi-span greenhouses.

Woodruff¹⁰⁾, Kacira et al.⁴⁾, and Lee⁶⁾ studied various naturally and mechanically ventilated greenhouse types by using a CFD numerical model. They mainly investigated the effects of weather conditions, greenhouse structural specifications, internal and external shading screens, number of greenhouse spans, and presence of plants and benches on the air exchange rates in greenhouses.

Lee⁶⁾ simulated the natural ventilation of a 2-dimensional four and one-half-span greenhouse in a CFD numerical model and compared it to a control volume energy balance model. Assuming the results of the control volume energy balance model as the standard, the results of the steady state CFD model during a sunny day showed errors (negative values) as high as 15 % in the morning and comparable errors (positive values) in the afternoon. Such errors were assumed to be due to heat storage in the floor, benches, and greenhouse structure and the CFD model was found to be the most reliable.

Lee⁷⁾ numerically analyzed the temperature distribution in a naturally ventilated multi-span greenhouse with plants by a CFD simulation program using the standard k- ϵ turbulence model. The computed CFD results of air temperature distribution showed a maximum error of $\hat{A}\pm 3.2$ % for west and east winds compared to air temperatures measured in the greenhouse for the same boundary conditions. The measured air temperature distribution showed that the air came into the greenhouse through the leeward side vent opening for low wind speed.

Materials and methods

1) CFD numerical model

The CFD technique numerically solved the Reynolds-averaged form of the Navier-Stokes equations^{2,5)} within each cell in the domain. The equations were discretized on a curvilinear grid to enable computations in complex and irregular geometries. The Reynolds-averaged process considered the instantaneous fluid velocity to be the sum of a mean and a fluctuating component of turbulence^{1,3)}. Since the high-frequency and small-scale fluctuations of turbulent flow could not be directly quantified, turbulence numerical modeling related some or all of the turbulent velocity fluctuations to the mean flow quantities and their gradients.

The standard k- ϵ turbulence model was used in this study because the results were found to be most typical to known ventilation flows^{2,4,5,10)}. The k- ϵ turbulence model was an eddy-viscosity model in which the Reynolds stresses were assumed to be proportional to the mean velocity gradients, with the constant of proportionality being the turbulent eddy viscosity. The turbulent viscosity was obtained by assuming that it was proportional to the product of a turbulent velocity scale and length scale. In the k- ϵ model, these velocity and length scales were obtained from 2 parameters ; the turbulent kinetic energy (k) and the dissipation rate of k (ϵ).

Close to solid walls, there were boundary layer regions where the local Reynolds number was so small that viscous effects predominated over turbulent effects²⁾. To account for this effect and for the large gradients of variables near the wall, the wall function method of Launder and Spalding⁵⁾ was used in the CFD model. Wall functions, when used in conjunction with the standard k- ϵ equations, were intended to reproduce the logarithmic velocity profile of a turbulent boundary layer near the wall.

Fluent V4.5 was a two-part package consisting of a preprocessor, Geomesh, and a main module, Fluent/UNS2). Geomesh was used to create geometry and generate structural grids, and the triangular grids were developed to efficiently model the complex geometries of greenhouse structures. Fluent/UNS was used to specify physical models, boundary conditions, and fluid properties in the computational domain. The inlet air flow was assumed to be incompressible, vertically uniform in speed, and all the computations were performed assuming steady-state conditions.

The Boussinesq model^{2, 5)} was activated for the buoyancy effect in the computational domain. Thermal boundary conditions were defined at all the fluid inlets and at all the wall/fluid interfaces in the CFD computational domain. At the fluid inlet, the air temperature, air velocity, air velocity direction, atmospheric pressure, gravitational acceleration, turbulence intensity, and characteristic length were specified. The thermal conditions of density, specific heat, viscosity, and thermal conductivity were also specified for the fluid inlets. For the walls, several thermal boundary conditions were specified such as surface temperature, emissivity of the wall, and conductive heat transfer coefficient.

2) Experimental procedures

A simulated four-span, double polyethylene greenhouse (a) and a hinged open roof single-layered glass greenhouse (b) were designed with a side vent and roof vents ([Fig. 1](#)). The four-span greenhouse was

slightly modified from a four and one-half-span, double polyethylene greenhouse at Quailcrest farm located near Wooster, Ohio⁶). The glass greenhouse was assumed to have a similar gutter configuration to that of the double polyethylene greenhouse. It was assumed to be a peaked-roof house with hinged roof panels that opened and closed via rack-and-pinion drives. For convenience, the spans between gutters were called the first, second, third, and fourth spans from west to east.

Weather data were collected on hot summer (35th,f) days for westerly and easterly winds from June 1 to August 30, 1997 near Wooster, Ohio (40th47'N, 81th55'W, elevation 310 m), and generalized for the CFD model inputs shown in [Table 1](#). The input data sets were based on 4 averaged values for 4 min when the weather conditions such as wind speed, wind direction, and solar radiation were stable⁶). Air density, viscosity, specific heat, thermal conductivity, and emissivity of various materials were calculated from the table of thermophysical properties^{8, 9}). In the 2-dimensional CFD models, no end wall effects were assumed because the input data used in this study were collected when the wind direction was generally perpendicular to the vent openings.

In this study, the 2-dimensional CFD models were developed to investigate the effects of side vent location, side vent opening size, roof vent opening type, number of spans, wind speed, and wind direction on the natural ventilation of multi-span greenhouses without plants and benches. The CFD-computed results of volumetric air change rate per minute (A.C./min), vent opening efficiency, and airflow distribution were compared according to greenhouse structural specifications and weather boundary conditions. The visual representation of the airflow distribution in the greenhouse was obtained via vectors with the CFD model.

Side vent placement was very important to prevent plant damage and yet avoid short-circuiting of airflow out through an adjacent roof vent. The effect of the west side vent location on the natural ventilation of a four-span double polyethylene-covered greenhouse was investigated for west and east winds of 0.5, 1.0, and 2.5 m/s when the vertical roof and side vent opening sizes were 0.76 and 0.9 m in height, respectively. The distance between the bottom of the west side vent opening and floor varied from 0.5 to 2.5 m.

The 2-dimensional CFD models were developed to investigate the effect of the vertical opening size of the west side vent on the natural ventilation of the greenhouse with west and east winds. All the vertical roof vent openings were 0.76 m wide and the distance between the bottom of the west side vent and floor was 0.5 m. The vertical opening size of the west side vent varied from 0.9 to 2.7 m.

The effects of the roof vent opening type and number of greenhouse spans on natural ventilation rates of multi-span greenhouses were investigated. The predicted natural ventilation rates of the double polyethylene greenhouse ([Fig. 1\(a\)](#)) and hinged open roof greenhouse ([Fig. 1\(b\)](#)) were compared to each other. The average wind speed of 2.5 m/s was assumed based on a statistical analysis of the weather data conducted in Ohio from 1991 to 1995¹⁰). The distance between the bottom of the west side vent and floor was 0.5 m for all cases. The vertical roof vent opening sizes of the double polyethylene greenhouse were 0.76 m in height while the horizontal roof vent opening sizes of the glass greenhouse were 6.2 m.

Results and discussion

1) Effect of side vent location on natural ventilation

[Fig.2](#) shows the predicted effects of side vent location, wind speed, and wind direction on the natural ventilation rates in a double polyethylene-covered four-span greenhouse when the vertical side vent and roof vent opening sizes were 0.9 and 0.76 m, respectively. The CFD-computed results showed that the west side vent location exerted the most pronounced effect on the total ventilation rate for a west wind where the rates were reduced by approximately 20, 16, and 14 % for winds of 2.5, 1.0, and 0.5 m/s, respectively when the west side vent was moved from the lowest to highest position. The results indicated that the lowest side vent location (0.5 m above floor) gave the highest natural ventilation rate for both wind directions and the west wind led to an average of 11 % higher natural ventilation rate than the east wind. An east wind of 0.5 m/s, however, showed a 17 % higher natural ventilation rate than a west wind of 0.5 m/s while a west wind of 2.5 m/s showed a 20 % higher natural ventilation rate than an east wind of 2.5 m/s. With low east wind speed, the combination of buoyancy and wind effects exerted a positive pressure on the fourth roof vent and the west side vent openings. This resulted in both vent openings being inlets and a greater natural ventilation rate than in the case of a west wind with the same speed.

The CFD-computed results in [Table 2](#) showed that the side vent was a very active vent opening as either an inlet or outlet depending on both wind speed and direction. The air mainly moved in through the side vent and fourth roof vent openings for an east wind of 0.5 and 1.0 m/s while the third and fourth roof openings were the only predicted inlets of airflow for an east wind of 2.5 m/s. When the bottom of the side vent was located at 0.5, 1.5, and 2.5 m above the floor, the percentages of airflow through the side vent as an inlet were 70, 44, and 37 %, respectively for an east wind of 0.5 m/s while 57, 44, and 42 %, respectively as an outlet for an east wind of 2.5 m/s. It indicated that the side vent was likely to become a more active vent opening as the side vent location was lower.

For a west wind, as shown in Table 2, the incoming air was predicted to enter the side vent and the first roof vent openings and to move out at all the other roof vents when the bottom of the side vent was located at 0.5 and 1.5 m above the floor. The incoming air, however, was predicted to enter the side vent and the fourth roof vents for a low west wind speed when the bottom of the side vent was located at 2.5 m above the floor. For the same vent configuration and a west wind of 2.5 m/s, approximately 59 % of the incoming air through the side vent was predicted to "short-circuit" out through the first roof vent opening. This also resulted in a very low velocity prediction near the plant level in the third and fourth spans in spite of a favorable overall natural ventilation rate as shown in Fig.2.

[Fig.3](#) shows the CFD-computed vectors of airflow in a double polyethylene multi-span greenhouse for a west wind of 2.5 m/s when the bottom of the west side vent opening was located at 0.5 m (a) and 2.5 m (b) above the floor. Fig. 3(a) shows that the predicted inlet air moved along the floor from west to east in the greenhouse when the side vent was located at 0.5 m above the floor. A large portion of the inlet air through the side vent located at 2.5 m above the floor, however, was predicted to move out through the first roof vent opening and the air flow was very low at the second, third, and fourth vents of the greenhouse.

2) Effect of side vent opening size on natural ventilation

[Fig. 4](#) shows the effects of the vertical west side vent opening size, wind speed, and wind direction on the natural ventilation rate in a double polyethylene-covered four-span greenhouse when the bottom of the side vent opening was located at 0.5 m above the floor. [Fig. 4](#) shows that the averaged natural ventilation rates with the vertical side vent opening sizes of 0.9, 1.8, and 2.7 m in height, were 0.42, 0.71, and 0.95 A.C./min, respectively for a west wind and 0.36, 0.64, and 0.78 A.C./min, respectively for an east wind. The CFD-computed results indicated that the west side vent opening size could markedly affect the natural ventilation rate of the greenhouse, especially for the west wind and high east wind speed.

[Table 3](#) shows the CFD-computed percentages of volumetric airflow at each vent opening based in the vertical west side vent opening size, wind speed, and wind direction. For west winds, the side vent was the only inlet of airflow with vertical side vent opening sizes of 1.8 and 2.7 m in height while the side vent and the first roof vent openings were inlets with a vertical side vent opening size of 0.9 m in height. For east winds of 0.5 and 1.0 m/s, the side vent became a more active inlet of airflow as the vertical side vent opening size increased while the side vent was predicted to be a significant outlet for an east wind of 2.5 m/s.

3) Effect of number of spans and roof vent opening type on natural ventilation

The predicted effects of the number of spans and vertical west side vent opening size on the natural ventilation rate in double polyethylene multi-span greenhouses for a west wind of 2.5 m/s are shown in [Fig. 5\(a\)](#). The CFD-computed results indicated that the natural ventilation rate decreased as the number of greenhouse spans increased while the natural ventilation rate was directly proportional to the vertical west side vent opening size for all cases. Even an 8-span greenhouse (60 m wide) was predicted to have a high natural ventilation rate when a large side vent opening was used. The CFD-computed results also showed that the natural ventilation was very low without the windward side vent opening. As shown in [Table 4\(a\)](#), the air generally was predicted to come into the greenhouse through the windward side vent and the first roof vent with a 0.9 m side vent opening while the side vent was predicted to be the only inlet of airflow with a windward side vent opening of 2.7 m in height. It was also predicted that the flow rates of the roof vents as outlets increased from windward to leeward walls when the windward side vent was open. When the windward side vent was closed, however, the air was predicted to mainly move into the greenhouse through the middle roof vents and move out through both end side roof vents.

The predicted effects of the number of spans and vertical west side vent opening size on natural ventilation rate for a hinged open roof multi-span greenhouse with a west wind of 2.5 m/s are shown in [Fig. 5\(b\)](#). Significantly higher natural ventilation rates were predicted compared to the double polyethylene greenhouses for all the spans, especially when no side vent or a small side vent was used. It indicated the influence of the roof vent opening size and shape and the possibility of air moving over the windward wall and the creation of reverse flow in the greenhouse at plant level.

No consistent relationship was revealed between the natural ventilation rate in the hinged open roof greenhouse and the number of spans and side vent opening with vertical windward side vent opening sizes of 0.0 and 0.9 m. This was because the air flow was predicted to pass up and over the west,

windward wall and come down in reverse flow as shown in [Fig. 6](#). With a side vent opening size of 2.7 m, the natural ventilation rate was predicted to increase proportionally to the number of spans. When the open roof multi-span greenhouse had more than 6 spans, the larger side vent opening was predicted to provide the optimum natural ventilation rates. As shown in [Table 4\(b\)](#), the CFD-computed results indicated that the roof vents acted as inlet or outlet of airflow according to the number of spans and windward side vent opening size while the windward side vents always acted as an inlet to airflow.

Fig. 6 shows the CFD-computed vectors of airflow in a hinged open roof greenhouse for a west wind of 2.5 m/s when the vertical windward side vent opening sizes were 0.0 m (a) and 2.5 m (b) in height. The fourth and first roof vents were the main inlet and outlet openings, respectively without the side vent open while the side vent and the fourth roof vent were the main inlet and outlet openings, respectively while the side vent was open. The CFD results predicted that the same ventilation patterns would develop as in the double polyethylene greenhouse when the windward side vent was fully open. When the windward side vent was closed, however, the air went up and over the windward side wall and entered the greenhouse at the fourth roof vent opening, creating a reverse flow across the greenhouse.

Conclusions

The CFD-computed results predicted that the west side vent location did not strongly affect natural ventilation rates in a four-span double polyethylene-covered greenhouse for both wind directions as much as the wind speed.

It was predicted that the lowest side vent location at 0.5 m above the floor resulted in a higher natural ventilation rate in the double polyethylene multi-span greenhouse for both wind directions than the higher vent location. The west wind cases were predicted to show an average of 11 % higher natural ventilation rate than the east wind.

An east wind of 0.5 m/s showed an average of 17 % higher natural ventilation rate than a west wind of 0.5 m/s with a west side vent opening while a west wind of 2.5 m/s showed an average of 20 % higher natural ventilation rate than an east wind of the same velocity.

The CFD-computed results indicated that the west side vent was a very active vent opening as inlet and outlet of airflow, respectively for low and high east wind speeds. The air mainly moved in through the side vent and fourth roof vent openings for an east wind of 0.5 m/s while the third and fourth roof openings were the inlets of airflow for an east wind of 2.5 m/s. It was also predicted that the side vent would become a more active vent opening as the side vent location was lower.

For the bottom of the 0.9 m side vent located at 2.5 m above the floor for a west wind of 2.5 m/s, approximately 59 % of incoming air through the side vent was predicted to move directly out through the first roof vent opening without reaching the other areas of the greenhouse.

The CFD-computed results indicated that the west side vent opening sizes markedly affected the natural ventilation rate in the greenhouse, especially for the west wind. For west winds, the side vent was the only inlet of airflow with the vertical side vent opening sizes of 1.8 and 2.7 m in height while the side vent and the first roof vent openings were inlets with a vertical side vent opening size of 0.9 m in height.

The natural ventilation rate in the double polyethylene greenhouse was predicted to decrease as the number of greenhouse spans increased while the natural ventilation was very low without the windward side vent opening. It was also predicted that the windward side vent opening size was very important for good natural ventilation of the multi-span greenhouse.

The hinged open roof vent greenhouses generated significantly higher natural ventilation rates than the double polyethylene greenhouses for 2, 4, 6, and 8 spans. It indicated the importance of the roof vent opening size and shape and the possibility of achieving reverse airflow at plant level when no side vent was used with the hinged open roof greenhouse.

For the hinged open roof vent greenhouse, the highest natural ventilation rate for the widest span tested (8 spans) was obtained with a side vent opening size of 2.7 m. When the multi-span greenhouse had more than 6 spans, larger side vent openings were predicted to generate better natural ventilation.

Abstract

Accumulation of trehalose, which is a disaccharide composed of 2 molecules of glucose, is generally considered to be a critical determinant in improving the stress tolerance of the baker's yeast *Saccharomyces cerevisiae*. To retain this accumulation in yeast cells, we constructed diploid homozygous trehalase (trehalose-hydrolyzing enzyme)-deficient mutants by the gene disruption method from commercial baker's yeast. During fermentation, degradation of intracellular trehalose was inhibited in the trehalase-deficient mutants. Their freeze tolerance was maintained at a higher level than that of the parent strain. Due to the improved freeze tolerance exhibited by the trehalase-deficient mutants, these strains may be suitable for use in the baking process of frozen dough.

Discipline: Food microbiology

Additional key words: bread

1...25): [References](#)

Introduction

In the baking industry, frozen dough technology has recently been applied due to its advantages in supplying oven-fresh bakery products to consumers, as well as improving labor conditions for bakers¹⁰. Standard commercial baker's yeast is generally susceptible to damage during frozen storage and does not retain a sufficient leavening ability after frozen storage. Freeze tolerance is an important characteristic for yeast used in frozen doughs, because post-thaw leavening activity is essential prior to baking. The ability to tolerate freeze stress depends on many factors, including the growth phase and rate, nutritional status, rate of freezing, and the intracellular amount of cryoprotective compounds^{12,18,21}. Although freeze-tolerant yeast strains have also been obtained by conventional mutation procedures^{14,16,25}, bread baked with such strains has less taste and flavor compared with bread baked with parent strains. The objective of this study was to develop freeze-tolerant baker's yeast from commercial strains using DNA recombinant techniques, without loss of the yeast's other beneficial properties.

Because disaccharide trehalose is considered to be a critical determinant of stress tolerance in the yeast *Saccharomyces cerevisiae* (*S. cerevisiae*)^{5,7,9,21}, we constructed trehalase-deficient mutants and investigated their freeze-tolerance. Two enzymes are capable of hydrolyzing trehalose: a neutral cytosolic trehalase (designated as Nth1p) and an acidic trehalase (designated as Ath1p)¹³. Both Nth1p and Ath1p have been purified from *S. cerevisiae*, and the corresponding genes have been cloned and sequenced^{1,6,11}.

In order to determine the effect of trehalase gene disruption during the baking process, we constructed trehalase-deficient diploid strains from commercial baker's yeast. We showed that these mutants accumulated higher levels of trehalose than their parent strain under optimal culture conditions for high trehalose contents, and that trehalose accumulation was correlated with a higher freeze tolerance in frozen dough baking. We also showed that commercial application of the mutant strains could be obtained by gene disruption.

Abstract

Cabbage seedlings exposed to non-freezing low temperature (5°C, f) under a 12 h photoperiod acquired the freezing tolerance, while the plants exposed to non-freezing low temperature in the dark did not acquire the freezing tolerance. On the contrary, in the case of reversal from cold acclimation, the freezing tolerance of the plants was reduced by exposure to normal growth temperature (20/15°C, f) regardless of light conditions. These changes in freezing tolerance coincided with the changes in the sugar contents of cabbage leaves. The plants subjected to water stress by withholding water displayed a higher degree of freezing tolerance and increase of sugar contents compared with the watered plants. Thus, it was assumed that cabbage seedlings required light to acquire the freezing tolerance after exposure to low temperature, while deacclimation was induced without light and it was confirmed that water stress increased to a certain extent the freezing tolerance in cabbage seedlings.

Discipline: Horticulture

Additional key words: cold acclimation, de-acclimation

1...15): [References](#)

Introduction

Cabbage is one of the most important vegetables in Japan and is often injured by cold or frost. Most of the overwintering plants acquire the freezing tolerance by exposure to non-freezing low temperature, and

this process is referred as cold acclimation. Freezing tolerance of plants is affected by various environmental factors¹⁾, besides temperature. Furthermore, cold acclimation is also influenced by several environmental factors. Drought and desiccation stress increased the freezing tolerance in rye²⁾, and winter wheat¹⁴⁾. On the other hand, it has been reported that cold acclimation is accompanied by biochemical changes affecting sugars^{9,11)}, proteins¹⁰⁾ and plasma membrane lipids¹⁵⁾. Sasaki et al. (1996)⁸⁾ showed that cabbage seedlings exposed to non-freezing low temperature (5°C) acquired a freezing tolerance. However, the role of light during cold acclimation and deacclimation and the relationship between the freezing tolerance and water stress in cabbage seedlings remained to be elucidated.

The analysis of the mechanism of acquisition and loss of freezing tolerance in cabbage could contribute to the stable production of cabbage and other vegetables. This study was conducted to investigate the effects of light during cold acclimation and deacclimation and water stress on freezing tolerance and sugar contents in cabbage seedlings.

Materials and methods

1) Plant materials and growth conditions

Seeds of cabbage (*Brassica oleracea* L. cv. Banchurisou) were sown in plastic pots filled with a soil mixture (Pretty Soil Gold N-140, Otsukasangyo, Nagano, Japan). Plants (one plant per pot) were grown in a growth chamber at 20/15°C (day/night) and under a 12 h photoperiod in which illumination was supplied by metal halid lamps (MLBOC400C-U, Mitsubishi Electric OSRAM, Yokohama, Japan) using a photosynthetic photon flux density (PPFD) of $230 \pm 10 \mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$.

2) Exp.1 Effects of light on cold acclimation and deacclimation

Three weeks after sowing, the seedlings were exposed to 5°C for 7 days under a 0 (dark) or 12 h (light) photoperiod as cold acclimation treatments. For deacclimation treatments, seedlings cold-acclimated by exposure to 5°C under a 12 h photoperiod for 7 days were transferred to a growth chamber at 20/15°C for 2 days under a 0 or 12 h photoperiod. In the plants subjected to the low temperature and deacclimation treatments, the freezing tolerance and sugar contents were determined.

3) Exp.2 Effects of water stress on freezing tolerance and sugar contents

The seedlings which unfolded 2 leaves and were watered daily, or not watered for 3 days, were grown in a growth chamber at 20/15°C under a 12 h photoperiod. The amount of water supplied to the plants exceeded $40 \text{ mL} \cdot \text{pot}^{-1} \cdot \text{day}^{-1}$. The soil water contents (mean \pm standard error) of the watered and non-watered treatments were $45.4 \pm 1.6\%$ and $22.3 \pm 0.9\%$, respectively. The plants that were watered and not watered were used for measuring the freezing tolerance and sugar contents.

4) Freezing tolerance test

The degree of freezing tolerance of the seedlings was expressed in terms of the electrolyte leakage determined by methods previously described⁸⁾. Leaf discs excised from the 2nd leaves of the seedlings were placed in a test tube. Test tubes were transferred to a chamber where the temperature was lowered to -8°C at a rate of 0.25°C/min. When the temperature in the chamber was -2°C, test tubes were

maintained at -2°C for 1 h and the leaf discs were sprayed with deionized water to initiate extracellular freezing. Test tubes were maintained at -2 , -4 , -6 or -8°C for 30 min and were allowed to thaw at room temperature for about 1 h. The warming rate was about $0.4^{\circ}\text{C}/\text{min}$. Test tubes in which deionized water (15 mL) was added were stored overnight at room temperature. Then the conductivity of the solution in the test tubes was measured. After heating in boiling water for 20 min, the conductivity was again measured. The degree of electrolyte leakage was calculated as a percentage of conductivity of the solution before heating to that after heating.

5) *Determination of soluble sugars*

Soluble sugar contents were measured by the method previously described¹²). The 2nd leaves were cut from the plants and their midribs were removed. The remainder of the leaf was extracted in 10 volumes of 80% (v/v) ethanol at approx. 75°C for 30 min. After cooling at room temperature, xylose (0.5% of the sample weight) was added as an internal standard, and the sample was homogenized. The homogenate was centrifuged at $1,500 \times g$ for 10 min. The pellet was re-extracted twice in 5 volumes of 80% (v/v) ethanol, the three supernatants were combined and dried in a vacuum centrifuge. The residue was dissolved in 1 mL of distilled water. The sample was passed through a SEP[®] "PAK C18 cartridge (Millipore Corporation, Massachusetts, USA) which had been equilibrated with water, after which 2 mL of distilled water was eluted. An aliquot (20 μL) of the eluate was analyzed by HPLC using an 830[®] RI refractive index detector (JASCO, Tokyo, Japan) and a Shodex SUGAR SP0810 column (Showa Denko Co., Tokyo, Japan). The column temperature was 80°C , and the mobile phase consisted of distilled water at a flow rate of 0.8 mL min^{-1} .

Abstract

Multivariate analysis of mandible measurements was applied to identify and to investigate the genetic relationships between 5 outbred stocks of female mice, Dlv:CD-1, Hg:CD-1, Crj:CD-1, CF-1 and Slc:ddY. (1) Principal component analysis revealed that CF-1 had a relatively large mandible with an obtuse muscular process and a low anterior mandibular body, whereas Hg:CD-1 had a smaller mandible and exhibited intermediate values in terms of muscular process shape and anterior height. Crj:CD-1 showed a moderately large mandible and a higher anterior mandibular body. While the mandibles of Dlv:CD-1 and Slc:ddY were comparatively similar to each other in that they were both medium-sized, the former had an acute muscular process projecting posteriorly whereas the latter had a less prominent process. These morphological relationships between the 5 stocks determined by principal component analysis were generally in agreement with Mahalanobisâ™ distance between stocks based on the same mandible measurements. (2) According to the results of discriminant analysis, the frequency of misclassification was 11.4%, or 9/79 head when actual mandible measurements were used in categorization and 10.1%, or 8/79, when relative values, which exclude the size effect, were used. These data indicate that the genetic constitution of the 3 CD-1 stocks examined in this study differed from one another. (3) Based on dendrograms calculated from actual mandible measurements and relative values, Dlv:CD-1 was more closely related to CF-1 or Slc:ddY, which are derived from mice of other origins, than the CD-1 stocks examined in this study. Thus genetic monitoring seems to be essential for outbred stocks as well as for inbred strains.

Discipline: Animal health / Genetic resources

1...8): [References](#)

Introduction

The CD-1 strain, one of the most useful outbred stocks (closed colonies) of laboratory mice, has been used for various testing conditions including those for drugs and biological products. In Uruguay, CD-1 mice have also been introduced to several research institutions by the Charles River Laboratories (USA) and have been maintained and used for the above-mentioned tests. Since the CD-1 mice were introduced separately into each institute and were maintained independently from generation to generation, it is possible that the genetic constitution of each stock may differ from one another. Therefore, investigations of the genetic relationships between the outbred stocks should be carried out.

For inbred strains of laboratory mice or rats, genetic monitoring such as strain identification and estimation of genetic relationships between strains has mainly been performed by the use of biochemical and immunological marker genes⁷⁾. These methods, however, are not as effective for outbred stocks such as CD-1.

Mandible analysis proposed by Festing¹⁾ is based on the assumption that the shape of the mandible is a heritable trait. This type of analysis is suitable not only for genetic monitoring of inbred strains but also for that of outbred stocks²⁻⁴⁾.

In light of the above-mentioned advantages of mandible analysis, the present study was undertaken to clarify the genetic relationships among several independently maintained CD-1 stocks.

Abstract

The analysis of the resting behavior of domestic animals must include the analysis of eyelid and eyeball movements and bodily motion. We developed an apparatus for measuring the movement of eyelids and eyeballs of domestic animals. The apparatus consists of a charge-coupled device (CCD) camera placed in the eyelid region of a head mask, and an infrared light-emitting diode as a light source. Two types of apparatus have been developed: one, using a wire system and the other, using a measurable telemetry system in an unrestricted state. The weight of the device with the wire system was about 50 g and that with the telemetry system was about 880 g. The operating time of the telemetry system was 24 h or more when nickel-hydrogen was used in the power supply. By using the wire system in calf, the movements of the eyelid and eyeball could be divided into four categories; fully open eyelid movement, half-closed eyelid movement, fully closed eyelid movement and eyeball movement. The results showed that the time of half-closed eyelids and fully closed eyelids while the animal was lying down was longest from

midnight to 7:00 a.m. and eyelids were half-closed or fully closed even during rumination. In the horse, the telemetry system device could be used continuously without discomfort for 24 h. Comparison of the eyelid movement and cortex brain waves, showed that the power spectrum of the cerebral cortex brain waves in an animal lying down with a half-open eyelid mainly consisted of d waves while when the animal was standing with a fully open eyelid, a waves also appeared.

Discipline: Animal industry

Key words: brain waves, behavior analysis

1...8): [References](#)

Introduction

Active movement and resting behavior, or the waking and sleeping behavior, of domestic animals can be distinguished according to changes in bodily motion⁴). However, the analysis of the resting behavior is insufficient when used by itself for the detection of changes in bodily motion. For the purpose of our study, the resting behavior of domestic animals may include any of the following conditions, fully closed eyelid, half-closed eyelid in a state of drowsiness, fully opened eyelid, and eyeball moving with fully opened eyelid in a state of quiescence, which might occur when an animal is lying down or stretched out on its stomach. In addition, resting behavior may also be identified by a half closed-eyelid or a fully closed eyelid while an animal is ruminating. Thus, resting animal's awareness occurs at several different levels. When rest is considered to reflect the actions of the parasympathetic nervous system, it was observed that the resting behavior was closely related to stress. It has also been reported that the difference in the frequency spectrum of brain waves indicates whether the eyes are open or closed because of the relationship between the activity of the eyelid and brain waves resulting from cerebral electrical activity^{7,8}). Therefore, the determination of a resting animal's awareness level is a necessary part of a more complete analysis of a domestic animal, which includes eyelid and eyeball movements and the determination of certain behaviors associated with specific bodily motions. It is possible to determine the level of a resting animal's awareness from its eyelid and eyeball movements. However, there are almost no reports on methods of measuring eyelid and eyeball movements in domestic animals.

Therefore, we developed an eye camera consisting of an ultra-compact CCD camera and infrared light-emitting diodes (LEDs). We installed the camera into the eyelid region of a head mask that was fitted onto domestic animals for measuring the eyeball and eyelid movements. Simultaneously, we developed a telemetry system for tracking the eyelid and eyeball movements. We used this equipment in experiments in which we tracked and measured the eyelid and eyeball movements of a calf. In addition, the experiment involved a comparison between cerebral cortex brain waves and eyelid movement. It is considered that such studies may eventually contribute to the improvement of feeding management in taking account of the welfare of the animal.

Physiological Role of Vitamin K in Fish -Review-

Miho UDAGAWA*

Physiology and Molecular Biology Division, National Research Institute of Fisheries Science

(Fukuura, Kanazawa, Yokohama, 236-8648 Japan)

*Correspondence author: fax +81-45-788-5001, e-mail udagawa@nrifs.affrc.go.jp

Received 27 December 19, accepted 27 January 2000.

Abstract

Basic information on the role of vitamin K in fish was described in relation to dietary intake. Vitamin K in the fish tissues was mainly concentrated in the liver and gonads, with a small amount in muscles. There was a difference in the concentration of vitamin K between demersal and pelagic fish depending on the habitat and between cultured fish and wild fish. The composition and content of vitamin K in the gastrointestinal tract which were very similar to those of the food consumed differed in the tissues, suggesting that all the vitamin K in food was not transferred to the tissues of fish. There was no clear indication that vitamin K deficiency affected the growth rate or mortality in fish, although it was reported that vitamin K deficiency caused anemia, prolonged prothrombin time, histopathological changes and bone abnormalities. Therefore, more studies are required to determine the role of vitamin K in fish.

Discipline: Fisheries

Additional key words: menaquinone, phylloquinone, fish nutrition

1...29): [References](#)

Introduction

Vitamin K was first discovered by Dam³⁾ as a substance playing an important role in the synthesis of blood-clotting factors. Vitamin K is a group name for a series of related compounds that act as cofactor for the microsomal enzyme $\hat{\Gamma}^3$ -glutamylcarboxylase. This enzyme is involved in the post-translational conversion of peptide-bound glutamate residues into $\hat{\Gamma}^3$ -carboxyglutamate (Gla), which occurs in a number of blood coagulation factors and bone proteins^{4,7,27}). Natural forms of vitamin K include phylloquinone (PK) and menaquinone (MK). PK designated as vitamin K₁ occurs abundantly in plant tissues while MK, vitamin K₂, is mainly produced by bacteria. Furthermore, a variety of diseases due to vitamin K deficiency has been reported in mammals. In particular, human infants, a few weeks old, are prone to hemorrhage due to vitamin K deficiency. In addition, the attention has since been increasingly focused on the importance of vitamin K for normal bone development. However, the role of vitamin K in fish has not been well-documented. In the following review, the distribution and absorption of vitamin K in relation to the intake of vitamin K in fish will be outlined.

Derivatives of vitamin K

There are several derivatives of vitamin K (**Fig. 1**) as follows: 1) PK called vitamin K₁, is produced by plants; 2) MK which is synthesized by microorganisms is called vitamin K₂ and has long side-chains arranged in MK-n series. MK-4 consists of short isoprene units and MK-9 is one of the typical long-chain MKs produced by bacteria; 3) Synthetic analogues of menadione (MD) designated as vitamin K₃ have no side-chains, and are utilized for animal and fish commercial diets.

Water-soluble salt of synthetic menadione, menadione sodium bisulfite (MSB) is generally supplemented in the commercial fish diets. Parts of PK, MK and MD are metabolized to MK-4 in the tissues¹³).

Fig.1. Chemical structure of vitamin K

Vitamin K in fish

Tissue distribution of vitamin K in fish varies with the feed habitat, for example, demersal and pelagic fish²²) as well as between cultured and wild fish^{21,23}).

Food habits differ markedly between pelagic fish and demersal fish. Pelagic fish feed on plankton and small fish, while demersal fish feed chiefly on benthos.

Benthos are the organisms which live in the benthic zone of the sea. The PK and MK contents in the pelagic

and demersal fish tissues are illustrated in [Fig. 2](#)²²). None of the samples showed even a trace of MK-9. In mackerel, MK-6 was detected unlike other long-chain MKs. The content of PK was much higher than that of MKs, particularly in the liver where the PK content was as high as 3-4 times that in the heart and kidney. However, only a trace amount of vitamin K was detected in the ordinary and dark muscle tissues. In striking contrast to mackerel, MK-4 appeared to be the major vitamin K in the heart and gonads of saury with a very low level of PK. Furthermore, a negligible amount of vitamin K was present in the liver. The total vitamin K content was, however, much lower than that in mackerel.

In the case of marbled sole, significant amounts of long-chain MKs (MK-6 and 7) were detected together with MK-4 in the heart and kidney. Furthermore, MK-8 was also found in the kidney. On the other hand, in sillago, PK and MK-4 were commonly distributed in various organs, whereas MK-6, 7 and 8 were found only in the liver. In both marbled sole and sillago, the PK level was higher than that of saury on the whole but very much lower than that of mackerel.

In another report, it was stated that the PK contents in the serum, heart, kidney, gonads and liver of wild sardine were much higher than those of cultured sardine, especially in the liver²¹). MK-4 contents in cultured sardine were significantly higher than those of wild sardine in the serum, heart, kidney, gonads

and liver.

In the tissues of wild ayu, PK appeared to be the major form of vitamin K, and MKs were present at very low levels ([Fig. 3](#))²³). Long-chain MKs in different forms were present in the liver, but their quantity was lower than that of PK. Only MK-6 was detected in tissues other than the liver. On the other hand, in the tissues of cultured ayu, the major form of vitamin K was MK-4, while MK-6 was detected only in the heart and kidney. Unlike in the wild ayu, no long-chain MKs were observed in the liver.

JARQ
---- Japan Agricultural Research Quarterly ----

Purpose: Dissemination to overseas countries of up-to -date information on achievements and trends of research activities pertaining to agriculture, forestry and fisheries that are carried out in Japan but would also be relevant to the needs of the respective countries, particularly in the developing regions.

History: *Japan Agricultural Research Quarterly (JARQ)* was established in 1966 by the Agriculture, Forestry and Fisheries Research Council, the Ministry of Agricultural and Forestry. Through the editorial services of the Tropical Agricultural Research Office also established in 1966, such a publication which aimed at introducing the achievement and trends of agricultural research activities in Japan to overseas readers was expected to contribute to the development of agriculture in the countries of the tropical and subtropical regions. In June 1970, the Tropical Agriculture, Forestry and Fisheries Research Council. The publication of *JARQ* was thereafter undertaken by TARC. In October 1993, TRAC was reorganized into the Japan International Research Center for Agricultural Sciences (JIRCAS) with the creation of the Fisheries Division. As a result, *JARQ* also covers the field of fisheries research.

Publication Information: *Japan Agricultural Research Quarterly (JARQ)* is published four times a year, by the Japan International Research Center for Agricultural Sciences, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki, 305-8686 Japan. The present circulation of each issue numbers 2,100, of which nearly two thirds are sent to more than 90 countries mostly in developing regions. Subscription is limited to institutions only, free of charge, and subscription inquiry should be directed to the Editorial Secretary of *JARQ* .

Editorial Policy: The Editorial Board serves as a screening committee. The Board members nominate candidates for the submission of papers for the forthcoming issues, and the decision is finalized during the Board meeting. Contributed papers are divided into two categories: **research articles** which summarize the findings of recent research activities of the author which may have been published elsewhere (but include also original contributions), and **research reviews** which review the objectives, procedures, and achievements of research activities by Japanese researchers on a specified research topic.

Editorial Inquiries: Send questions on editorial policy and procedure to the Editorial Secretary. Advice and comments are also welcome.

Abstract

In this manuscript the current status of direct visualization of gene location on chromosomes was reviewed by considering 5 aspects as follows: principle of *in situ* hybridization (ISH) method, historical perspective of mapping genes by *in situ* hybridization, improvement in the sensitivity of fluorescence *in situ* hybridization (FISH), visualization of location of useful genes on chromosomes, and prospects for visualization of useful genes.

Discipline: Experimental apparatus and method/Biotechnology/Plant breeding

Additional key words: physical mapping, rice, FISH

1...21): [References](#)

Principle of *in situ* hybridization (ISH) method

ISH is a method for the visualization of the location of nucleotide sequences on chromosomes, nuclei, and even in the tissues. The principle of the method involves the hybridization of labeled nucleotide sequences, or probes, directly to DNAs or RNAs with the complementary sequences in chromosomes, nuclei or tissues. The location of the labeled probes hybridized to the complementary DNA sequences in chromosomes, for example, is detected by fluorochrome-labeled antibodies that recognize the label of the probes under a fluorescence microscope. The ISH in which fluorescence is used to detect probes is referred to as "fluorescence *in situ* hybridization (FISH)".

Historical perspective of mapping genes by ISH in rice²⁾

In 1910, the rice chromosome number was determined to be $2n=24$ by Kuwada¹⁴⁾. It took, however, more than 80 years until all the rice chromosomes were identified objectively and a rice chromosome map was developed by Fukui and Iijima³⁾ using imaging methods¹⁾. The long time interval from the determination of the rice chromosome number to the identification of individual chromosomes can be ascribed to the fact that rice has the smallest genome size of 430 Mb, thus the smallest chromosome size, among those of the main cereals.

Attempts to visualize specific DNA sequences directly on rice chromosomes have been pursued for years without the use of an objective method for identifying rice chromosomes nor a chromosome map at the beginning of the 1980s. Fukui et al.⁶⁾ succeeded in physically locating 18S-5.8S-25S ribosomal RNA genes (45S rDNA) loci at the end of a pair of chromosomes with ¹²⁵Iodine-labeled ribosomal RNA probes. This was the first reproducible result of *in situ* hybridization (ISH) using repetitive sequences in rice (Fig. 1a). The location of 45S rDNA loci in rice was detected by non-radioactive (biotin-labeled) probes by coloration using Japonica rice in 1991⁸⁾ (Fig. 1b). FISH was successfully achieved in 1992 for the first time and variability in the number of 45S rDNA loci was revealed among the rice species⁵⁾ (Fig. 1c). Multicolor FISH using different fluorescent colors simultaneously for detecting 5S rDNA and 45S rDNA was developed in 1994 soon after the successful development of FISH. Presently the multicolor FISH is a common method widely utilized to locate different nucleotide sequences simultaneously, such as telomere sequences (green fluorescence) and rice A genome specific tandem repeat sequence, TrsA (red fluorescence) (Fig. 1d)¹⁸⁾.

Fig. 1. Recent advances in *in situ* hybridization (ISH) for the past 15 years

a: Detection of ribosomal RNA gene (rDNA) locus with radioactive ribosomal RNA.

b: Detection of rDNA by a non-RI labeling method.

c: Detection of rDNA loci in Indica rice by FISH.

d: Detection of multi-color fluorescence from different probes (telomere, green and TrsA, red) simultaneously.

All these efforts have enabled the detection of highly repetitive sequences on rice chromosomes reproducibly and efficiently. The development of both the chromosome map and the FISH method have contributed significantly to the physical mapping of DNA sequences in rice.

Improvement in the sensitivity of FISH

Once reproducible detection of the repetitive sequences on rice chromosomes using the FISH method was obtained in the early 1990s, the main objective of FISH was to enhance the detection sensitivity of the fluorescent signals. Even though the visual detection of repetitive sequences on rice chromosomes had become routine work, detection of a unique sequence was considered to be difficult because of the smaller sizes of nucleotide sequences.

[Fig. 2a](#) shows clones differing in sizes, which were used as probes in the FISH experiments to evaluate the sensitivity of detection of fluorescent signals on rice chromosomes. In the clones with insert sizes ranging from 399 kb to around 1 kb, attempts were made to determine whether their fluorescence could be visualized on rice chromosomes after FISH¹⁹). The largest clones were those of yeast artificial chromosomes (YAC) with 399 and 340 kb of inserted rice genomic DNAs. A bacterial artificial chromosome (BAC) with a 180 kb insert, and a cosmid clone with a 35 kb insert were also tested using the FISH method. The smallest clones were molecular markers cloned into plasmid vectors with around 1 kb inserts.

To visualize these clones, both the experimental procedures and the detection equipment were improved. First, the detection sensitivity of faint fluorescent signals from the probe DNAs was enhanced by the introduction of a cooled CCD camera. The camera was directly mounted on top of a microscope. Second, in the FISH protocol, a longer hybridization period between the labeled probes and chromosomal DNAs was used. The longer hybridization period ensured hybridization between the probes and complementary DNA in the chromosomes. All the clones from nearly 400 to 1 kb were successfully visualized by the improved FISH method. As a result, the detection sensitivity of FISH was enhanced by 400 times throughout the experiments¹⁹) ([Fig. 2b](#)).

Visualization of location of useful genes on plant chromosomes

1) Mapping of a resistance gene to gall midge, *Gm2*

[Fig. 3](#) shows the results of the improved FISH method using different DNA clones as probes. All the clones contained useful genes such as disease-resistance genes. The result of FISH using a YAC clone (YAC5212) with a 340 kb rice genomic DNA was presented, because YAC5212 is flanking a gall midge (*Orseolia oryzae*) resistance gene, *Gm2*. Gall midge is a major dipteran insect pest of rice in India, China, Africa and Southeast Asia and its resistance genes are now being cloned. Fig. 3a shows the YAC signals on the pair of rice chromosome 4²¹). Fluorescent signals are detected in the interstitial region of long arms indicating the physical location of *Gm2*. The position of *Gm2* was also confirmed by the FISH using 2 RFLP markers genetically linked to *Gm2*.

2) Mapping of a resistance gene to leaf blast, *Pi-b*

The physical location of the resistance gene to rice leaf blast was then examined. Rice blast caused by *Pyricularia oryzae* (*Magnaporthe grisea* (Hebert) Barr) is the most important fungal disease of rice. The resistance gene, *Pi-b* was cloned into a BAC clone (BAC123) which has a 180 kb insert of rice genomic DNA. Because the location of the genomic DNA on rice chromosomes was unknown, the FISH method was employed to physically determine the actual location of the BAC clone or the position of the gene,

Pi-b.

Fig. 3b shows the signals from the BAC clone at the end of the long arm of rice chromosome 2¹⁷). Haploid rice plant derived by anther culture was used for chromosome preparations. Thus one single-tagged chromosome shows clear doublet signals which are essential for the discrimination between genuine signals from noises. Thus the chromosomal location of the *Pi-b* gene was determined at 2p1.2 according to the rice chromosome map²).

We further analyzed the BAC signals on the ten chromatids of rice chromosome 2 by the imaging method to determine the precise location of the gene on the chromosomes. As a result, the *Pi-b* gene was located at the position of 96.16 ± 0.91 from the end of the short arm when the total chromosome length of chromosome 2 was 100.00¹⁷). This method was also employed to determine the 5S ribosomal RNA genes on rice chromosomes. The 5S rDNA locus was allocated to the position of 39.3 ± 2.6 on chromosome 11 (11p1.1) from the end of the short arm¹⁰).

3) Mapping of a resistance gene to bacterial blight, *Xa-21*

The smaller rice genomic DNA of 35 kb nucleotide sequences cloned into a cosmid vector, was examined. The clone contained a resistance gene, *Xa-21* to the rice disease, bacterial leaf blight (*Xanthomonas oryzae*). Bacterial leaf blight is also a major rice disease widely distributed in Asian countries. The same improved FISH method was used to locate *Xa-21* on the rice chromosome. In this case, since we used the Indica rice variety IR36, a diploid plant material, the signals were observed in a pair of rice chromosomes.

Fig. 3c shows the fluorescent signals from a pair of rice chromosomes. By using the uneven condensation pattern, the rice chromosomes were identified as rice chromosome 11 and the doublet signals were clearly observed in the interstitial region on the long arm (11q1.3)¹⁹).

4) Mapping of the molecular marker, *Xnp 247*

Molecular markers are very useful for the construction of linkage maps and more than 2,000 molecular markers were developed to construct the rice linkage map¹¹). The size of the molecular markers varies and the size of molecular markers, such as RFLP markers is often less than a few kilo basepairs. The RFLP markers played an important role in the construction of many linkage maps at the beginning of genome mapping. We applied the FISH method to locate a RFLP marker (*Xnp 247*) with 1.29 kb of rice genomic DNA.

Fig. 3d shows the signal position from the RFLP marker. The doublet signals were clearly detected at the end of rice chromosome 4 (4q2.1)¹⁹). The results indicate that even a nucleotide sequence with about 1 kb could be successfully detected by the improved FISH method. It also means that practically all the functional genes could be directly detected on the chromosomes by the improved FISH method¹⁷). Self-incompatibility-related genes of *Brassica* spp. have already been mapped by using FISH^{9,11}).

The physical mapping of the nucleotide sequences also reveals a discrepancy between the physical length of the chromosomes and the genetic distance calculated by the recombination values. [Fig. 4](#) shows 2 examples of the discrepancy detected in rice¹⁹) and barley⁴). Comparison of the chromosomal location of *Xa-21* determined by FISH and linkage analyses revealed a remarkable discrepancy between the total length in the two maps. The linkage map of chromosome 11 showed a much longer length when the chromosome map and the linkage map were aligned by the two landmarks i.e. the centromere and the

position of *Xa-21* now determined¹⁹⁾ (Fig. 4a). As demonstrated in the barley chromosome map that was developed by imaging methods⁴⁾ and linkage map, the length of the satellite part, that is the terminal region of the chromosome 6 was markedly over-estimated in the linkage map. The discrepancy was again confirmed by a detailed comparison between the chromosome and dense linkage maps in barley¹²⁾. The over-estimation of the terminal length in the linkage map compared to the actual length of barley chromosomes determined by FISH and/or imaging methods suggests that recombination occurs frequently only in the terminal region of the barley chromosomes.

Although the discrepancy between the overall length of the chromosome and linkage maps was demonstrated in rice chromosome 11 (Fig. 4a), it remains to be determined whether the frequent recombination observed only in the terminal chromosomal regions could also occur in rice and other plant species as a general tendency.

Prospects for visualization of useful genes

Visualization or mapping of useful genes is important in genetic analyses. Since, not all the plants have as dense linkage maps as rice¹³⁾ and it is usually time-consuming and laborious to construct a dense linkage map, FISH is a useful and efficient alternative method in many plant species. FISH could be applied for the mapping of genes and clones regardless of plant species.

When molecular markers that sandwich a certain character can be found, the distance between the markers could be obtained by using FISH on chromosomes and extended DNA fibers (EDFs)²⁰⁾. Moreover, it may be possible to clone the gene by a FISH-oriented method and not by an ordinary map-based cloning method. First, FISH using the linked marker(s) could enable to determine the chromosomal position of the target gene. Then the laser dissection⁷⁾ or the ordinary dissection method could be applied to collect the chromosomal fragments with the signals. Finally, clones in the chromosomal regions could be obtained by the use of degenerated oligo-primer (DOP)-PCR method using the dissected chromosomal fragments as the templates. Direct amplification of ribosomal RNA genes¹⁶⁾ and \pm -amylase genes¹⁵⁾ by using the laser-dissection method has been successful in some cases.

In conclusion, the visualization of useful genes is important not only to determine their actual location on the chromosomes, but also it may be possible to clone the genes in conjunction with the chromosome dissection method even in plants with limited genome information. It is anticipated that the visualization method represented by FISH will be more useful when it is combined with new methods to manipulate chromosomes and even DNA fibers.

Abstract

Transgenic taro (*Colocasia esculenta* Schott) plants were obtained by high-velocity particle bombardment. The plasmid pREXHGUS, carrying the hygromycin resistance gene, was used as a selection marker. Highly regenerative taro callus was obtained from the apical meristem, and maintained in liquid culture. The callus was chopped into small fragments with a forceps, then transformed and selected on LS medium containing BA, NAA and hygromycin. Since the transformed calli obtained showed vigorous growth on LS-BN medium with 20 mg/L hygromycin, this concentration was considered to be suitable for the selection of transgenic taro. The transformants were confirmed by amplification of the GUS gene, and Southern hybridization. The expression of the foreign gene was demonstrated by the GUS activity.

Discipline: Plant breeding

Additional key words: callus, hygromycin-resistance gene, GUS gene

Introduction

Taro originated in India and adjacent areas of Southeast Asia, and is now widely cultivated in Asia and Oceania¹⁸). In some Oceanian countries, this crop is one of the main sources of starchy food. Since taro propagates mainly with tubers, the occurrence of virus diseases is one of the main problems affecting its cultivation, along with taro leaf blight in tropical countries¹²). Once a clone is infected with virus, its productivity may be reduced. It is difficult to remove the virus under natural conditions of cultivation. Although shoot tip culture *in vitro* has been used to remove virus particles, the problem of reinfection with virus still remains. Recent biotechnological research has revealed that transformation with the coat protein gene or some other viral genes, confers resistance to virus diseases^{1,4}). The objective of the present study was to breed a virus-resistant cultivar of taro. Since taro is a monocotyledon, *Agrobacterium*-mediated transformation is considered to be difficult. Although protoplast culture of taro has been reported¹³), this technique is very laborious and it is difficult to obtain regenerated plants, in addition somaclonal variation may occur more frequently. Therefore, protoplast culture is not suitable for direct transformation of taro, and instead particle bombardment is most appropriate for the transformation of taro. Few studies on the transformation of taro have been carried out. Here we report the transformation of taro using a particle bombardment system.

Materials and methods

1) Plant material

A triploid cultivar of taro (*Colocasia esculenta* Schott), 'Eguimo', was used in the present study. Eguimo is one of the major cultivars used in Japan, and callus induction and shoot regeneration of this cultivar have been developed⁶⁾.

2) Plasmid

A plasmid, pREXHGUS, was constructed based on the pUC18 plasmid ([Fig. 1](#)). A selection marker, the hygromycin phosphotransferase (hpt) gene, was driven by a 35S promoter harboring one copy of the enhancer, and a beta-glucuronidase (GUS) gene containing the phaseolin intron 1 gene was driven by the 35S promoter containing 7 copies of the cauliflower mosaic virus (CaMV) 35S enhancer region¹¹⁾.

3) Induction and maintenance of callus

Linsmaier and Skoog⁹⁾ medium (LS medium) supplemented with 2 mg/L benzyladenine, 1 mg/L naphthaleneacetic acid and 3% sucrose was used as a basic medium (LS-BN medium). The shoot tips (0.5 to 1 mm) were removed from surface-sterile tubers and planted on LS-BN medium solidified with 2% gellan gum, then cultured at 25°C (16 h photoperiod, 36 $\frac{1}{4}$ m² sec⁻¹) to induce callus. The induced calli were maintained on the solidified medium by subculturing every 2 or 3 weeks. As a target for particle bombardment, the calli were chopped into small pieces (2 to 3 mm in diameter) with a forceps, and cultured in liquid LS-BN medium with rotary shaking at 100 rpm at 25°C. These calli were maintained by weekly chopping and subculture.

4) Particle bombardment

The calli (ca. 2.0 g) were placed on a sterile filter paper (70 mm in diameter). Then, the filter paper was placed on a 9 cm petri dish filled with solid LS-BN medium and cultured at 25°C for 2~24 h.

Biolistic PDS-1000/He (Bio-Rad) was used. Before the bombardment, the pressure in the chamber was reduced to 660 mm Hg. Gold (1.6 μ m in diameter) or tungsten (1.1 $\frac{1}{4}$ μ m in diameter) particles were coated onto the plasmids as previously described⁷⁾, then delivered from a distance of 9 cm to the taro calli on a filter paper at a pressure of 1,100 psi.

A total of 96 runs were conducted.

5) Optimization of culture duration and hygromycin concentration

The calli were bombarded at 0, 4, 6 and 8 days after chopping. The bombardment procedure was the same as that described above. After 48 h of bombardment, GUS activity was examined as described by Kosugi et al.⁸⁾ by counting the number of blue spots. This experiment was repeated twice. The data points were subjected to logarithmic transformation, then analyzed statistically.

For optimization of the hygromycin concentration, the calli (120 to 195) were placed on hormone-free LS medium and LS-BN medium containing 0, 5, 10, 20 and 40 mg/L hygromycin. After 40 days of culture, callus survival was examined. Then, surviving calli were subcultured onto the same medium containing 10 mg/L hygromycin, and after 40 days of culture the number of surviving calli were counted.

6) Maintenance and selection of transformants

After the bombardment, the calli were cultured for 2 days on the same filter paper at 25°C. The treated

calli were then transferred to liquid LS-BN medium supplemented with 20 mg/L hygromycin (Hyg), then cultured for 5 days with rotary shaking at 100 rpm. After 5 days of shaking culture, the calli were transferred to solid LS-BN medium with 20 mg/L hygromycin, then cultured at 25°C under a 16-d photoperiod. Resulting green calli were transplanted onto solid LS-BN medium with 10 mg/L hygromycin for 30 days, then on hormone-free LS medium supplemented with 5, 10 and 20 mg/L hygromycin for induction of plantlets.

The flow chart of taro transformation is shown in [Fig. 2](#). Selected transformed plantlets and non-transformed control plants were used for GUS analysis.

7) PCR and Southern blot analysis

For PCR amplification, DNA was isolated from fresh leaf tissue according to the method of Liu et al.¹⁰. The presence of the transferred gene was assayed by PCR using oligonucleotides specific for the GUS genes. The upstream and downstream primers employed were (5'-ATGTTACGTCCTGTAGAAAC-3') and (5'-GTCCAGTTGCAACCACCTGT-3'), respectively. For Southern blot analysis, genomic DNA was isolated from fresh leaf tissue as previously described¹⁴, digested with *Bam*HI, *Eco*RI, *Hind*III, and *Pst*I, respectively, then blotted onto a nylon membrane. Plasmid DNA was labeled with digoxigenin using a DIG-DNA labeling kit (Boehringer Mannheim) then used as a probe. Hybridization and detection were performed according to the manufacturer's protocol.

Results

1. Effect of culture duration after callus chopping

Since taro calli grow as a mass, they need to be chopped into small pieces for efficient delivery of the particles. The effect of the culture duration after callus chopping was examined ([Table 1](#)). Bombardment just after chopping resulted in rather poor transient expression of the GUS gene. However, the expression ability recovered almost fully after 4 days of culture (Fig. 3a). Therefore, calli after 4~8 days of culture were used subsequently.

2) Effect of antibiotic concentration on callus growth

Effects of various concentrations of hygromycin in LS medium on callus growth were examined ([Table 2](#)). The growth of untransformed callus was effectively suppressed by 20 mg/L hygromycin. After 40 days, surviving calli on the media containing 5 or 10 mg/L hygromycin were further cultured on a new medium containing 10 mg/L hygromycin, for an additional 40 days. None of the calli survived.

3) Callus growth after bombardment

Most of the calli on the solid LS-BN medium with 20 mg/L hygromycin turned dark brown 30 to 60 days after bombardment, then died. However, a small number of yellowish to greenish calli were observed among the dark brown calli (Fig. 3b). These calli were transplanted onto hormone-free LS medium with 10 mg/L hygromycin to induce plantlets (Fig. 3c). Antibiotic resistance of the regenerated plants was examined on LS medium supplemented with 5, 10 and 20 mg/L hygromycin. Some plants did not grow, or wilted, on the medium containing 10 mg/L hygromycin (Fig. 3d). Others showed normal and rapid growth on the same medium. Two of these plants were propagated vegetatively.

4) GUS and DNA analysis

The plantlets were stained with X-gluc solution, and the young leaves and tracheal tissue of roots showed a blue color (Fig. 3e). The genomic DNA was

Results

extracted from the plants showing normal growth on the medium containing hygromycin. The presence of the introduced gene was examined by PCR. A 650-bp band was observed in these plants after gel electrophoresis. A band of the same size was also observed when the original pREXHGUS plasmid was used as a template ([Fig. 4](#)). The presence of the foreign gene was further examined by Southern blot analysis. The DNA was digested with restriction enzymes, separated by gel electrophoresis, then blotted onto a nylon membrane, probed with the digoxigenin-labeled pREXHGUS. The hygromycin-resistant plants showed positive signals while the non-transformed controls did not show any bands ([Fig. 5](#)).

Discussion

1) Regeneration system for taro

The system used in the present study was originally developed by Karube et al.⁶⁾ using a triploid cultivar, Eguimo. The calli of Eguimo showed a very high regeneration ability in this system. Moreover, the calli were easily maintained on solid or liquid LS-BN medium. They readily differentiated plantlets on the hormone-free medium, and were considered to be a suitable target for transformation. A similar regeneration system can be established in other triploid cultivars. However, taro shows a wide range of genetic diversity^{5,17)}, and cultivars are classified into 2 varieties: var. *antiquorum* and var. *esculenta*. Cultivars grown in tropical areas are diploid and classified into var. *esculenta*¹⁸⁾. Using a cultivar from the Solomon Islands, a regeneration system for taro has also been reported^{15,16,21,22)}. Although a detailed description of the cultivar was not given, cultivars from the Solomon Islands should be diploid and classified into var. *esculenta*³⁾. With minor modifications, the transformation system described here is considered to be suitable for other cultivars including diploid ones. To maintain a fine suspension of callus, the callus should be chopped when subcultured. However, the results of bombardment just after chopping were not satisfactory, and therefore the calli may have been under some stress, inducing a low transformation competence.

2) Selection of taro transformants

Choice of a selection marker gene and the concentration of selective agents are key factors for successful transformation. Kanamycin is widely used for the transformation of various plant species. However, Wilmlink and Dons²⁰⁾ have reported that hygromycin is more suitable for the selection of monocot transformants. In wheat, rice and barley, hygromycin is commonly used as a selection marker for transformants. Moreover, in our preliminary experiment, taro calli survived on a medium containing up to 200 mg/L kanamycin (data not shown). Therefore, in the present study, we tried to select taro transformants using hygromycin. This antibiotic induced a clear suppression of callus growth at a concentration of 20 mg/L (Table 2). Therefore, selection of transformed calli with 20 mg/L hygromycin is considered to be optimal.

Some of the untransformed calli survived during 40 days of culture, but finally died when transplanted onto new medium containing 10 mg/L hygromycin. To obtain transformants rapidly, regeneration medium containing 10 mg/L hygromycin was used. Since some of the untransformed plants may possibly survive under these conditions, regenerated taro plants showing rapid growth and budding from the base on medium containing 10 mg/L hygromycin should be selected as transformants.

Efficiency of transformation is still rather low: a total of 2 independent transformants were obtained from 96 runs. Each run involved one petri dish containing 2.0 g of calli. The number of blue spots also varied considerably in each experiment, and this may have been due to the physiological status of the calli used. More detailed studies are required to obtain more efficient and stable conditions for transformation.

3) Breeding of disease-resistant taro cultivars

Since taro is widely cultivated in Asia and Oceania, the present study has shown that this technique is applicable to the breeding of taro. The occurrence of virus diseases is one of the main problems for taro growers. For example, dasheen mosaic virus and cucumber mosaic virus have been detected in taro

cultivated in Japan^{12,19}). Both viruses have been well studied at the molecular biological level. Transformation of these viruses with coat protein (CP) genes may enable to confer virus resistance to taro. Another possibility is to breed taro varieties resistant to leaf blight, which is caused by a fungus, *Phytophthora colocasiae*, and is a serious problem in tropical areas^{12,18}). Transformation with chitinase genes has been reported to produce plants resistant to fungal diseases²). This technique may be useful for breeding disease- resistant taro varieties.

Abstract

Recent advances in research on the life history, natural enemies, sex attractant, and practical control of the citrus leafminer (CLM) in Japan are described. Adult CLM overwinters within canopies of the citrus trees in the warmer districts of the citrus belt where the overwintering females begin to oviposit in mid-March. The moth passes 9 to 10 and 5 generations per year in the southwestern and northeastern parts of the citrus belt, respectively. Developmental zero and effective heat units for development from egg to adult emergence are 12.1°C and 206 degreedays, respectively. Eighty per cent or more larvae were killed by parasitoids and unknown factors before pupation during the summer-autumn seasons. Dominant parasitoids are *Sympiesis striatipes* in mainland-Japan and *Cirrospilus ingenuus* and *Citrostichus phyllocnistoides* in the Southwestern Islands. Biological control of CLM by native parasitoids is not sufficiently effective in Japan because *Ageniaspis citricola*, a most effective biological control agent in tropical Asia, has not been detected in Japan. A sex attractant, (Z,Z)-7,11-hexadecadienal showed a high activity for male moths in Japan, but was ineffective for those in foreign countries. The sex attractant appeared to be useful for the forecasting of seasonal occurrence, and control measures by using this substance should be initiated. Insecticides are commonly used for the control of CLM on young trees. Nicotine sulfate, IGRs, imidacloprid, alanycarb and pyrethroids are sprayed 4 to 5 times at 5- to 10-day intervals during the flush developing period. Recently, CLM has become resistant to pyrethroids in some districts of Kyushu. To avoid the spread of insecticide resistance of CLM, an attempt was made to use the effective parasitoid, *A. citricola*, through introduction from Taiwan and Thailand to Japan.

Discipline: Insect pest

Additional key words: parasitoid, sex attractant

Introduction

The citrus leafminer, *Phyllocnistis citrella* Stainton (CLM), is a serious pest in nurseries and on top-grafting trees of citrus, and also on citrus growing in plastic greenhouses in Japan.

CLM originated in tropical Asia from Afghanistan to China, and was introduced to Japan in the 1600s⁶⁾. CLM had been spreading slowly over adjacent areas, and became known also in the temperate zone of Asia, Australia, Pacific Islands, South Africa (miss-identification?) and eastern part of Africa by the beginning of the 1980s. Then its distribution spread rapidly: it was confirmed in southern Florida in late May of 1993^{6,7)}, in Florida, most of the Caribbean region, the southern part of the USA^{2,8)} and the northern part of South America by September in 1994, and lastly in Uruguay in January, 1997. It also first occurred simultaneously on the Mediterranean coast of Europe¹¹⁾, in the Middle East¹⁹⁾, North Africa¹¹⁾ and Reunion Island¹³⁾ in 1993 to 1995.

This paper describes recent contributions to studies on CLM biology and current status of control of CLM in Japan.

Outline of citriculture in Japan

The citrus cultivation belt of Japan stretches along the southwestern coast of Honshu, Shikoku and Kyushu, extending from 35° to 31°N ([Fig. 1](#)). It belongs to an area with relatively cool winter temperatures among the citrus cultivation zones of the world. Mean air temperature in a year and in January ranges from 14 to 17°C and 4 to 7°C, respectively, and the daily minimum air temperature sometimes falls below 0°C in mid-winter. Small-scale citrus orchards are also dispersed about all over the Southwestern Islands.

Among the citrus cultivars planted in Japan, about 65% consist of Satsuma mandarin, followed by Iyo (10%), Natsudaidai (5%) and Hassaku (4%).

About 77% of the citrus orchards are located on slopes with an inclination above 5° for the following reasons: plains are used for rice paddy fields, citrus trees on plains are often damaged owing to freezing night temperatures in winter, and high quality fruits are obtained usually from sloping orchards with good drainage.

The citrus trees have generally 3 flush seasons; the spring flush from early April to early May, the summer flush from June to August and the autumn flush from early to late September. Because of the low winter temperature, there are no young leaves during more than 5 months from October to early March. The spring shoots are very important as fruit-bearing branches of the next year, while the summer and autumn shoots are less important or often useless in mature trees. Therefore, the optimum method of tree management is to suppress the growth of the new shoots from summer to autumn; or, secondarily, to cut off the new shoots emerging during these seasons.

On the other hand, in young or top-grafting trees, the summer shoots are necessary to build up the tree shape. In addition, in plastic greenhouses, the summer shoots are also useful as fruit-bearing twigs of the next year. The summer and autumn shoots must be healthy for cultivation, and not damaged by pests

such as CLM.

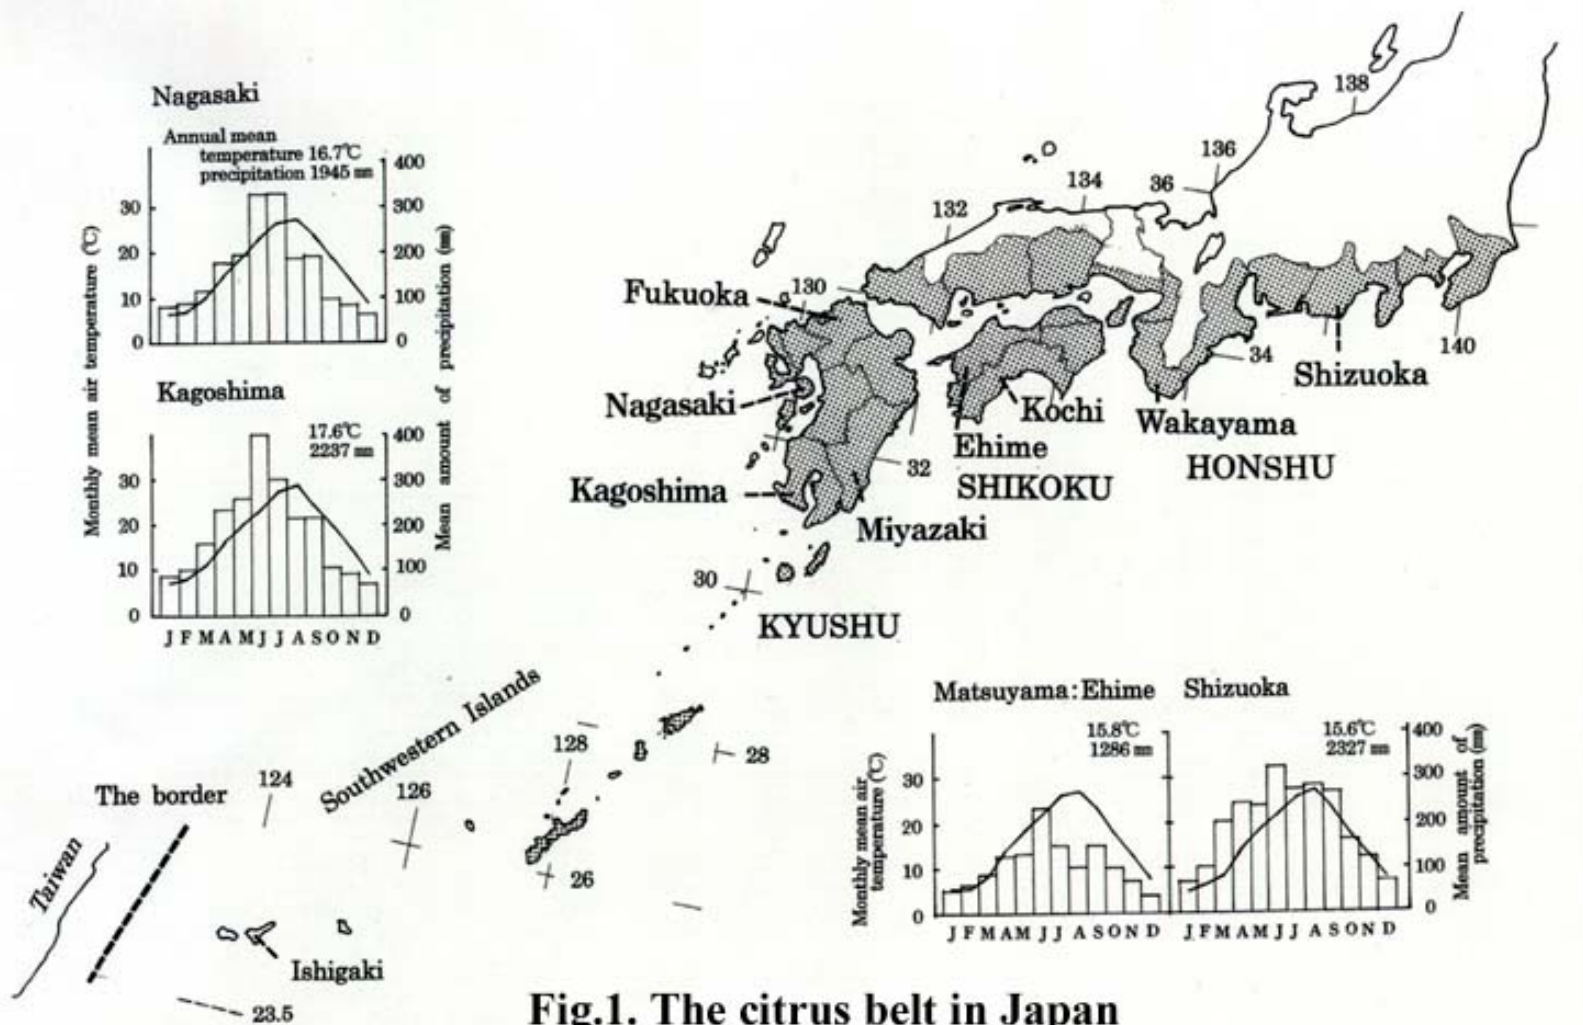

Fig.1. The citrus belt in Japan

BACK

Life history of CLM

Yamamoto^{20,21}) first observed that the adult of CLM overwintered within canopies of citrus trees in Miyazaki Prefecture in the southern part of Kyushu. Thereafter, overwintering adults were observed in several warmer districts of the citrus belt such as Kagoshima, Nagasaki (Kyushu), Kochi (Shikoku) and Wakayama (Honshu), though their presence has not been confirmed in some orchards located in rather cool districts of the belt. For example, based on observations made in 1992-1995 in Shimizu (Shizuoka Prefecture: near the northeastern end of the belt), mines formed by the 1st-generation larvae were found in 1992, 1994 and 1995, but not in 1993. These results suggest that the density of the 1st generation varies among years and that CLM probably does not always overwinter every year in Shimizu.

Key factors for the fluctuations in the density of overwintering CLM adults have not been clarified, but it is assumed that the population density before winter and temperatures during winter are important. A small amount of flushes and/or too early flushing in autumn tend to reduce the number of overwintering adults. Low temperatures during winter also appear to be harmful to CLM. Winter diapause of CLM has not been confirmed. Because the ovaries of female moths emerging in autumn are absorbed while exposed to low temperatures before winter⁵), CLM females seem to be in diapause. On the contrary, because male moths are sexually active during winter as described later, CLM males do not appear to have a winter diapause.

Most adults emerging in autumn seem to die during the winter, because their density in spring is very low even in the warmer districts of southern Kyushu where the moths constantly overwinter every year. In rather cool regions such as Fukuoka and Ehime, adults of CLM often occur from June corresponding to the 2nd-generation flight season in the overwintering districts. It is suggested that short distance migration or movement of adult moths occurs from the overwintering sites to northern and non-overwintering parts of the belt during the 1st flight season every year. It was confirmed that the overwintering female moths started to oviposit from mid-March on the sprouts of cultivars with early germination such as oranges²¹) and Ponkan.

Based on observations using traps baited with sex attractant in Kuchinotsu (Nagasaki Prefecture), the emergence of the 1st generation seemed to start from early to mid-May¹⁵). Developmental zero and effective heat units for the development of CLM were estimated at 12.1°C and 238 degree-days respectively, by Yamamoto²³). However, the latter value was rectified to 206 degree-days by Ujiye¹⁵) based on the results of further tests. Using these values, CLM was estimated to have 7 to 8 complete generations per year in Kuchinotsu¹⁵). It was also estimated based on field population trends that CLM passed 9 to 10 generations per year in Miyazaki²¹), 7 to 8 in Kochi⁹) and 7 in Wakayama¹⁰). In these districts, the presence of overwintering adults of CLM was confirmed. On the other hand, Yoshida and Takei²⁵) observed 5 generations in Shizuoka, where the winter conditions are sometimes too severe for adults to overwinter as mentioned above.

Sex ratio of CLM was about 1:1. A female moth mated on the early morning of the day after emergence²²), and laid 55 to 133 eggs during her life span²¹).

Eggs of CLM are laid singly on both the upper and lower surfaces of a citrus leaf, sometimes also on green shoots and seldom on young fruits. Oviposition occurs on leaves more than 5 mm in length. Eggs are seldom laid on hardened leaves; if eggs were deposited on such leaves, hatching larvae would die without mining within the leaves.

The larvae have 4 instars; the 1st to the 3rd instar larvae are sap-feeders, and the 4th is a spinning larva which can not feed on the leaf epidermis due to the degeneration of the mouth parts. The sap-feeder makes a serpentine mine in which it feeds within the epidermis leaving only the cuticular layer. It finally reaches the leaf margin where it molts to a spinning larva after enlarging the terminal part of the mine (Figs. 2, 3). The spinning larva makes a pupal cell by bending the leaf edge and pupates inside¹⁴).

Natural enemies

As shown in Table 1, 24 species of parasitoids emerged from the mines of CLM collected from about 50 locations all over Japan¹⁷⁾. Among them, *Sympiesis striatipes* and *Quadrastichus* sp. were the dominant species in many citrus orchards. *Cirrospilus phyllocnistis*, *Chrysocharis pentheus* and *Zaommomentedon brevipetiolatus* were also major parasitoids in some orchards of the mainland. *Citrostichus phyllocnistoides* and *Cirrospilus ingenuus* were the dominant or major species in the Southwestern Islands in the subtropical region. During the larval stages of the summer generations, 80% or more miners were killed by parasitoids and unknown factors. Most of the parasitoids attacked mainly the late 3rd to the 4th instar larvae when the host mines were fully developed with a certain amount of injury¹⁶⁾. Heavily infested leaves curl and fall off the tree. Citrus canker, *Xanthomonas campestris* pv. *citri* (Hasse) Dye, can easily invade from the cuticle-removed mine traces to internal tissues of the leaf. For these reasons, in spite of the high parasitism rates, biological control of CLM by the native parasitoid complex seems to be difficult in Japan.

In Taiwan and Thailand, the polyembryonic encyrtid, *Ageniaspis citricola* was recognized as the most effective biological control agent of CLM^{17,18)}. Because *A. citricola* does not occur in Japan, attempts were made to introduce it from Thailand and Taiwan in the summer of 1995. Although the attempt failed because of the death of the wasps during transport, further efforts should be made in future.

Although larvae and pupae were found to be killed by unknown predators, the predator species and their effects have not been identified.

Sex attractant

Ando et al.¹⁾ confirmed that (Z,Z)-7,11-hexadecadienal strongly attracted male CLM moths in the field. In a trap baited with a rubber septum containing 1 mg of the substance, the number of male moths caught per day was 30 to 90 times higher than that in a trap with a virgin female, and this level of attracting ability was maintained for more than 2 months. Male moths were caught not only in the traps placed in the citrus orchard, but also in those placed in a wood located at a distance of 200 m or more from the nearest citrus groves¹⁵⁾. Males were attracted to the sex attractant mainly from May to November, and a small number of males were also caught on warm and windless days even in the winter season. Based on these results, it was confirmed that the sex attractant was useful for forecasting the CLM seasonal occurrence.

The attracting ability of the substance to male moths was evaluated throughout Japan and in some areas in foreign countries in which CLM occurred. The male moths were caught in traps placed in the citrus-growing regions from Shizuoka to Ishigaki Island in Japan. A small number of CLM moths were also caught in traps set in Nepal. However, in other countries such as Thailand, Taiwan, Turkey, China, Egypt, Spain, Reunion Island and Uruguay, males were not attracted by this substance.

Control

As stated above, since the spring population density of CLM is very low, it is not necessary to control CLM before late June in most parts of the citrus belt in Japan.

On the other hand, it is so important to protect the new shoots of the young or top-grafting citrus trees from the infestation of the CLM summer generations, that insecticides such as nicotine sulfate, IGRs, imidacloprid, alanycarb and pyrethroids need to be sprayed. These were applied 4 to 6 times at several day intervals from the beginning of germination to the end of shoot growth. As a rule, nicotine sulfate, IGRs such as diflubenzuron and tflubenzuron, and pyrethroids and imidacloprid are sprayed at intervals of 5 days, 7 days, 7 to 10 days, respectively, in Japan.

Susceptibility of CLM to many pyrethroids has decreased recently in the western part of Kyushu^{3,4,12}) and populations resistant to pyrethroids are expanding gradually to the east, so that this group of insecticides is becoming ineffective in these areas. To control CLM, organo-phosphorous insecticides such as penthoate, phosmet, and isoxathion had been used until about 20 years ago, but they also can not be used presently because of resistance²⁴). Petroleum oils are commonly sprayed in summer to control CLM in Australia, Israel, etc., but oil sprays after late July should be avoided owing to the decrease of the Brix content of fruits in Japan.

In general, special insecticide sprays for CLM are not applied on the mature Satsuma mandarin trees. However, some insecticides are customarily applied to control other main pests such as yellow tea thrips (*Sciltothrips dorsalis*), white-spotted longicorn beetle (*Anoplophora malasiaca*), and arrowhead scale (*Unaspis yanonensis*) in the citrus orchards. Although these insecticides seemed to influence the incidence of mortality of CLM, under these conditions, about 100% of new leaves are likely to be heavily infested with CLM during the summer to autumn seasons every year. In order to suppress the population density of CLM, it is recommended to cut off all of the infested shoots as a cultural control method for CLM.

Conclusion (some problems for the future)

For nurseries, top-grafting trees, trees planted in plastic greenhouses, and susceptible cultivars to citrus canker, many insecticides are applied to control CLM at short-term intervals during the seasons of shoot development in Japan. These continuous sprays of insecticides can not only induce CLM resistance to insecticides but also eliminate natural enemies of many citrus pests from citrus orchards. An additional problem is the increased cost of operating pesticide sprays. Consequently, attempts should be made to use only natural enemies and sex attractants for the control of CLM in Japanese citrus orchards.

Natural enemies: As stated above, the native natural enemies were not sufficiently effective as biological control agents for CLM in Japan. An encyrtid parasitoid, *Ageniaspis citricola* appeared to be the most effective parasitoid for the natural control of CLM in Thailand and Taiwan. The wasp which has been recently introduced from these countries to Australia, United States and Israel, established successfully and was able to reduce the CLM population markedly under the new circumstances. An attempt to introduce *A. citricola* from Thailand and Taiwan to Japan was made in the summer of 1995, resulting in failure because of the death of the wasps during transport. Additional efforts should be made to introduce *A. citricola* from tropical Asia or secondarily colonized areas such as Florida and Australia

to Japan. Though it remains to be determined whether *A. citricola* is able to overwinter under the long, cold Japanese winter conditions, attempts should at least be made to introduce the encyrtid from Taiwan to Ishigaki Island which is located of the same latitude as the northern part of Taiwan.

Sex attractant: It was suggested that (Z,Z)-7,11-hexadecadienal could be utilized for forecasting the occurrence of CLM moth, but suppressive effects on CLM were obtained based on small-scale field tests using the sex attractant as a mating disruptant. It appears that many mated females flew into the sex-attractant-treated field from the surrounding untreated ones. Large-scale testing using large amounts of the sex attractant should be performed in large fields. In Japan, however, as most of the citrus orchards are located on slopes where a gassy sex attractant can not drift in the air for a long period of time, it may be difficult for the synthesized sex attractant to disturb the sensibility of the male moths occurring throughout the citrus orchards.

Kuroko and Kumata, Japanese experts in the taxonomy of Gracillariidae, identified the specimens collected from Thailand and Morocco as *Phyllocnistis citrella*, which is the same species as the citrus leafminer occurring in Japan. However, the synthesized substance strongly attracted Japanese CLM males, while it did not attract the moths occurring in other countries. This difference of sensibility to the synthesized sex attractant may indicate that *P. citrella* has differentiated into some biotypes. Consequently, (Z,Z)-7,11-hexadecadienal used in these studies was synthesized as an analogue from one component of the pink bollworm sex pheromone and confirmed to be a sex attractant of CLM based on random screening tests in the field¹⁾. The substance was assumed to be at least one component of the sex pheromone of CLM based on its strong attractiveness for male moths of CLM. It is necessary, however, to extract the true pheromone from the virgin female, to determine whether it is the same material as the synthetic one, and whether it contains other minor components, in order to utilize this substance for effective control or monitoring of the populations in various parts of the world.

Abstract

This study dealt with the relationship between the characteristics of irrigation ponds and water quality. We conducted a statistical analysis of 556 irrigation ponds located in urbanized rural areas and flat rural areas throughout the country, and examined a number of indicators of water quality such as pH, chemical oxygen demand (COD), contents of total phosphorus (T-P) and total nitrogen (T-N). There were no strong correlations between the characteristics of the irrigation ponds and water quality. We then conducted a similar analysis of the ponds after classifying them into 4 groups based on hydraulic and meteorological characteristics. In this analysis, a strong relationship was found for the water quality in each group of ponds. We also studied the nitrogen load in the effluent from the catchment basins and found that diffuse non-point-source nitrogen was the major constituent. Relative intensity of the factors affecting water quality was investigated by multiple regression analysis and box plot analysis.

Discipline: Irrigation, drainage and reclamation

Additional key words: basin characteristics, statistical analysis, diffuse non-point source, water quality preservation, load management

Introduction

In Japan, there are about 213,890 irrigation ponds. Of these, the irrigation area of 68,850 ponds is larger than 2 ha and together they cover a total area of 1,235 thousand ha and contain an effective volume of 4,769 million m³ of water⁶). This volume of water amounts to about 16% of the 30,470 million m³ of the effective volume of water contained in dams in Japan⁴) and about 8% of the 58,700 million m³ used yearly for agriculture³). The ponds are an important source of water for agriculture. They are also considered to be closed and are a valuable component of local open-spaces, fulfilling multiple purposes in many areas.

With increasing development and a tendency toward crowded living, the inflow of gray water to irrigation ponds may cause pollution and the resultant abnormal algal bloom may lead to environmental problems, for example the death of fish, stench, and destruction of scenery. This deterioration of water quality by factors such as water inflow and nitrogenous and phosphorus sediments is a result of socioeconomic activity in the catchment basins. It is essential to analyze the basin characteristics, including land utilization, agricultural practices, weather, and sources of pollutant loading for the preservation of the water quality in irrigation ponds. An understanding of how the characteristics of the basins and the hydraulic properties of the ponds influence the water quality may provide effective information to promote the preservation of the water quality in future.

Method of analysis

We examined the water quality of irrigation ponds from 1991 to 1993. Nationwide, approximately 25,000 irrigation ponds have an irrigation area of more than 5 ha in urbanized agricultural areas or agricultural areas⁵). From these, 852 were sampled from prefectures across the nation in proportion to the number of ponds in each prefecture.

In principle, sampling was carried out 5 times at sluice gates and from a depth of approximately 50 cm at each pond during the irrigation season (May through October).

Of the 852 irrigation ponds, in some river water was introduced except for basin use, others were used for other purposes, such as aquaculture, golf courses, industries and farming, and for some of them the information we collected could not be used. The data from these types of ponds were excluded in the analysis of water quality characteristics because the actual conditions were not clarified and it was difficult to estimate the occurrence of nutrient loading. Therefore in principle, we examined 556 irrigation ponds in the present study.

These 556 irrigation ponds were then classified into groups to analyze the influence of major environmental factors, such as water depth, retention time, and hours of sunlight on the fluctuation of water quality. Although it was possible to group the ponds by combining each factor, considering the shallow irrigation ponds studied in this report, the hours of sunlight were found to be the factor that influences primary productivity, such as growth of plant plankton. Retention time and water depth were also used as a measure to group the ponds. The uses of the irrigation ponds were other factors that influenced the water quality. Based on these factors, the following 4 groups were analyzed in this report.

For the water depth and retention time, median values were determined by statistical analysis of whole irrigation ponds.

Group I Long period of sunlight (≥ 1900 h/year) and shallow irrigation ponds (< 4.0 m).

Group II Short period of sunlight (< 1900 h/year) and shallow irrigation ponds (< 4.0 m).

Group III Long retention time (≥ 60 days) and deep irrigation ponds (≥ 4.0 m).

Group IV Short retention time (< 60 days) and shallow irrigation ponds (< 4.0 m).

General conditions of irrigation ponds

[Table 1-a](#) shows the statistical values of the characteristics of the irrigation ponds. The average values of the indicators of water quality of the irrigation ponds were as follows: COD, 9.02 mg/L; T-N, 1.36 mg/L; T-P, 0.10 mg/L; pH, 7.6; and EC, 143 μ S/cm. Of these values, pH, COD, and T-N exceeded the standards for water for agricultural use (paddy rice, [Table 1-b](#)). When the average nutrient concentrations in summer exceeded 0.5-1.5 mg/L for T-N and 0.02-0.10 mg/L¹) for T-P, eutrophic conditions were likely to prevail.

The average retention time ([effective storage capacity of the pond]/[volume of inflow water into the pond]) was 114.1 days, which is approximately equivalent to 1/4 of the general retention time of lakes and marshes in Japan (approximately 1.2 years).

Land use in the catchment basins of the irrigation ponds was as follows: 70% for forests, 8% for paddy fields, 6% for farms, 4% for orchard areas, and 2% for grasslands ([Fig. 1](#)). Non-agricultural land use accounted for the remaining 10%. Consequently, land use was characterized by a high ratio of forests.

Water quality in irrigation ponds and characteristics of catchment basins

1) Correlation between water quality in irrigation ponds and catchment basin characteristics

Our data failed to reveal a strong correlation between the hydraulic properties of the irrigation ponds or basin characteristics (such as agricultural practices, land use, and environmental conditions) and pond water quality. For example, there was no strong correlation between the retention time and T-N value ([Fig. 2 \(1\)](#)) or between the proportion of forests in the basins and the T-N value in the ponds ([Fig. 2 \(2\)](#)). We performed single correlation analyses between the indicators of water quality and each of these characteristics, but the results were identical.

When classified into 4 groups, however, the irrigation ponds showed a correlation between each pond property and water quality indicators ([Tables 2](#) and [3](#)). In Group I, average values of COD, T-N, and T-P exceeded the averages for all the irrigation ponds and also the averages for each of the other groups. In Group III, average COD and T-P values were lower than in the other groups.

In Group I, there was a low correlation between the retention time and COD compared with all the irrigation ponds and the other groups. In Group I there was a strong correlation between the COD and the T-P value compared with all the irrigation ponds and the other groups. Group II showed a strong correlation between the T-N and T-P values, suggesting that the N/P ratio was relatively stable. In Group III there was a strong correlation between the COD and the T-P value, indicating that phosphorus may be the limiting factor for eutrophication. In Group IV, no strong correlation was found between any of the indicators of water quality.

The correlations between the water quality indicators in each group suggest that they affect the variation of water quality in irrigation ponds.

2) Outflow characteristics of nitrogen load from the catchment basins

Fig. 3. Nitrogen load from effluent in the catchment basins

The proportion of nitrogen load in the catchment basins of irrigation ponds (Fig. 3) was determined by the unit method. The nitrogen load from paddy fields, forests, and areas with non-agricultural land use was calculated by multiplying the T-N concentration of rainfall by the amount of precipitation during the period of irrigation.

The nitrogen load from farms and orchards was calculated by multiplying the amount of fertilizer applied during the irrigation period by the discharge rate of 30%²⁾.

The nitrogen load from livestock was estimated by using the documented value for cattle/head/day and the documented value for pigs/head/day⁸⁾. The nitrogen load from the households in the basins was estimated from the documented⁷⁾ value of 6.0 g/person/day of treated household drainage from septic tank (mixed drainage and urine) and 1.45 g/person/day of untreated mixed household drainage.

Although land use in the basins of the irrigation ponds consisted of forests (70%), farmland (20%), and other land uses (10%) (from Fig. 1), agricultural land use accounted for about 51% of the nitrogen load, indicating that agriculture exerts a major influence on water quality in irrigation ponds. The nitrogen load per unit area in the basins was 90 g/ha/d (standard deviation 153 g/ha/d; median value 36 g/ha/d). Since 78% of the nitrogen load was derived from diffuse non-point sources, such as farmland and forests, it might be difficult to control or manage the load.

BACK

3) Multiple regression analysis of water quality and catchment basin characteristics

Variables were selected by multiple regression analysis taking the indicators of water quality as the objective variables and the characteristics of irrigation ponds and their catchment basins as explanatory variables. Because the number of cattle raised in the basins was relatively low, we excluded the density of farm animals from the variables before performing the analysis. The standard of variable selection was set up as $F_{in} = F_{out} = 2.0$ for the F value of the variance ratio, and was estimated by the methods of forward selection and backward elimination. [Table 4](#) shows the standardized partial regression coefficients between the indicators of water quality (objective variables) and the characteristics selected as a result of variable selection. The proportion and Variance Inflation Rate (VIF) were calculated by carrying out a multiple regression analysis taking the individual explanatory variables selected from Table 4 as the objective variables and the other variables as the explanatory variables. The value of VIF was 1.0-2.7 and the explanatory variables were found to be independent. The absolute values from Table 4 are considered to reflect the degree to which individual indicators of water quality were influenced.

Based on these considerations, the characteristics of irrigation ponds and their catchment basins that most affected water quality were as follows:

for COD, depth of water, annual average temperature, and annual precipitation;

for T-N, proportion of forests in basins, yearly hours of daylight, and proportion of farmland in basins;

for T-P, depth of water, yearly hours of daylight, and non-agricultural land uses.

Land use characteristics influence water quality, particularly the T-N. In comparison with the T-N, COD and T-P values are affected by a variety of characteristics other than land use. However the proportion of forests in basins affected all of the above indicators of water quality: i.e. the values of all the indicators of water quality tended to decrease in proportion to the increase of the forest areas in basins.

4) Analysis by box plot

When there are biases or outliers in the distribution of research data, the correlation coefficient is not always an appropriate index to describe the correlation among variables. We used parallel box diagrams⁹⁾ to analyze the relationships among variables in these cases.

In this analysis, all the data of the variables on the horizontal axis were arranged from minimum to maximum values and then divided into 5 sets, each containing an equal number of data. A box diagram of the variables on the vertical axis was made for each of the 5 data sets. The position of each box plot on the horizontal axis corresponded to the position of the central value in each horizontal data set. The central horizontal line in the box plot represented the 50% value (median), and the upper and lower hinge values were 75 and 25%, respectively; thus 50% of all the data were included within the height of the box. The maximum and minimum values in each set were represented by the upper and lower vertical lines ([Fig. 4](#)).

In the parallel box plots, the correlations are not indicated quantitatively with a coefficient, but the relative tendencies among the variables can be observed.

We analyzed the relationships between each water quality indicator (COD, T-N, and T-P) and irrigation pond characteristics by this method. The characteristics derived from this analysis coincided with the results of the multiple regression analysis as follows:

- (1) The pond depth and the proportion of forests in the catchment basins showed a negative correlation with all the water quality indicators ([Figs. 5 \(1\) and 5 \(2\)](#)).
- (2) A positive correlation was found between yearly daylight hours and COD. Although there was a positive correlation between the COD and retention time up to about 100 days, there was no correlation with the COD for longer retention times ([Figs. 5 \(3\) and 5 \(4\)](#)).
- (3) T-N showed a positive correlation with the area of upland fields. There was a positive correlation between T-N and nitrogen applied as fertilizer up to about 0.4 kg/ha. However, there was no clear correlation at levels of application beyond that value ([Figs. 5 \(5\) and 5 \(6\)](#)).
- (4) No significant correlation could be found between T-P and any irrigation pond characteristics except for the positive correlation with the pond depth and the proportion of forests in the catchment basins.
- (5) There were positive correlations among the water quality indicators, such as COD, T-N, and T-P ([Figs. 5 \(7\) and 5 \(8\)](#)).

Conclusion

Although the mechanisms responsible for the fluctuations of water quality cannot be clearly determined by statistical analysis alone, the following information is necessary to preserve the water quality in irrigation ponds.

Since current agricultural practices result in COD, nitrogen, and phosphorus load mostly occurring from diffuse non-point sources, it is difficult to control or manage the load. And we consider that the improvement of the methods of fertilizer application and water management in the fields may not drastically decrease the occurrence of pollutants in the short period.

Water quality in irrigation ponds can be improved by reducing the source materials, pollutant runoff into the irrigation ponds, and the amount of pollutants in the irrigation ponds. Although many engineering methods involving the construction of drainage treatment facilities, by-passing the waterways, compact oxidizing of the waterways, use of aquatic plants, and dredging of the ponds can be applied, it is difficult to achieve effective and long-term control by a single method at this time.

When a comprehensive evaluation of the situation is taken into consideration, on a long-term basis, it will be important that the basin characteristics of each irrigation pond be thoroughly analyzed and appropriate engineering steps be taken for water quality preservation. These steps should include the use of load management to structurally remove the sources of pollutants.

Abstract

The efficiency of insects as crop pollinators depends on their biological characteristics in relation to the crop and the environment in which they are needed. For glasshouse pollination in Japan, stingless bees are potentially promising pollinators for the following reasons: they are harmless to beekeepers and glasshouse workers, they visit a wide range of crops (polylecty), they are tolerant of high temperatures, they are active throughout the year, they can be transported easily, and they do not pose an environmental risk by escaping and invading natural habitats as they would not survive the Japanese winter. There are still, however, some limitations to using stingless bees in such areas, one of which lies in how to improve methods for propagating and maintaining the colonies throughout the year. To address this problem we suggest the development of a new type of hive box.

Discipline: Crop production/Horticulture

Additional key words: bee-keeping, meliponiculture

Introduction

Stingless bees are social bees which lack a functional sting. They store honey and pollen, and are sometimes called stingless honey bees¹⁷). Since they occur in perennial colonies in tropical and sub-tropical climates, it is impossible for them to survive naturally throughout the cold season in countries with a temperate climate such as Japan. Considering that these people-friendly and ecosystem-friendly bees could be used as crop pollinators, we introduced colonies of several species from Australia and other countries, and investigated methods for keeping and multiplying hives.

The general biology of stingless bees has been described by various authors^{17,23,28}), and pollination by

stingless bees in tropical areas has been reviewed recently⁹⁾. Most of the research, however, has been conducted in the areas where the bees live. Very little work on using stingless bees introduced from overseas has been performed in Japan, much less from the practical pollination point of view. Sakagami introduced the concept of domestication of stingless bees first into Japan²²⁾. Maeta et al. imported 7 species of stingless bees, *Trigona minangkabau*, *T.moorei*, *T. itama*, from Southeast Asia; *Nannotrigona testaceicornis*, *Plebeia droryana*, *T. angustula*, *T. barocoloradensis* from Brazil, with a view to testing them as pollinators of strawberries and published a note stating that *N. testaceicornis* was the most effective one and that economical fruit production could be maintained by the introduction of colonies into glasshouses¹⁵⁾.

In this paper we describe the use of insects as crop pollinators in Japan, and also the potential of the stingless bee, *T. carbonaria*, from Australia to be kept and utilized successfully as pollinators under glasshouse conditions.

Status of pollinator utilization in Japan

Where no pollinators are available, many crops need hand or mechanical pollination. Multiple use of insecticides and expansion of single cropping, both of which have been conducive to development of modern agriculture, have also led to the decrease of natural pollinator populations. In addition, cultivation under structures, such as glasshouses or greenhouses, where no rain, wind, or natural pollinators could be expected, has been disseminated in response to the rising demand for fruits and vegetables. These agricultural conditions have stimulated the demand for efficient manageable pollinators for crops.

Three species of insects have had a great impact on crop pollination recently in Japan.

The first is *Osmia cornifrons*, a solitary bee used since 1945 and now essential for the pollination of crops, especially of apples. The pollinating ability of *Osmia cornifrons* on apple is considered to be much higher than that of the honey bee. *Osmia cornifrons* is so efficient at pollinating crops that it was introduced into the USA in 1977 for small orchards on the East coast, and into Denmark for greenhouse crops. Its life cycle is very simple: the mated female makes a series of cells in the tubes it selects for nesting in spring; when foraging trips occur, each cell is filled with a honey pollen mixture on which it lays an egg; a new adult emerges within the nest in early autumn and overwinters therein; she appears out of the nest and mates and then makes foraging trips for a new nest in the following spring. The foraging period coincides with the flowering of apple. Since *Osmia cornifrons* bees nest in bamboo or reed and readily accept artificial nests, beekeeping is simple for the farmer to manage with minimal skill. Presently the bees are being used as apple pollinators in more than 18,000 ha of orchards in the northern part of Japan, and furthermore the bees will be applied to other crops by shifting the adult emerging time through the control of the hibernation temperature.

The second useful insect pollinator is the European bumblebee, *Bombus terrestris*, which is a social insect. Unlike honey bees or stingless bees, the colonies are annual and only queens fertilized the previous autumn survive the winter in hibernation alone and appear in spring to start up new colonies by themselves. The first adults produced by the queen are all workers. With the progression of the season, the colony becomes more populous. Males and new queens are produced at the climax of colony development around summer. The males of the colony, whether they mated or not, die before the onset of the winter season. So do the workers. In the case of artificial nests, the colony around the climax of its development can be used for crop pollination for about 2 months. The bumble bee is considered to be an efficient pollinator of some crops because buzz-pollination of crops that require it such as Solanaceae can be achieved. Buzzing bees cling to the ends of the anthers and vibrate their indirect flight muscles, leading to pollen release.

The colonies have been imported from Europe since 1991 for pollination of tomatoes alone in glasshouses, and now more than 30,000 colonies are imported per year. These bees are popular because farmers can manage them by themselves.

The third insect is the honey bee, or the European honey bee, *Apis mellifera*. This well-known social insect is an important pollinator of orchards, fields, and large-scale glasshouses partly because of its large colony population (over 10,000 individuals), long distance flights (more than 2 km), wide range of plants on which it forages (more than 80% of cultivated crops), and availability of established beekeeping

techniques. In fact, honey bees are used widely as pollinators overseas but not in Japan. Most of the Japanese farmers who need pollinators do not keep the honey bees by themselves, but, if necessary, have professional beekeepers manage the colonies. There are only 5,000 professional or semiprofessional beekeepers in Japan, the small number of which limits the use of honey bees as pollinators.

Both bumblebees and *Osmia cornifrons* bees have been commonly used mainly because the farmers can manage the bees by themselves unlike the case of honey bees. A study aimed at breeding a mutant strain of honey bees with non-stinging characteristics by using gamma radiation has been initiated so that the farmers can manage the colonies for pollination with ease¹⁾.

Only honey bees and stingless bees are highly eusocial species living in perennial colonies which are easy to keep in hives and to be moved to any place, when necessary. As a highly eusocial bee group, stingless bees also share various useful characteristics, and could be expected to be effective crop pollinators.

Stingless bees and honey bees

Social insects show some of the following characteristics: cooperation among adults in brood care and nest construction; overlapping of at least 2 generations; and reproductive division of labor²⁹⁾. Those which display all 3 of the above characteristics are called eusocial insects. Of over 10,000 different species of social insects existing today, honey bees of the subfamily Apinae and stingless bees of the subfamily Meliponinae, have attained the most advanced social levels and they are called highly eusocial insects. The colonies of other social insects die when the fertile individual dies. But honey bees and stingless bees live in perennial colonies by replacement of the queen when needed. European honey bees and Oriental honey bees (*A. cerana*) have been kept for a long time in Europe and Asia (beekeeping or apiculture), and stingless bees have been kept in Central and South America (stingless beekeeping or meliponiculture) due to their perennial colonies.

[NEXT](#)[TOP](#)

Biology of stingless bees

The characteristics of stingless bees including *T. carbonaria* are reviewed here.

1) Distribution

Stingless bees are considered to have their center of origin in Africa and have dispersed to other tropical and subtropical parts of the world, based on paleontological and biogeographic data. This hypothesis is also supported by the fact that their primitive species with a well-developed sting system live in Africa exclusively²⁷).

Stingless bees belong to the subfamily Meliponinae in the family Apidae. In general, stingless bees are easily distinguished from other bees by the following 3 characters: reduction and weakness of the wing venation; presence of the penicillum; and reduction of the sting²⁸). In contrast to Apinae which consist of only 4 main species and less than 10 species in total in the one genus *Apis*, Meliponinae are a fairly large group with diverse morphology and biology. The group contains more than 400 species. At least 250 species have been described in South and Central America where research has been most advanced. About 50 species live in South Asia and Malaysia, and 20 in Australia, Papua New Guinea, and the Philippines and as many as 40 are native to Africa. Since the forests in the tropical areas mostly consist of entomophilous plants, stingless bees are of great importance for the pollination of many wild plants in addition to tropical crops²¹).

2) Species used for stingless beekeeping

The important genera for stingless beekeeping are *Melipona* and *Torigona*. Crane listed 14 species of *Melipona* and 21 of *Torigona* that have been used in traditional beekeeping⁴). *Melipona* species are restricted to Central and South America, and are of historical significance because of their long-time culture for the production of honey and wax. *Torigona* species are present in all the tropical continental areas, and traditional hive beekeeping with them has occurred in tropical America and occasionally in Asia. Most *Torigona* species are relatively small, and long-winged. *Melipona* species are short-winged and tend to be larger, some being as large as honey bees⁴).

T. carbonaria is very common in coastal Queensland in Australia and extends as far south as Sydney, being the southernmost species of all stingless bees in the world¹⁶).

3) Defense mechanisms

The stingers are vestigial and non-functional but the bees have various and efficient means of defense for colonies. Some species adopt aggressive ways of defense, like biting (*T. cupia*, *T. fuscipennis*), emitting a caustic liquid from the mouth (all species of *OxyTorigona*), releasing unpleasant odors (*T. capitata*, *M. marginata*) and irritating by crawling into eyes ears, etc. However, the most common strategy of defense is to make their nests and the entrance invisible to intruders. Therefore, most species do not harm people or animals.

T. carbonaria is a gentle species and can be manipulated with ease. The insects defend the nest by sealing up all unnecessary nest openings, and sometimes crawl over persons, and give tiny nips with their mandibles when their nest is disturbed⁶).

4) Nest structure

A few species of stingless bees build their nests in underground cavities such as termite mounds, most of them belonging to primitive groups, e.g. genera of *Meliplebeia*, *Plebeia*, and *Nogueiraps*. Some other species build an exposed nest which is surrounded by hard and sometimes brittle layers hanging on tree branches in the air. Those species do not seem to have ever been considered for beekeeping.

Fig.1. Brood comb of the shinglee bee, *Trigona carbonaria* showing a spiral type.

The most common type of nest is found in a tree cavity. The nest is usually made of 5 parts; brood comb, involucrum, store pots, batumen, and an entrance. The comb consists of brood cells, in each of which a single young is reared, and surrounded by a sheath of cerumen, or involucrum (Fig. 1). Therefore, the cavity where the brood cells are present is called a brood chamber. Cerumen is made of a mixture of wax secreted from the glands on the abdomen of workers and propolis, which is derived from resins collected from plants. Honey and pollen are stored in pots quite different from the brood cells. These storage pots are usually placed above and below the involucrum, and made of cerumen. The extra space in the tree cavity is sealed by batumen plates, usually made of cerumen and mud. The entrance of the nest is a simple hole. It often extends from the nest as a tube, and also continues inside the nest cavity. There are pillars and connectives inside the nest to support all the other structures within the batumen plates. The brood cells of the combs are in contact with one another, and the combs are usually horizontal, but in some species like *Torigona carbonaria*, the combs form a spiral. In subgenera, such as *Plebeia*, *HypoTorigona*, *Trigonisca*, *Torigona*, and *Tetragona*, some species construct cluster-type nests. This type of nest contains a cluster of brood cells irregularly arranged instead of combs. Unlike the nests with combs, cluster-type nests can take advantage of small and irregular spaces¹⁷).

Only the African species *Dactylurina staudingeri* has vertical, double combs, each consisting of 2 layers of horizontal cells opening in opposite directions, as in the case of honey bees²⁸).

5) *Reproduction*

There are 2 ways of reproduction in social insects as follows: (1) development of a colony, or increase in the number of individuals, which depends mainly on the egg-laying ability of queens. The number of eggs laid per day varies among species and does not change appreciably with the season as in the case of European honey bee subspecies; (2) colony reproduction, or increase in the number of colonies. In stingless bees, like honey bees, all the new nest foundations result from a fission of the colony. New colonies are formed by reproductive swarming with a queen and workers, but the procedure is quite different from that of honey bees^{17,23}). In honey bees, an old queen leaves the mother nest when reproductive swarming occurs, but in stingless bees young virgin queens leave, and the connection between the mother and daughter nests can last for weeks and even months. Typical formation of new colonies in stingless bees proceeds as follows: a new nesting site is searched for and identified by workers; the workers transport the necessary materials both for construction and for food from the mother nest; the new nest except for brood cells is complete; a young virgin queen flies to the new site from the mother nest along with drones; mating flights are made; and the new nest is occupied by adult bees including the new queen¹⁷). It has been reported that *T. julianii* and *T. varia* carry out some construction work in the new nest before the young queen arrives¹⁸), and that stingless bees do not necessarily need to fly during mating³). Variations in the swarming process have been reported¹¹).

[NEXT](#)[TOP](#)

6) Population of nests

The number of workers comprising the colony ranges from a few hundreds to several thousands depending on the species and other factors. Wille & Michener²⁶⁾ presented a list of the populations: from *Torigona corvia* 7,200 to *T. buyssoni* 136, including the major meliponiculture species: *T. schrotkyii* 300, *T. mosquito* 1,175, *T. mirandula* 2,281-4,076, *T. cupira* 2,900, *T. clavipes* 5,000-8,000, *M. marginata* 243, *M. fasciata* 2,00. The color of the workers is black, brown, red yellow, and white depending on the species. A mature colony of *T. carbonaria* consists of about 10,000 individuals¹⁰⁾.

7) Division of labor

Two kinds of division of labor can be observed in the social life of the stingless bees as in that of honey bees: division of caste referring to the reproductive system, and division of labor among workers, productive system.

The females are divided into 2 castes, queens and workers. Caste dimorphism is strongly developed. Queens are much larger than workers, lack corbiculae (the pollen-carrying structures on the hind legs) and wax glands.

As workers age, their tasks change. Their sequence of activities can be divided into stages as follows²⁸⁾: self-grooming (just after emergence from the pupae); incubation and repairs in the brood chamber; construction and provisioning of cells, and feeding of young adults and the queen; reconstruction of the involucre and guard duty at the entrance; and collection of pollen, nectar, and propolis. Basically the sequence of the workers' activities is similar to that in honey bees.

8) Thermoregulation

Honeybees are able to maintain the temperature around the brood at 34-36°C. The temperature is raised with their own body heat, generated by shivering the wing muscles, and lowered, if necessary, by fanning their wings at the nest entrance to draw cooler air into the nest or gathering water into the nest to spread over the comb. Generally, stingless bees are not as efficient as honey bees in controlling the nest temperature, especially when the temperature is low, they are inefficient in raising it. This may be a factor that limits stingless bees to tropical and subtropical areas. When the temperature is high, they lower the temperature by fanning their wings at the nest entrance partly for ventilation as honey bees do. Only a few species, *Torigona spinipes* and *T. duckei*, however, are known to have the ability to regulate the nest temperature within certain limits¹⁷⁾. Our studies show that *T. carbonaria* can not easily control the temperature in the hive ([Fig. 2](#)).

9) Queen behavior and oviposition

The honey bee queen flies when swarming occurs, while the stingless bee queen flies only once in her life. Once she has mated and begun to lay eggs, her abdomen enlarges and she loses the ability to fly. As a result, she remains in the old nest. In contrast to honey bees, stingless bee queens are reared continuously, and tolerated in the nest for a time. Some of them establish new colonies through swarming or take over the old queen, but most are killed by workers¹⁷⁾.

Stingless bees provide the brood cells with the food all at once, and then close the cell just after the queen lays an egg. In the genus *Torigona*, the rearing method of queens and workers is similar to that of honey bees. Queens are reared in special large cells at the margins of the comb and filled with more larval food than workers' cells. The production of a queen depends on the amount of food during the larval stages, and any fertilized egg can become a queen or a worker, that is, growing into a queen is purely the result of a greater larval food supply, and the caste is determined trophically. In contrast, queens and workers are reared in cells with the same size and caste is determined genetically in *Melipona*. Kerr suggests that the caste genes regulate juvenile hormone production¹³).

10) Foraging

The last stage of the workers' activity is foraging. Like honey bees, stingless bees collect pollen, nectar, and propolis. Most of the stingless bee species are polylectic, foraging a wide range of crops for pollen.

In contrast to honey bees, since stingless bees can forage without the help of near ultraviolet light, they can easily forage in a greenhouse with a roof made of ultraviolet-absorbing film²⁴). The colonies of *T. fuscobalteata* were being kept without any problems in foraging in an environmentally controlled chamber (10 m², 26°C, 13L:11D with fluorescent lamps) provided properly with plant flowers²). *T. angustula*, *T. bipunctata*, and *T. carbonaria* can also be successfully kept in the same conditioned chamber.

11) Flight range

Stingless bees show a compact flight range compared with honey bees. The workers of honey bees can forage over 2-3 km, while those of the stingless bee can forage over 1 km at most. There are some correlations between flight range and the body size of the workers¹²). According to Kerr¹²), small bees like those of the subgenus *Plebeia* (3-4 mm) have a flight range of about 300 m, medium-sized bees, as in the case of the subgenus *Torigona* (5 mm), have a flight range of about 600 m, large bees (10 mm) have a flight range of about 800 m, and very large bees (13-15 mm), i.e. *Melipona fuliginosa*, have a flight range of about 2,000 m²⁸). Flight activity of stingless bees is constantly influenced by the weather conditions⁸). In *M. marginata*, the flight activity is correlated positively with the temperature and negatively with RH, but the behavior indicates a flexible response to prevailing weather conditions¹⁴). In *T. carbonaria*, foraging bees fly over a maximum distance of 500 m and usually prefer to fly over a distance of about 100 m from the nest¹⁰).

12) Communication

Like the honey bees, many species of stingless bees are able to communicate the location of a food source. They use a chemical secreted from the mandibular gland and sunlight for orienteering. Foraging workers stop at intervals of a certain distance and leave scented spots on the way from a good source of food to the colony. Other bees leave the nest and begin to follow the odor trail outward²⁸). In *Torigona postica*, the foraging workers seem to be able to act as guide bees by leading the others in a group back and forth for several trips⁵). Some species of stingless bees such as *T. angustula* communicate with sounds and zigzag running. In *M. quadrifasciata* and *M. merillae*, returning foragers produce sound impulses varying proportionally to the distance of the

food source⁷⁾. In *T. carbonaria*, a foraging bee that has located a good food source marks it with a chemical scent to help other workers find it.

13) Longevity of colonies

The colony of stingless bees could last permanently by replacing the queen successively as long as a lethal disaster does not occur. Generally, the longevity of the queens seems to be longer than that of the honey bees which is 3-5 years²⁸⁾. We obtained a colony of *T. fuscovariata* from Thailand in 1995, when the colony was 12 years old. We have kept it under environmentally closed conditions for more than 3 years since then. It is still in good condition and there has not been any exchange of queen. The workers of stingless bees also seem to live considerably longer than those of honey bees. For instance, *T. xanthotricha* workers spend about 6 weeks in the nest and then about the same length of time in the field, a lifespan about double of that of a honey bee²⁰⁾.

14) Pollination efficiency

Although few quantitative data are available on the influence of pollination by stingless bees on crop yield, many species are considered to be useful for pollination of plants⁹⁾, although some species can not be used. *T. silvestriana*, *T. fulviventrid* and *T. textacea* damage the corolla of *Thunbergia grandiflora*³⁰⁾.

T. carbonaria is polylectic and an effective potential pollinator of crops such as the nut-bearing tree, *Macadamia integrifolia*, and also quickly adapts to new plants previously unknown^{10,25)}. In fact the foraging bees thrive on a wide variety of Japanese flowering plants they have never seen before, which we provided in our experiment. Two hives per 10 a of crop fields would be recommended for sufficient pollination¹⁰⁾.

Stingless beekeeping

Before honey bees were imported to South and Central America, stingless bees were the only honey producers in these areas. Even presently hives of stingless bees are kept for honey harvest, and some researchers have outlined in detail the management and domestication of several stingless bee species. Various kinds of hives have been designed according to the species to facilitate honey harvesting and avoid the destruction of the nest¹⁹).

1) Hives for *T.carbonaria*

Researchers in Australia have developed various types of hives for *T.carbonaria*⁶). As shown in Fig. 2, *T.carbonaria* are not able to control the temperature in the hive, compared with honey bees. The tolerance of low temperature in *T.carbonaria* adult bees is not appreciably different from that in the honey bees ([Fig. 3](#)). The honey bees form a cluster when the ambient temperature is fairly low, as the temperature in the hive remains within the optimum range, unlike *T.carbonaria*. Therefore, the major problem for keeping them in Japan is how to maintain them safely under warm conditions. We have tried to design a hive in reference to Heard's works, so as to make the bees survive throughout the year and even enable them to multiply the colony in Japan. The hive consists of two boxes, an inner hive box and an outer box ([Fig. 4](#)). The inner box is designed with three stories to contain a brood space, food storage space, and feeding space. The brood space can be divided for propagating the colony. The outer box is equipped with a heater system which keeps the hive at a fixed temperature even in the winter season.

2) Splitting the colony

To multiply the colony, the nest, especially brood, should be split. The layers of *T.carbonaria*'s brood cells form a single spiral, that is, a single comb. The summit and the advancing edges of the spiral comb are a growing portion where new cells are constructed and added along them. When the summit reaches the ceiling of the brood chamber, the growing portion appears again at the bottom to repeat its rise¹⁶). To split a nest, the inner box is prized open while the brood in a brood space is cut in half. New empty inner boxes are then added to each half of the original inner box. Then 2 new nests are formed. There is no problem with the new nests which contain the original queen. Consequently the other one does not contain queens. However, in this species, usually several large cells contain developing queen bees, scattered throughout the brood comb. One of these cells will grow to become a queen⁶).

By using this type of hive boxes, we have succeeded in keeping the colonies of *T.carbonaria* in Japan with a view to using them as pollinators of crops in glasshouses.

Abstract

Rapid and easy analysis of qualitatively important components is required for the fair-trading of green teas. Flow injection analysis combined with immobilized enzymes was applied for that purpose, and the target compounds were amino acids (total amino acids, L-glutamic acid and ³-amino butyric acid) and ester-type catechins.

Discipline: Food / Tea industry

Additional key words: immobilized enzyme, biosensor, theanine, catechins, GABA

1...8): [References](#)

Introduction

Studies on green tea have revealed the relationship between the quality or taste and its chemical constituents³). Amino acids (such as theanine and glutamic acid) give the UMAMI taste and high-grade teas contain a large amount of them. Catechins are related to the astringency and bitterness. The balance between amino acids and catechins is important for the optimum taste of green tea. Although high-performance liquid chromatography (HPLC) or colorimetric methods can be applied to the determination of the concentrations of amino acids and catechins, these methods are time-consuming and laborious. Recently, near infrared spectroscopy has been applied for the rapid analysis of tea components¹). The spectrometer itself can be used even by untrained persons, while the determination of calibration curve parameters for each tea component is very laborious and the parameters determined can only be applied to the samples which show similar characteristics as those used for calibration. Moreover the instrument itself is expensive. Thus other methods for rapid measurement of the contents of chemical components of tea are required.

Flow injection analysis (FIA) may be an effective method for that purpose. The selectivity of the analysis can be provided using the enzyme reactions. This paper describes the simultaneous flow injection determination of the concentrations of total amino acids and glutamic acid by FIA using biosensors, combined with enzyme immobilized membranes and oxygen electrodes. The analysis of ester-type catechins ((-)-epigallocatechin gallate and (-)-epicatechin gallate) using enzyme reactors and

pH-sensitive transistors is outlined. Finally, γ -aminobutyric acid (GABA) determination using an enzyme reactor and a fluorometric detector is described.

Simultaneous determination of total amino acids and glutamic acid⁴⁾

High-grade teas are rich in amino acids, and theanine is the dominant amino acid in tea leaves. We observed that the biosensor for amino acids (amino acid sensor), when combined with L-amino acid oxidase-immobilized membrane and an oxygen electrode, responded linearly to the concentration of theanine⁵⁾. The reaction is as follows.

The oxygen consumed by this enzyme reaction was monitored by the oxygen electrode. The sensor responded to theanine, asparagine, arginine, glutamine and serin but did not respond to glutamic acid or aspartic acid among the major amino acids found in tea leaves. The amino acid sensor was then calibrated with theanine, which gave the highest response among the major amino acids in tea leaves. The contents obtained by this method are referred to as "total amino acids". As the amino acids to which the sensor responded are abundant in high-grade green teas, the sensor is expected to show a higher response to the infusions of high-grade teas. The use of this amino acid sensor was a convenient method to analyze the concentrations of total amino acids in tea infusions and estimate the quality of teas, but still it took about 10 min for the analysis of one sample⁵⁾.

The amino acid sensor did not respond to glutamic acid, while glutamic acid gave the strongest UMAMI and is one of the major components for tea quality. Sometimes sham teas are produced by the addition of sodium glutamate to enhance the taste of tea in the manufacturing process. Determination of the content of glutamic acid in tea is also important, and we found that the glutamate sensor, which was composed of a glutamate oxidase-immobilized membrane and an oxygen electrode, was effective for the analysis of the concentration of glutamic acid in tea infusions⁶⁾.

For more rapid and simultaneous analysis of the concentrations of total amino acids and glutamic acid, a flow injection system was developed by setting the glutamate sensor upstream of the amino acid sensor ([Fig. 1](#))⁴⁾. The filtered tea infusions could be directly injected into the flow system. Glutamic acid and total amino acids in the infusions were then analyzed using the glutamate sensor and the amino acid sensor, respectively.

The results of determinations in tea samples by this method were compared with those obtained using the HPLC method (Fig. 2). Correlation coefficients were significant for the practical use of both sensors. Using this flow injection system, 30 tea infusions could be analyzed in one hour for both the concentrations of glutamic acid and total amino acids. High-grade green tea showed a higher response to the amino acid sensor as expected, while sham teas to which glutamate had been added showed a high response to the glutamate sensor. This system was therefore effective for the rapid and objective estimation of tea quality and could be used to detect glutamate addition to green teas.

FIA determination of ester-type catechins⁷⁾

Catechins are associated with the astringent and bitter taste of tea. Tea catechins that have a gallate moiety through ester linkage show a stronger astringency³⁾ and such catechins are called ester-type catechins. Major ester-type catechins in tea are (-)-epigallocatechin gallate (EGCg) and (-)-epicatechin gallate (ECg), and usually the content of the former is several times higher than that of the latter.

The analysis of ester-type catechins is therefore important for the evaluation of the taste and quality of green teas. A rapid analytical system was developed for ester-type catechins (Fig. 3)⁷⁾. In this system the enzyme tannase was used to catalyze the following reaction.

Fig. 3. Flow injection analysis system for ester-type catechins

D: distilled water, **B:** buffer (10 mM phthalate buffer, pH 5.5), **P:** peristaltic pump (total flow rate 0.7 mL/min), **Dp:** pulse-damper, **I:** injection valve (sampling loop 100 μ L), **C:** coil, **T:** tannase-immobilized reactor (1 mm i.d. \times 20 mm), **A:** bovine serum albumin-immobilized reactor, **F:** pH-ISFET electrode, **Re:** reference electrode, **W:** waste, **M:** ISFET pH/mV meter, **R:** recorder.

The gallic acid formed can be detected by the pH shift using a pH electrode. The transistor electrode (pH-ISFET) was used here as a pH electrode to reduce the size of the system, by setting it in the flow cell. The enzyme reactor, which was filled with tannase-immobilized glass beads, was connected upstream of the electrode. After a standard EGCg solution was injected, the gallic acid formed in the reactor was detected by the change of the electric potential of the pH-ISFET. However when the tea infusion was introduced, the pH shift due to the tea interfered with the analysis. A dummy reactor, which immobilized albumine instead of the enzyme, and a pH-ISFET electrode were prepared as control.

In this system a linear response to EGCg was observed with selected buffers. The gallate-releasing activity of the immobilized tannase from ECg was the same as that for EGCg. Filtered tea infusions could be introduced every 3 min, and the results were compared with the HPLC method ([Fig. 4](#)). The correlation was significant for practical and rapid evaluation of the astringency of the green tea infusions.

Determination of γ -aminobutyric acid in GABA-enriched tea⁸⁾

In the normal production of green tea, the content of γ -aminobutyric acid (GABA) is less than 0.1%, while anaerobic treatment of fresh leaves leads to a considerable increase of the content of GABA²⁾. Since the consumption of GABA-enriched tea decreases the blood pressure in humans with hypertension, such teas are sold as "GABARON CHA" in Japan. As the effective component is GABA, it is necessary to analyze GABA easily and rapidly at the site of tea manufacturing and trading.

The enzyme complex called GABAse has been identified and it catalyzes the following reaction.

$\text{GABA} + 2\text{-ketoglutaric acid} + \text{H}_2\text{O} + \text{NADP}^+ \rightarrow \text{succinic acid} + \text{glutamic acid} + \text{NADPH} + \text{H}^+$

NADPH is a fluorescent compound, and the fluorescence due to the enzyme-catalyzed reaction can be measured with a fluorescence detector. In the FIA ([Fig. 5](#)), GABAse was immobilized on glass beads and the beads were set in a silicone tube, which was used as an enzyme reactor. The injection valve was connected upstream and the detector was located downstream of the reactor, respectively⁸⁾.

For tea samples, the fluorescence from tea components interfered with the precise analysis of the sample. A guard column for HPLC packed with C₁₈-silica was connected upstream of the detector to prevent the interference. The flow from the reactor was acidified by acetic acid before entering the C₁₈ column to improve the efficiency of the removal of the interfering substances and prevent the packed material in the column from deteriorating.

Using this system, the sample could be injected every 4 min. The results of determinations by this method were compared with those by the authentic HPLC method ([Fig. 6](#)). The correlation was significant for the rapid determination of the GABA content of GABA-enriched teas at the tea manufacturing factories.

Conclusion

We developed flow injection determination systems for the major components of green tea. These methods significantly reduced the time required for the analysis compared to the authentic methods. Moreover, since the buffer solutions and the wastes are harmless, they can be safely used by untrained workers at the tea factories. These newly developed methods are suitable for the estimation of the quality of teas by tea manufacturers and traders.

Abstract

A thymic lymphoma was found in a 14-month-old Holstein steer. Use of antisera applicable to paraffin-embedded sections showed that the tumor cells were of T-cell lineage. Although the cells were characterized histologically by the presence of irregular nuclei, electron microscopic examination disclosed that they were cleaved. Although nuclear convolution and cleavage are important in the subtyping of some human lymphomas, these characteristics may not be related to the immunophenotype of the tumor cells in bovine lymphomas.

Discipline: Animal health

Additional key words: bovine, T-cell

1...24): [References](#)

Introduction

Nuclear convolution which is a cytological marker for human T-cell malignancies may be present in human thymic lymphomas²⁴). Valli et al.²¹) divided canine, feline and bovine lymphoid tumors into cleaved and non-cleaved types, but complex indentations of tumor cell nuclei producing serpentine profiles were recognized ultrastructurally in a canine cutaneous lymphoma²⁰). In addition, the presence of nuclei showing a convoluted or cloverleaf-like conformation was verified by electron microscopy in canine⁹) and swine^{7,8}) thymic lymphomas. There is no convincing evidence that nuclear convolution occurs in bovine lymphomas including the thymic form. Here we describe a case of bovine thymic lymphoma, with emphasis placed on the ultrastructural observation of the shape of the nucleus in the tumor cells.

Materials and methods

Tissues were fixed in 10% neutral buffered formalin and processed according to standard methods for paraffin embedding. Sections were stained with hematoxylin and eosin (HE). Additionally, selected sections were stained by the avidin-biotin-peroxidase complex immunoperoxidase technique (ABC). The following monoclonal antibodies were used: anti-human CD79a (HM57) (Dako, Denmark) and anti-major histocompatibility complex class II (MHC II) (H42A) (VMRD, USA). Anti-human CD3 (Dako) was also utilized. An immunoperoxidase staining kit (BioGenex Laboratories, USA) was used in the subsequent processes. For electron microscopy, small pieces from formalin-fixed tissues were post-fixed in 1% osmium tetroxide, embedded in epoxy resin, stained with uranyl acetate and lead citrate, and examined by transmission electron microscopy (TEM).

Results

1) Clinical and macroscopic observations

A 14-month-old Holstein steer was anorexic and emaciated, with a swollen brisket, enlarged lymph nodes in the neck region, severe jugular vein distention, and edema in the intermandibular space. The animal's temperature was 40.7°C rectally, the pulse was 104 per minute, and the respiration was 44 per minute. Hematological values were as follows: hematocrit, 34%; white blood cell count, 9,900 cells/ μ L; red blood cell count, 6,390,000 cells/ μ L. Atypical lymphoid cells were occasionally observed on smears of the peripheral blood. Antibodies to bovine leukemia virus were not detected by the agar gel immunodiffusion test. Since the animal was considered to have a poor prognosis, it was euthanatized. At necropsy, there was a massive enlargement of the thymus. The retropharyngeal, cervical, axillary and bronchomediastinal lymph nodes were markedly enlarged, and the largest measured more than 20 cm in the greatest dimension.

2) Light microscopy

The thymus and affected lymph nodes were almost entirely replaced by neoplastic tissue, and hemorrhages and necrotic foci were observed. There was a moderate infiltration of neoplastic cells in the heart, and a slight one in the liver and kidneys. The neoplastic cells were medium to large in size, and many cells showed irregular nuclear contours (Fig. 1). The nucleoli were medium-sized or inconspicuous, and the chromatin was finely clumped. Mitotic figures were abundant.

3) Immunohistochemistry

In the thymic tissue, the neoplastic cells gave a positive reaction for CD3 (Fig. 2), but not for CD79a and MHCII.

Fig. 1. Thymus: Light-microscopic feature

Neoplastic cells displaying irregular nuclei predominate in this field. Mitotic figures are visible (arrows) (HE \times 630).

Fig. 2. Thymus: Immunohistochemical feature

Almost all the tumor cells stained intensely or weakly for CD3. There are no positive deposits in a blood vessel and surrounding connective tissue (center) (ABC \times 400).

4) Electron microscopy

Most of the tumor cells showed nuclear irregularity of varying degree. Some nuclei were slightly irregular and others were cleaved (Fig. 3), though a few cells contained more irregular nuclei (Figs. 4, 5). The cells had poorly to slightly developed organelles, which had a tendency to localize in one portion of the cytoplasm. Occasional cells contained several dense bodies near the Golgi complex (Fig. 6), but compact accumulation of the bodies was seldom observed.

Fig. 3. Thymus: Nuclear shape

Arrows indicate nuclear cleavage. Binuclear profiles (arrowheads) presumably result from ultrathin sectioning of single cleaved nuclei (TEM $\times 3,750$).

Fig. 4. Thymus: Nuclear shape

Compared with the cloverleaf pattern, this nucleus shows shallow clefts (TEM $\times 6,000$).

Fig. 5. Thymus: Nuclear shape

Tumor cell nuclei are irregular in contour, and one cell apparently shows a partially folded nucleus (lower right) (TEM $\times 4,500$).

Fig. 6. Thymus: Cytoplasmic organelle

Electron-dense bodies are located at one pole of the cell, but are not organized into a compact mass (TEM $\times 12,000$).

Discussion

In a bovine thymic lymphoma, the neoplastic lymphocytes were considered to be of thymic T-cell origin based on the immunostaining of formalin-fixed, paraffin-embedded tissue sections using a rabbit anti-human T-cell, CD3 polyclonal antibody¹⁾. This antibody has been used for the identification of T-cell lymphomas in other animals including dogs, cats³⁾, pigs¹⁹⁾ and a monkey¹⁶⁾. On the other hand, MHCII and CD79a were useful B-cell markers, respectively, in bovine and equine lymphomas^{2,18,22)} and in various animal species^{3,15,19)}. The present case where a reaction with CD3 alone was observed could be categorized as a T-cell lymphoma.

The presence of clustered dense bodies, which have been identified as lysosomes, was reported to be an ultrastructural characteristic of T-cell neoplasms in humans²⁴⁾, pigs⁶⁻⁸⁾ and a monkey¹⁶⁾. Similar bodies have been described in bovine cutaneous lymphomas derived from T-cells^{12,13)}, and were also observed in our case though the majority of them was not as compactly arranged.

In humans, follicular center cells sometimes display cleaved nuclei, which are considered to be the most important cytological finding in B-cell lymphomas, whereas nuclear convolution is characteristic of T-cell lymphomas¹⁷⁾. Thrall et al.²⁰⁾ demonstrated the presence of nuclear convolution in a canine cutaneous lymphoma resembling Sezary syndrome in man. In bovine cutaneous lymphomas, by contrast, the tumor cells contained round, oval or cleaved nuclei^{5,12,13)}. In a canine mediastinal lymphoma, the cells showed cloverleaf-like, convoluted nuclei⁹⁾. Likewise, convolution or multilobation was observed in swine thymic T-cell lymphomas^{7,8)}. Although Parodi et al.¹⁴⁾ reported that the convoluted form of tumor cells was confirmed by electron microscopy in bovine thymic lymphomas, the nuclei showed only a slight irregularity in the electron micrograph. In our case, slightly irregular or cleaved nuclei were detected. A few nuclei appeared to be more irregular, but were partially indented in contrast to convoluted nuclei with extensive folding²⁰⁾. Such an irregularity could be interpreted as a variation of cleavage^{11,17)}. Conversely, nuclear convolution was reported to be present in cases of bovine B-cell lymphoma^{18,23)}, although no ultrastructural examination was performed.

Lymphoproliferative diseases resembling mycosis fungoides (cutaneous T-cell lymphomas) are uncommon in dogs, and nuclear indentation or lobulation is generally less conspicuous than in humans and is not usually detected by light microscopy¹⁰⁾. Vernau et al.²³⁾ classified bovine lymphoid neoplasms observed by light microscopy based on the tumor cell size and nuclear shape, and presented high power photomicrographs depicting nuclear convolution or cleavage. The tissues, however, seemed inadequately preserved for cytological observation, because the tumor cells showed indistinct cell boundaries with or without pyknotic nuclei. In the subsequent study, Vernau et al.²²⁾ reported the absence of correlation between the immunophenotype and cell type or nuclear morphology in bovine B-cell lymphomas. The identification of nuclear profiles may be difficult in routine paraffin-embedded sections⁴⁾, and there is no convincing ultrastructural evidence of nuclear convolution in bovine T-cell lymphomas.

Abstract

After castration of 2 male Japanese Black calves, hemangiopericytomas developed in the subcutis near the scrotum. Their pericytic origin was demonstrated by the absence of focal densities, positive immunoreactivity for alpha smooth muscle actin, and absent staining for desmin. A similar neoplasm has been reported in a castrated male Japanese Black calf. It is considered that hemangiopericytomas in calves may be closely related to castration and certain bovine breeds.

Discipline: Animal health

Additional key words: castration

1...12): [References](#)

Introduction

Hemangiopericyoma is a relatively common subcutaneous neoplasm of dogs that is considered to originate from pericytes, but the tumor cells have never been unequivocally proven to be pericytes by histochemical and electron microscopic examination⁵). In contrast, a bovine hemangiopericyoma was

considered to be of pericytic origin based on immunohistochemical and ultrastructural findings⁷⁾. Here we describe 2 additional cases of hemangiopericytoma. It is assumed that such tumors may occur mainly in castrated male Japanese Black calves.

Materials and methods

Case 1 was an 8-month-old, castrated male Japanese Black calf exhibiting 2 tumor masses (4 x 3 cm) and 3 smaller ones (2 x 1.5 cm) near the scrotum. These subcutaneous tumors, protruding above the surface of the skin, could be surgically excised with minimal bleeding, because they were not connected to the underlying musculature. Case 2 was an 8-month-old, castrated male Japanese Black calf with a raised tumor nodule (4.5 x 2 x 1.5 cm) in the subcutis near the scrotum. The tumor, which was surgically removed, was not encapsulated and showed somewhat indistinct borders. All the tumors in cases 1 and 2 were similar macroscopically. The tumors were rubbery in consistency, and were grayish white to pink in color.

Tissues were fixed in 10% buffered formalin, embedded in paraffin wax, cut at 4 μ m, and stained with hematoxylin and eosin (HE). For immunohistochemistry (IH) and electron microscopy (TEM), formalin-fixed tissues were treated as described previously^{4,7)}.

Results and discussion

The neoplasms in cases 1 and 2 showed very similar histological, immunohistochemical and ultrastructural features. The neoplastic tissues in cases 1 and 2 were present in the dermis and subcutis, and the borders with surrounding connective tissue were well defined. The tumor tissues were composed of diffusely distributed cells, and there was an edematous, mucinous or fine fibrillary stroma between the cells. In some areas, neoplastic cells grew in a storiform pattern (Fig. 1), and it was uncommon to find cells arranged in a concentric fashion around blood vessels with varying sizes (Figs. 2, 3) or hair follicles. The most predominant cells were slender spindle cells with fusiform nuclei. However, some cells were larger in size and varied from plump spindle cells to ovoid or stellate cells, with large oval nuclei. Mitotic figures were seldom observed.

Immunohistochemically, the neoplastic cells in cases 1 and 2 were positive for vimentin, and the vast majority were also positive for alpha smooth muscle actin (SMA) (Fig. 4). Desmin-positive neoplastic cells were absent.

Fig. 1. Case 1: Intertwining bundles of slender spindle cells produce a typical storiform pattern (He x 100)

Fig. 2. Case 1: Blood vessels of various sizes (arrows) are present in the center of concentric whorls of tumor cells (HE x 200)

Fig. 3. Case 2: Tumor cells form whorls around capillaries that contain red blood cells (arrows) (He x 200)

Fig. 4. Case 2: Tumor cells showing SMA positivity are arranged in fascicles and encircle a hair follicle (right) (IH x 200)

In both cases the most outstanding ultrastructural feature of the neoplastic cells was the presence of extremely elongated cell processes, from which a large number of microvillous projections protruded in case 2 (Figs. 5, 6), while they were inconspicuous in case 1 (Fig. 7). The rough endoplasmic reticulum (RER) was moderately well developed. Subplasmalemmal densities could be observed, unlike focal densities. In case 2, a few cells showed highly irregular nuclear contours or contained glycogen particles (Fig. 8).

In a bovine hemangiopericytoma⁷⁾, the tumor cells, characterized by a perivascular whorl formation, SMA positivity and absence of focal densities, were considered to have arisen from a pericyte⁷⁾. Because the same features could be confirmed, the present neoplasms were diagnosed as hemangiopericytomas. The perivascular whorled pattern, however, was less conspicuous compared with that in the previous case, and in the neoplasms described here tumor cells were arranged distinctly in a storiform pattern in some areas. It is highly probable that such neoplasms have been mistakenly diagnosed as fibroblastic or fibrohistiocytic tumors showing a storiform pattern.

Fig. 5. Case 2: Many microvillous projections protrude from the surface of tumor cells (TEM x 3,750)

Fig. 6. Case 2: A capillary containing erythrocytes is surrounded by tumor cells with microvillous projections (TEM x 4,500)

Fig. 7. Case 1: As shown in Fig. 5, tumor cells display long slender cytoplasmic processes, with few microvillous projections (TEM x 3,750)

Fig. 8. Case 2: Aggregates of glycogen particles (arrows) are detected in a cytoplasmic process, and the nucleus of an adjoining tumor cell shows an irregular contour (TEM x 9,000)

As in the case of bovine hemangiopericytoma, the typical histological pattern in canine hemangiopericytomas is characterized by the presence of layers of tumor cells arranged in a concentric fashion around a small central lumen, but this pattern is often lacking and the lumen is mostly devoid of any erythrocytes^{3,9)}. Madewell et al.⁶⁾ showed that canine hemangiopericytomas were ultrastructurally similar to their human counterpart neoplasms, which apparently differed from canine and bovine hemangiopericytomas in the growth pattern⁷⁾. In contrast, Pérez et al.⁸⁾ considered that canine

hemangiopericytomas were pericytic in origin based on the following immunohistochemical results; muscle actin was expressed by some tumor cells in 22 out of 44 cases analyzed, but desmin was absent. It is, however, difficult to rule out the possibility that the actin-positive, desmin-negative cells were myofibroblasts, because myofibroblasts were indistinguishable from pericytes by immunohistochemistry alone^{4,11}). Thus, there is a considerable controversy regarding the histogenesis of canine hemangiopericytomas, and there has never been a conclusive evidence that they are derived from pericytes^{5,9}).

Trauma is related to human soft tissue sarcomas¹⁰) and testicular tumors¹²), but the etiological role has not been determined. A Sertoli cell tumor was detected in a bullock, but its exact etiology was unknown²). It was suggested that a vulval myofibroblastoma in a cow was affected by sex hormones¹). Because the present and previous neoplasms occurred at sites different from operation wounds⁷), a hormonal imbalance after castration may have contributed to the development of the neoplasms. In addition, since the tumors occurred in 3 young animals of the same breed, it is suggested that Japanese Black calves may be prone to the development of hemangiopericytomas.

Abstract

In March 1997, outbreaks of foot-and-mouth disease (FMD) affected pigs in Taiwan. To assess the potential risk of transmission and spread of FMD, a survey on normal movement pattern in livestock farms was carried out in Kagoshima Prefecture, Japan. In a total of 20 farms (9 for pig farrow-to-finish operations, 6 beef cattle farms and 5 dairy cattle farms) participating in the survey, all the movements to or off the farms (e.g. animals, materials and people / number of contacts and destination) were recorded daily over a period of one-week using a questionnaire. The movements were classified into 4 grades: risk 4 (very high) to risk 1 (low), respectively, assigned to the types of contacts. The movements off the farm were more frequent than those to the farm in each livestock farm. In particular the movements off the pig farms were concentrated on animal shipping to slaughterhouse with grade risk 4. Mean distance of shipping also extended over a radius of more than 20 km of the control zone for FMD emergency in Japan. Should an outbreak of FMD be detected in a pig farm, FMDV might, therefore, have already spread prior to the diagnosis of the disease over the FMD control zone.

Discipline: Animal health

Additional key words: epidemiology, risk analysis

1...8): [References](#)

Introduction

Foot-and-mouth disease (FMD) which is a highly contagious viral disease that affects primarily cloven-hoofed animals, often with serious economic consequences, is classified into list A of animal diseases to be reported to the Office International des Epizooties (OIE)³. The outbreak of FMD can result in a dramatic decrease in livestock productivity and loss of foreign markets for livestock and animal products²).

Foot-and-mouth disease virus (FMDV) is present in all the physiological secretions of infected animals. High

concentration of FMDV can be detected in the saliva hours before clinical lesions appear and in feces and milk up to 4 days before clinical signs occur. Thus, infected animals not yet showing clinical signs of the disease may be efficient transmitters of the virus¹⁾.

Since March 1997, outbreaks of FMD caused by the porciphilic strain of the virus have affected pigs in Taiwan⁴⁾. The Japanese Government has strictly regulated the ban on importation of all animals and animal products from Taiwan.

If an outbreak of FMD occurs in Japan, all the movements of the animals and animal products would be restricted to limit the spread of FMD to the control zone within a radius of 20 km based on the Manual for Control of Overseas Animal Diseases⁵⁾. A model that predicts the direction and extent of all the livestock movements within the control zone prior to an outbreak of FMD is expected to be developed in Japan, because, in New Zealand, a decision support system (DSS) has already been developed to help control a FMD emergency: EpiMAN (NZ)⁷⁾. A similar DSS for use in the EU was also developed as EpiMAN (EU)⁶⁾.

In order to confirm FMD dissemination through normal movements relating to animals, materials and people from infected premises, a questionnaire survey was conducted on the movements during a period of one-week in Kagoshima Prefecture, Japan. In this paper the potential risk of transmission and spread of FMD was assessed based on the results of the survey.

Materials and methods

1. Selection of the pilot area

The pilot area was selected in close cooperation with the Aira Livestock Hygiene Service Center, Kagoshima Prefecture, and set up approximately in the same way as the FMD control zone, around infected premises, within a radius of 20 km in the Aira region. The area was located on the border of neighboring 2 Prefectures (Kumamoto and Miyazaki), as shown in Fig. 1.

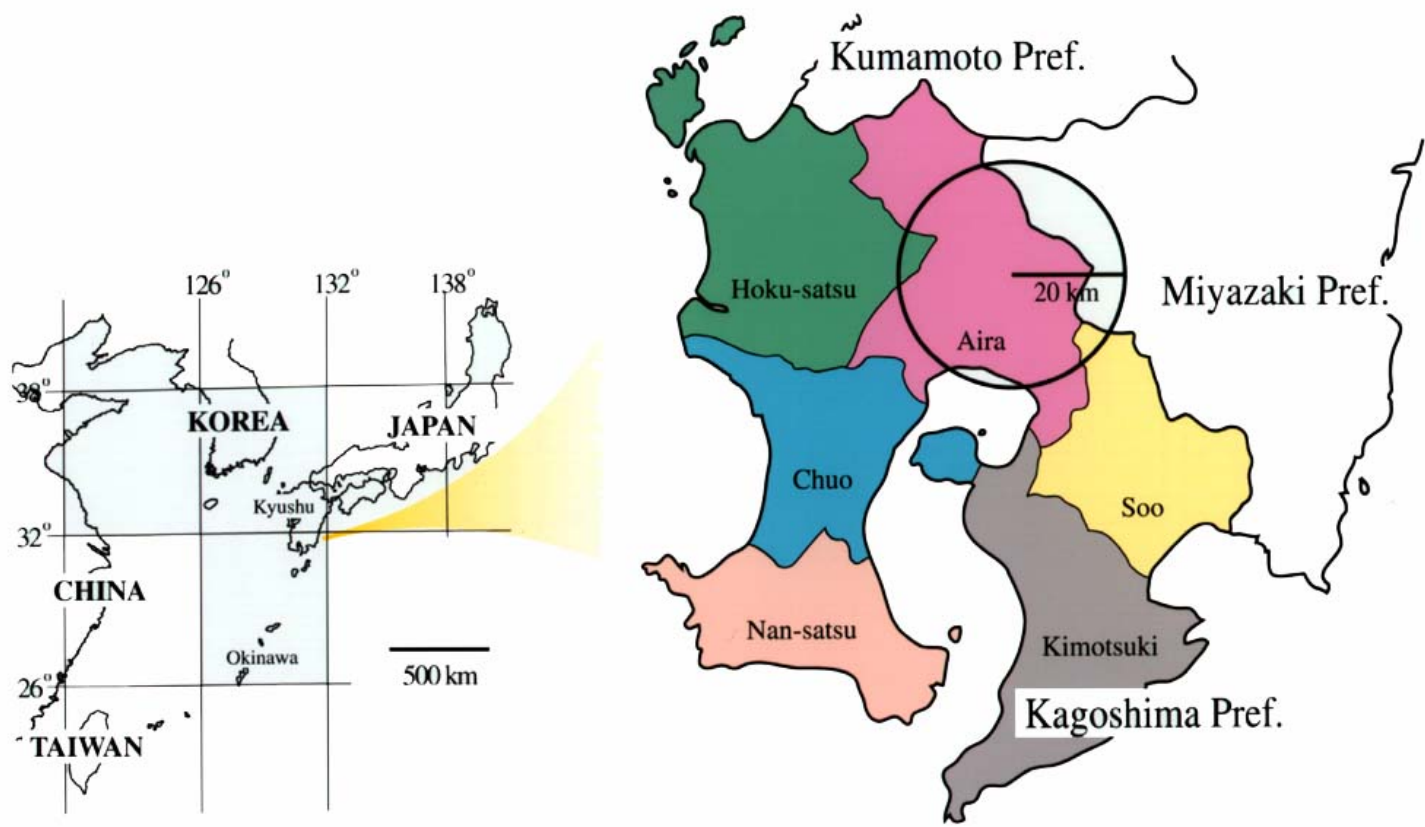

Fig.1. Location of the pilot area in the Aira region, Kagoshima Prefecture, Japan

2. Data collection

As shown in [Table 1](#), a total of 2,191 livestock farms with pigs or cattle were located within the pilot area. Also, the pilot area was characterized by a high density of pigs and a large number of small holders of beef cattle for breeding. Then, 20 farms within the pilot area were selected for the survey through the Aira Livestock Hygiene Service Center. The farms consisted of pig farrow-to-finish operations (9 farms), beef cattle for breeding (6 farms) and dairy cattle farming (5 farms).

A questionnaire survey was conducted during a period of one-week between August 26 and September 1, 1997. The participating farmers were visited and veterinary inspector officers of the Aira Livestock Hygiene Service Center asked questions about general issues and livestock management. The farmers were also asked to record all the movements to or off their farms (e.g. animals, materials and people / number of contacts and destination) everyday for a period of one-week using a questionnaire.

For animal movements to or off the farm the following data were recorded: date, species, number of animals in transport, own vehicle used for transport ("Yes" or "No"), origin and destination address and types (e.g. farms with pigs or cattle, agricultural cooperatives, live-animal market, animal traders, slaughterhouses or others).

3. Definition of potential risk of transmission and spread of FMD

Risk and types of contacts were designed assuming that the farm had been recently infected with FMD, but with the animals not showing any clinical signs. Classification of the potential risk of transmission and spread of FMD was based and modified according to the expert rules developed in New Zealand⁷⁾ or The Netherlands⁶⁾. The types of contacts were classified into 4 grades of risk, as shown in [Table 2](#). Also, the movements were divided into 2 types (to or off the farm). As a result, all the movements were classified into 9 categories of risk assigned to the types of contacts: 5 <to> and 4 <off> the farm, as shown in [Table 3](#). The distance (km) between the origin and destination of the movements was defined as the shortest way in a road map.

4. Data compilation and analyses

All the data were coded and entered into Excel (Microsoft) on a personal computer. For example, a cross-assortment of the types of contacts or their distance for each farm was carried out using spreadsheets of Excel (Microsoft) for a period of one-week. All the data analyses were carried out according to the procedures of the SAS program⁸⁾ with HP-9000 UNIX workstation on MAFFIN (Ministry of Agriculture, Forestry and Fisheries Information Network, Tsukuba). Continuous data such as number or distance of contacts were analyzed using UNIVARIATE and GLM procedures of the SAS program⁸⁾

Table 3. Assignment table of risk for all the movements (to or off the farm)

Grade	Categories of movements (to/off the farm)
4	to Animal introduction (e.g. other farms, live-animal market, etc.) off Animal shipping (e.g. slaughterhouse, etc.)
3	to Visitors related to livestock management (e.g. veterinarians, artificial insemination technicians, animal traders, etc.) off Farmers going out for livestock management to Purchase of animal feed off Transportation of feces or manure
2	to Purchase of livestock materials (e.g. equipment, straw, etc.)
1	to Visitors in general (e.g. family, friends, mailman, etc.) off Daily life activities (e.g. shopping, etc.)

Results

1. Number of contacts during a period of one-week in the livestock farms

The cross-assortment table for 9 categories of movements for each livestock farm is presented in [Table 4](#). As shown in the sum of movements to or off the farm, the movements off the farm were more frequent than those to the farm. Particularly, total movements off the farm classified into grade 3 (high-risk group), accounted for about 34% (143/423). For the grade risk 4 (very high-risk group), the movements were recorded 3 times for animal introduction and 14 times for animal shipping. Shipping from the pig farms to the slaughterhouse was recorded 13 times during a period of one-week.

2. Movement patterns during a period of one-week in the livestock farms

As shown in [Table 5](#), total movements including those to and off the farm during a period of one-week were not statistically significant among the livestock farms ($p=0.537$). However, comparison of means between the movements to and off the farm was significant ($p=0.003$). As a result, the movements off the farm were more frequent than those to the farm in each livestock farm.

3. Distance (km) of grade risk 4 and 3 movements in livestock farms

The cross-assortment table of the movement distance (km) is presented in [Table 6](#). The mean distance of the movements from the origin to the farm ranged from 15 to 58 km, and that off the farm to the destination from 3 to 153 km. In particular, the mean distance of animal shipping, for grade risk 4, from the pig farm to the slaughterhouse exceeded the radius of 20 km of the control zone for FMD emergency in Japan. Also the movements, namely "farmers going out", for grade risk 3, varied and covered a very long distance (e.g. maximum 900 km for pig or 116 km for beef cattle farms).

Discussion

Under the WTO system, increased trade of livestock, decreased transit time of animals and animal products, and changes in sanitary standards between exporting and importing countries may result in the exposure to FMD and accidental reintroduction of FMD into Japan. Also, because the last outbreak of FMD in Japan was recorded in 1933 and due to the limited number of cases under quarantine, most of the livestock farmers or persons related to animal health in Japan have not been familiar with the disease for a long period of time.

In March 1997, suddenly, outbreaks of FMD associated with smuggled pork from Mainland China affected pigs in Taiwan. Prior to the recognition of the outbreaks, Japan was importing large quantities of pork products (about 260,000 metric tons) from Taiwan. It was considered that the overall risk of transmission of FMD to Japan due to the outbreaks in Taiwan might be very high at that time. If an outbreak of FMD were to occur in Kagoshima Prefecture, since Kagoshima has the largest livestock number and quantity of animal products, particularly in the case of pigs in Japan, economic damage would markedly affect the animal industry in this area.

Thus, this was the first opportunity to survey FMD in Japan, in spite of the small scale of the investigations that covered only 20 livestock farms and a period of one-week in Kagoshima Prefecture compared with the experience of New Zealand⁷⁾ or The Netherlands⁶⁾.

On the other hand, through the survey, the transmission and spread of FMD from infected premises were determined. For instance, we observed that the pig farms, in particular, those for large-scale farrow-to-finish operations, were frequently shipping animals to slaughterhouses, as shown in Table 4. Furthermore, the mean distance of shipping exceeded the radius of 20 km of the FMD control zone (50.3 km in Table 6). Moreover, the movement of "farmers going out for livestock management" was recorded in 83 instances in the 20 farms and the distance covered by the movement ranged from 900 to 3 km (mean: 152.8 km).

Therefore, the survey was useful for FMD control as information on the potential risk of transmission and spread of FMD could be obtained. These data showed that, if an outbreak of FMD were to be detected in a pig farm, FMDV might, therefore, have already spread prior to diagnosis of the disease over the FMD control zone. Then, the introduction of animals and animal products affected with FMDV from countries with FMD into Japan should be strictly prohibited through a variety of regulations.

Received 1 December 1999, accepted 28 December 1999.

Abstract

A methodology was presented for selecting a farming system from multiattribute discrete alternatives by multicriteria analysis. An *ex ante* evaluation of vegetable production systems was performed in addition to a review of previous case studies to demonstrate the usefulness of this methodology and difficulties in applying it. The various methods used in the studies were classified into 3 groups: the compensatory, the non-compensatory, and the distance-based approaches, and were reviewed from a practical viewpoint. Since problems with weighting occurred in many case studies, special attention was paid to weights, especially to their meaning and the way to assess them. On the basis of this discussion, a method using multiattribute value functions was utilized for the evaluation. Labor-saving vegetable production systems under development, in which a self-propelled harvester was introduced and thinning was eliminated, were compared with the conventional system at the farm level based on criteria of profitability and farmwork characteristics. Determination of which labor-saving production system appears more desirable and a framework to effectively investigate “what-if” questions were provided.

Discipline: Agricultural economics

Additional key words: multiattribute value functions, vegetable production system

1...14): [References](#)

Introduction

Many alternative technologies have been proposed for improving farm management. For example, production systems using innovative farm machinery and management practices to mitigate environmental degradation have been studied; results related to profit and loss, working hours, ease of labor, soil erosion, chemical and nutrient contamination, etc., were analyzed or estimated using field experiments, survey methods and simulation techniques. These kinds of information are by themselves considered to be useful for farmers and extension services.

The attributes used for measuring the performance of the systems, however, are in general conflicting with each other. Costs increase when labor-saving machinery is introduced into farm management; margins may decrease when management aims at preserving the environment. Therefore, it is necessary to determine how to evaluate and select a farming system.

The purpose of this study was to develop an approach to select a multiattribute discrete alternative using multicriteria analysis. In Section 2 the methodology was outlined and difficulties were explained through a review of previous studies. In Section 3 the methodology was applied to the evaluation of labor-saving production systems for vegetables.

Methodology and review of previous studies

In this study farming systems were evaluated through solving the following decision problem: to select a solution from a discrete set of alternatives using a set of criteria. These problems (selection problems¹¹) have been studied by discrete multicriteria analysis which attracts much attention because of its ability to deal with ill-structured problems as compared with multiobjective programming (continuous multicriteria analysis).

The methods were classified into 3 groups. First, in the compensatory approach, multiple attributes were aggregated into overall values by, for example, multiattribute value (utility) functions in which the concept of tradeoffs plays a crucial role. Second, in the non-compensatory or outranking approach, aggregation procedures based on concordance and discordance concepts were introduced; the concepts were derived from outranking relations, which indicate that an alternative is at least as good as another one. Third, in the distance-based approach such as compromise programming, the distance between an ideal point and the alternative was minimized.

In the following part, previous case studies will be reviewed and the difficulties in applying these methods will be outlined^{6,7}. After surveying compensatory approaches such as methods using multiattribute value functions, other methods including outranking approaches will be considered.

A method based on an additive multiattribute model has been widely applied for ranking alternatives using an importance order of attributes without specifying numerical values of attribute weights^{8,9,14}. Farming practices were evaluated from the viewpoint of profitability and environmental quality of soil and water. The method, however, was associated with the following problems. (1) The meaning of rank-ordered weights based on the relative importance of attributes was ambiguous. (2) The intervals of overall values were sometimes too wide to make decisions (to develop dominance relationships). (3) The fact that the structure of a value tree (a hierarchy of criteria) may affect the final results was not taken into account. Another method using ranking information on weights (pairwise ranking) has been applied for assessing alternative cropping systems from profitability and environmental quality perspectives³. The weighting procedure of the method, however, was also based on intuitive meaning, although weights based on importance judgments, not derived from attribute ranges, may distort rescaling of single-attribute value functions.

A common technique to alleviate the range problem is swing weighting. This technique has been applied to the evaluation of vegetable production systems from the viewpoint of profitability and farmwork⁴. Since the first step of the assessment is the development of a rank order, the ranked swing weights are also applicable to case studies instead of using intuitive ranked weights.

An outranking approach has been utilized for sorting cropping systems based on their impact on groundwater quality¹. The revised "weighting with cards" method² has been used, although the concept of weights is quite different from the case of additive multiattribute value functions. The concept of weights which does not involve tradeoffs has also been used in the Analytic Hierarchy Process (AHP), though the aggregation procedure is based on compensation. Although this method has been applied to the evaluation of alternative farming systems^{10,12}, there are numerous limitations related to the notion of weights⁵; the method has been criticized even by advocates of outranking approaches². The differences in the interpretation of weights suggest that using more than one type of methods may complicate the interpretation^{6,13}, although it seems to be a safe approach and some authors follow that procedure; for instance, the AHP and compromise programming are used for the same example¹².

An application: evaluation of labor-saving production systems

In this section an application of multiattribute value functions is presented. The decision problem this case study addressed is whether to introduce labor-saving production systems for daikon (*Raphanus sativus* L.) cultivation. The issue is the tradeoff relationship between profitability and working hours with reference to ease of labor. The decision maker was a representative farmer at Hiruzen Heights (440-520 m elevation) in the northern part of

Okayama Prefecture, Japan. Since this is an *ex ante* evaluation, interval representation was introduced into models to cope with imprecision and uncertainty in data as well as in preferences⁴).

1) Evaluation criteria

Farm profitability and farmwork characteristics were used as 2 main criteria that summarize the information contained in many indicators for the evaluation. [Fig. 1](#) illustrates the calculation process. Since the profitability is based on the profit before accounting for unpaid family labor, there is no overlap or redundancy between the 2 attributes. Farm profitability was based on the net profit, which is affected by the percentage of germination, the percentage of the number of openings with germination to the total number of openings in plastic mulch, and the percentage of a yield of high quality to a gross yield. Farmwork characteristics were derived from working hours for each task such as seeding or harvesting.

2) Alternatives

Farming systems, alternatives in decision analytic terminology, can be defined as combinations of components and were developed using the strategy-generation table shown in [Table 1](#). The following 3 production systems for daikon were generated:

1. The conventional system, in which 2 (or 3 in the case of seeding, thinning, harvesting, and carrying) family workers (plus a few hired workers for thinning) cultivate a farm of 5 ha by sowing 2 seeds per opening in a plastic mulch and harvesting by hand.
2. The first improved alternative (labor-saving alternative A, LS-A for short), in which 2 (or 3 in the case of seeding, harvesting, and carrying) family workers cultivate a farm of 5 ha by sowing 1 seed per opening to eliminate thinning work and harvesting with a self-propelled harvester to improve the ease of the work.
3. The second improved alternative (LS-B), which is the same as LS-A except that seeding and harvesting labor is entrusted to an agricultural cooperative.

3) Results

Overall values of each alternative were obtained through the aggregation of weights for each attribute and single-attribute values. The swing weight for profitability was 0.769 and the weight for farmwork characteristics was 0.231. Sensitivity to the weights will be analyzed later. The values are shown in [Table 2](#).

Using the overall values, the relationship among alternatives is represented graphically as (7) in [Fig. 2](#). The representation shows that the conventional system was weakly preferred to LS-A, the conventional system and LS-B were indifferent, and LS-B was weakly preferred to LS-A. Since this is a preliminary analysis of new production systems, sensitivity analysis is expected to provide significant results. Thus, the following discussion will focus on the effects of changes in value judgments and in technical improvements.

The stability of the current results can be represented by weight intervals within which the preference relations do not change. For example, the current relation (7) does not change within $W_1 = [0.718, 0.784]$ and $W_2 = [0.216, 0.282]$. The stability of the results can be expressed as intervals of data that preserve the preference relations in the same way. The current relation (7) does not change within the interval of yield per unit that fluctuates from 0.68 to 1.12 times of the current level provided that the ratio of the high quality price to the low quality price does not change.

As Fig. 1 shows, the percentage of germination and the percentage of a yield of high quality to a gross yield affected the net profits and consequently overall values. These effects can be examined in a two-way sensitivity analysis. Fig. 3 illustrates the results. A point on the graph was defined by a pair of parameters; the first number is the percentage of openings with germination; the second number is the ratio of the percentage of high quality in the labor-saving systems (LS-A or LS-B) to the percentage of high quality in the conventional system. The regions

surrounded by lines, which were numbered from (4) to (11), correspond to the preference relations shown in Fig. 2. The *status quo* was located at (0.9, 0.8). The figure shows that if improvements in the percentages were to be realized, LS-A and LS-B would be preferred to the conventional system, although neither of them would be strictly preferred to the conventional system due only to these technical improvements.

Fig.3. Effects of technical improvements

Concluding remarks

Research on the relationship between farm income and labor utilization is important for evaluating a farming system as illustrated already; it is a traditional theme and many case studies using multiobjective programming or goal programming have employed these criteria⁷⁾. However, the growing concern about the severity of environmental problems such as pollution of groundwater, which may account for the recent increase of case studies using multicriteria analysis, will require that more complex problems be dealt with. Since criteria and alternatives do not exist beforehand and decision makers and perspectives are plural in that case, attention should be paid to problem structuring.

Abstract

Experiments were carried out to analyze the root and water dynamics simultaneously using a minirhizotron on an Alfisol soil in the semi-arid tropics in 1993. Sorghum (CSH 5), pearl millet (ICMV 221), pigeonpea (ICP 1-6), groundnut (ICGS 11) and cowpea (EC 82-7) were used to describe the relationship between the root length density (RLD) and water uptake by roots per day (WU). During the periods from 37 to 46, from 51 to 59 and from 72 to 77 days after sowing, the average values of RLD of sorghum and pearl millet at the soil depth of 15-60 cm were consistently higher than those of pigeonpea, groundnut and cowpea, whereas the average values of WU of the cereals were not always higher than those of the grain legumes. Thus, there was no significant relationship between RLD and WU for the 5 crops due to the higher values of the specific root water uptake (SRWU) of grain legumes than those of cereals in each period. In this study, it was demonstrated that WU and SRWU as well as RLD for the 5 crops could be estimated by using the minirhizotron since dynamic values of the root length of the 5 crops and soil moisture content (SMC) in each soil layer could be quantified from data-sets by frequent observations and with limited sampling errors. Therefore the minirhizotron was found to be a suitable tool for simultaneous monitoring of the root and water dynamics in soil layers except for the soil surface.

Discipline: Crop production

Additional key words: cereals, grain legumes

(Received August 30, 1999; accepted October 29, 1999)

Introduction

The minirhizotron method, which is a nondestructive, rapid and efficient root measurement technique, was applied to observe root development using a microvideo camera in the observation tube^{3,8}. In a similar manner, the soil moisture content (SMC) was estimated by a neutron probe method using an aluminum tube. The minirhizotron and the neutron probe methods are nondestructive and allow continuous observations from the same spot in different soil layers. Thus, these methods are suitable for monitoring time-course changes in root development and SMC. Since the tubes using the minirhizotron and the neutron probe methods are usually embedded in soil separately, it is difficult to estimate the relationship between the root and water dynamics due to soil heterogeneity, artifacts of tube installation and so on. As few studies have been carried out to minimize these factors, attempts were made to analyze the root and water dynamics *in situ* simultaneously. In our previous study⁹, since there was a close positive correlation of neutron counts between aluminum and acrylic tubes, we were able to estimate SMC even by using the acrylic tube based on the following regression equation: $y = 0.97x - 0.044$, $r^2 = 0.99$, where x represents the neutron count for the soil moisture measurement using an acrylic tube and y that using an aluminum tube. The objective of this study was to determine whether the minirhizotron was a suitable tool for simultaneous monitoring of the root and soil water dynamics in soil layers.

Materials and methods

The experiment was conducted during the 1993 rainy season on an Alfisol at ICRISAT Asia Center, near Hyderabad, India. The initial characteristics of the soil in the experimental area were as follows: pH, 6.78 (1:2 soil/water ratio); inorganic N content, 22.9 mg kg⁻¹ soil and NaHCO₃-extractable P, 3.34 mg kg⁻¹ soil. Medium duration pigeonpea (*Cajanus cajan* L. Millsp. cv. ICP 1-6), hybrid grain sorghum (*Sorghum bicolor* L. Moench cv. CSH 5), pearl millet (*Pennisetum glaucum* L.R.Br. cv. ICMV 221), groundnut (*Arachis hypogaea* L. ICGS 11) and cowpea (*Vigna sinensis* Endl. cv. EC 82-7), which are staple food crops in the semi-arid tropics, were sown on broad beds on 25 June 1993. Spacing for the sole crops was as follows: for pigeonpea, 75 x 20 cm; sorghum, 50 x 15 cm; pearl millet, 50 x 15 cm; groundnut, 37.5 x 10 cm and cowpea, 50 x 10 cm. All the plots received a uniform basal application of 25 kg N ha⁻¹ as urea and 20 kg P₂O₅ ha⁻¹ as single superphosphate prior to sowing, which were incorporated into the soil up to 20 cm by disc plowing before sowing. The experimental layout consisted of a randomized complete block design with 3 replications. The size of each plot was 6 x 12 m, consisting of 12 broad beds with a 90 cm width. Heading of pearl millet and sorghum occurred at 51 and 78 days after sowing (DAS) and flowering of groundnut, cowpea and pigeonpea occurred at 30, 51 and 142 DAS, respectively. The crops were harvested at maturity, 85 DAS for pearl millet and cowpea, 114 DAS for groundnut and sorghum and 209 DAS for pigeonpea.

Monitor, Video tape recorder,
Camera control unit, Batteries

Fig.1. Diagrammatic representation of the minirhizotron

Root length of the crops was measured by the minirhizotron method (CIRCON MV9011 agriculture system with MV9390 color CCD microvideo camera) at 31, 46, 60, 74, 84, 105, 143 and 169 DAS. The transparent plastic minirhizotron tubes (58 mm in diameter and 100 cm in length) were installed at a 45° angle between rows of each crop before sowing (Fig. 1). This experiment was carried out in an Alfisol with a hardpan layer below 60 cm. Root length at 15 cm intervals up to 60 cm depth was calculated from the number of roots observed on a video display¹⁵⁾. Soil moisture was measured with a soil moisture meter (Model 3332, Troxler Electronic Laboratories Inc., N.C., USA) at 15 cm intervals up to 60 cm depth except at the soil surface using the same transparent acrylic tube as in the minirhizotron method at 7, 23, 37, 46, 51, 59, 72, 77, 93, 107, 119, 143, 157, 172 and 213 DAS. Usually, SMC at the soil surface was measured by the gravimetric method. Thus, we analyzed seasonal changes in SMC at the depths of 15-30, 30-45 and 45-60 cm, where consecutive data could be obtained in the same spot in this study. The values of SMC on a weight basis in each layer were converted to the values on a volume basis by multiplication by the bulk density for an estimation of water uptake by roots per day (WU). The values of the bulk density at the depths of 15-30, 30-45 and 45-60 cm were 1.69, 1.59 and 1.59 Mg m⁻³, respectively. The WU was estimated based on the volume of water extracted within the respective soil layers per day. The specific root water uptake (SRWU) referred to the volume of water extracted within a soil layer per unit root length per day⁶⁾.

During this study, rainfall which amounted to 695.2 mm was mainly distributed at the onset of the rainy season (June-November) ([Fig. 2](#)). Nine, 6 and 7 mm of water were used for irrigation at 79, 143 and 155 DAS, respectively.

BACK

Results

1) Seasonal changes in SMC

Seasonal changes in SMC at the soil depths of 15-30, 30-45 and 45-60 cm determined with a minirhizotron for 5 crops are depicted in [Fig. 3-a, b and c](#), respectively. Water flow was assumed to be one-dimensional with the increase in SMC on successive dates being attributed to rainfall and irrigation and the decrease attributed to the root uptake. Fluctuation range in SMC was lower at the soil depth of 15-30 cm, followed by the soil depth of 30-45 cm and the widest range in SMC was obtained at the soil depth of 45-60 cm during the sampling period, presumably due to the presence of a hard layer below 60 cm depth. Since a decrease in SMC on successive dates was obtained during 3 periods from 37 to 46, from 51 to 59 and from 72 to 77 DAS before the harvest of pearl millet and cowpea as shown in Fig. 3, these periods were selected to estimate the WU of the 5 crops.

2) Estimation of total root length (TRL), RLD, WU and specific root water uptake (SRWU) of 5 crops using the minirhizotron

The seasonal changes of TRL of the 5 crops are depicted in [Fig. 4](#). The values of TRL of pearl millet and sorghum were higher than those of cowpea, groundnut and pigeonpea except at 31 DAS. During the periods from 37 to 46, from 51 to 59 and from 72 to 77 DAS, the average values of RLD of sorghum and pearl millet at the soil depth of 15-60 cm were consistently higher than those of pigeonpea, groundnut and cowpea, whereas the average values of WU of cereals were not always higher than those of the grain legumes ([Table 1](#)). Thus, there was no significant difference between the RLD and WU of the 5 crops in each period ([Fig. 5-a, b and c](#)) due to the higher values of SRWU of grain legumes than those of cereals. The average values of SRWU for groundnut, cowpea and pigeonpea were higher than those for pearl millet and sorghum, namely 2.5 to 5.8 times higher during the period from 37 to 46 DAS, 2.4 to 8.0 times during the period from 51 to 59 DAS and 2.5 to 5.8 times during the period from 72 to 77 DAS.

Discussion

The main advantage of the minirhizotron method is the ability to monitor root growth and death throughout the growing period^{3,8}. On the other hand, one disadvantage is the quantitative discrepancy with the conventional destructive method in the soil surface layers^{1,2}. Katayama et al.¹⁰ showed that in the surface soil layers, the ratios of RLD observed using the minirhizotron compared with the monolith method were below unity, indicating that the RLD value obtained by the minirhizotron is likely to be underestimated. Underestimation at the soil surface may be due to the effects of light leaking through the top of the minirhizotron tubes above the soil surface¹¹ and to temperature differences at the glass-soil interface^{7,12,15}. Katayama et al.¹⁰ reported that the values of TRL of pearl millet and sorghum were significantly higher than those of cowpea, groundnut and pigeonpea when the monolith method was used due to the higher RLD values of cereals compared with grain legumes at the soil surface. Polley et al.¹⁴ reported that the root biomass of the C₄ monocots is concentrated in the upper 20 cm layer of soil. Thus, it is assumed that the values of TRL of the 5 crops shown in Fig. 4 were underestimated.

In this experiment, it was found that the WU of pearl millet and sorghum with higher RLD values was not always greater than that of groundnut, cowpea and pigeonpea with lower RLD values due to the higher values of SRWU of grain legumes than those of cereals. Difference in stomatal conductance

between C₃- and C₄-pathway species may be partially responsible for the variation in water use⁴. However, the discrepancy between RLD and WU of cereals and legumes in this study was in agreement with the results obtained in cereals and legumes of C₃-pathway species by Hamblin and Tennant⁶. They reported that cumulative uptake water by roots for wheat from the soil profile over the period from 70 to 110 DAS was very similar to that of lupin, although the value of the TRL per unit ground area of wheat was 9 times as high as that of lupin⁶. They also showed that the apparent water uptake per RLD per day was greater for lupin than wheat since lupin had large and abundant metaxylem vessels in roots, which give a much lower axial resistance of roots, compared with wheat⁶. Moreover, the discrepancy between RLD and WU in monocotyledonous and dicotyledonous species consisting of maize, sorghum and sunflower, was also reported elsewhere^{5,13}.

In this study, it was demonstrated that WU and SRWU as well as RLD for 5 crops could be estimated using the minirhizotron since the dynamic values of the root length of the 5 crops and SMC in each soil layer could be quantified based on data-sets by frequent observations and with limited sampling errors. Therefore the minirhizotron was found to be a suitable tool for simultaneous monitoring of the root and water dynamics in soil layers except for the soil surface.

Abstract

The consumption of chemical fertilizers in 1996 amounted to 511,700 t for nitrogen (N), 610,100 t for phosphorus (P₂O₅), 441,200 t for potassium (K₂O). The area of orchard fields was 314,900 ha in 1995 and the ratio to the total cultivated area was 6.4%. If the same amount of chemical fertilizer is applied to each field, the total application to orchard fields should be 32,700 t for nitrogen, 39,000 t for phosphorus and 28,200 t for potassium, respectively. In this report, we estimated the input of chemical fertilizers to orchard fields based on the results of official surveys of orchard area and the standard application rate based on the cultivation guidelines adopted in 37 prefectures. In 1995, the input for main fruit tree species amounted to 50,600 t for nitrogen, 36,400 t for phosphorus and 40,700 t for potassium. The output of nutrients from the orchard fields was estimated based on the results of field experiments for the nutrient uptake of fruit trees as follows: 39,800 t for nitrogen, 9,100 t for phosphorus and 35,300 t for potassium for mature fruit-bearing trees. The ratio of estimated input to output was 1.3 for nitrogen, 4.5 for phosphorus and 1.2 for potassium, respectively. These results indicate that the amount of chemical fertilizer application to the orchard fields may be appropriate for nitrogen and potassium but is excessive for phosphorus. However the total nutrient balance was not calculated exactly in Japanese orchard fields because the total nutrient input could not be determined owing to the paucity of statistical data on organic matter application and also the total output could not be calculated due to the paucity of field experimental data.

Introduction

Many temperate and some tropical fruit trees are planted in Japan because the country consists of many islands extending from the temperate to the subtropical zone. The total area of fruit trees decreased from 430,000 ha in 1975 to 308,000 ha in 1996. Especially the area of citrus fruits decreased remarkably and the area in 1995 was about half of that in the 1975s. This decrease of the area is due to the decrease in the fruit demand. The demand for citrus fruits per capita per year decreased from 25 kg in 1975 to 11 kg in 1995. This situation is attributed to the diversification of eating habits or food culture associated with the changes in the economic conditions. The increase of fruit importation is also likely to affect the decrease of area. Along with the changes in the marketing environment, the quality of fruits is becoming more important than the quantity for sales. These changes led to a decrease in the rate of fertilizer application to orchard fields because, based on many field experimental data, emphasis was placed on the production of high quality fruits under suitable low application rates. However, the surplus fertilizer that was applied previously may affect the environment around the orchard fields. As the sustainability of agriculture has become a social problem, it remains to be determined whether fertilizer or organic matter application results in a load to the surroundings of orchard fields. We attempted to estimate the nitrogen (N), phosphorus (P_2O_5) and potassium (K_2O) balance in relation to chemical fertilizer application by compiling the results of surveys and field experiments to determine the nutrient balance in Japanese orchard fields.

Input of nitrogen, phosphorus and potassium associated with chemical fertilizer application

The standard application rate of fertilizer to orchard fields was determined based on the results of field experiments in most of the prefectures. We compiled the rates from the cultivation guidelines adopted in 37 prefectures. The rates are generally determined depending on the species and age of the fruit trees. The yield of fruits and the soil type of orchard fields are also key factors to determine the rate in some prefectures.

1) Species of fruit trees

[Table 1](#) shows the mean of standard application rates of nitrogen, phosphorus and potassium for mature fruit-bearing trees. These results indicate that much more fertilizer is applied to orchard fields with evergreen and tropical fruit trees. The means of rates ranged from 204 to 350 kg per ha for nitrogen (N), 115 to 239 kg per ha for phosphorus (P_2O_5) and 160 to 310 kg per ha for potassium (K_2O). The rates for the late maturing citrus species, Navel orange, 'Iyo' tangor, 'Hassaku' pummelo mandarin and Natsudaidai, were higher than those for the early maturing species, 'Unshu' mandarin. But in the case of Unshu mandarin, the rates for the late maturing varieties were almost the same as those for the early maturing varieties although the late maturing varieties were harvested in the same season as the late maturing citrus species. For the deciduous fruit tree species, the rate for Japanese pears was the highest and about twice that of apple and grapevine trees for nitrogen. These differences may depend on the nutrient uptake and the characteristics of root distribution. The rates for the evergreen fruit trees that did not bear fruits were also higher than those for the deciduous fruit trees that did not bear fruits as well as mature fruit-bearing trees ([Table 2](#)).

2) Age of fruit trees

The standard application rates of fertilizer for the trees that did not bear fruits (from 3 to 5 years old) ranged from one-third to one-fifth of those of mature fruit-bearing trees (10 or more years old) (Tables 1, 2). The application rate of fertilizer to each mature fruit-bearing tree should range from 6 to 10 times that of trees that did not bear fruits because the planting density of the latter trees is about twice that of the mature fruit-bearing trees. This difference may be due to the size of the trees. The rates for bigger mature fruit-bearing trees should be higher than those for smaller trees that did not bear fruits because fertilizer is usually applied under the trees. The rates for mature fruit-bearing trees usually increase until the trees become about 15 years old. However, the rates are almost the same after 15 years in many fruit tree species, while the rate for Unshu mandarin increases until 50 years after planting.

3) Yield of fruits

As the yield increased, the application rates of fertilizer increased for each fruit tree species. The rates for the high-yielding species such as citrus fruit and pineapple trees were generally higher than those for the other fruit trees (Table 1). However the yield of apple trees was high although the application rate was low. And the yield in plastic greenhouses was about 1.5 times higher than that in orchard fields with the same fertilizer application rates in the case of Unshu mandarin. These differences may be due to the climatic conditions during the growth period of fruits. The ratio of application rate to yield was higher for chestnuts, loquats and cherry tree which gave a low yield ([Table 3](#)). But the ratio was significantly low in apple trees and half or one-third of that of the other trees.

4) Soil type

The application rates of chemical fertilizer were determined for certain soil types in some prefectures. The rate was generally higher in sand-dune regosols and lower in andosols. This difference between the soil types is usually not as conspicuous as that between fruit tree species. However this difference must affect the rates of each fruit tree species because the main area of citrus species consists of yellow soils whereas that of apple and grapevine trees consists of brown forest soils.

[NEXT](#)[TOP](#)

Output of nitrogen, phosphorus and potassium

The output of nutrients from the orchard fields is mainly estimated based on the nutrient uptake of fruit trees. However, there are few field experimental data because it is very difficult to determine the nutrient uptake of fruit trees in orchard fields. In one field experiment, 2 middle-sized trees were selected at first. One tree was cut in spring and the other tree in winter. The nutrient uptake was calculated by the difference in the dry weight between the 2 cut trees and the nutrient content of each section. [Table 4](#) shows the total nutrient uptake of 11 fruit tree species that was calculated based on the results of the field experiments^{1-12,14}. These results show that the nutrient uptake of evergreen fruit trees was higher than that of deciduous fruit trees, while the potassium uptake of chestnut trees was lower than that of the other trees compared to nitrogen and phosphorus¹. On the other hand, the phosphorus and potassium uptake of kiwifruit was higher than that of the other trees⁷. However, it is difficult to determine the nutrient uptake of each fruit tree species because the age of the sample trees and yield of fruits were different and the soil type was also different in each experimental field. A larger number of experimental data should be collected to determine whether these differences are associated with the nutrient requirement of each fruit tree species.

Nitrogen, phosphorus and potassium balance in relation to chemical fertilizer application

The input of chemical fertilizer to the orchard fields was calculated by the following formula based on the orchard area determined in the official surveys¹³ and the average value of the rates of chemical fertilizer application compiled from the cultivation guidelines adopted in 37 prefectures.

Input (t) = Orchard area (ha) x Chemical fertilizer application rate (kg/ha)/1000

The input of fruit-bearing trees and trees which did not bear fruits was 50,600 t for nitrogen, 36,400 t for phosphorus and 40,700 t for potassium, respectively in 1995. The output from fruit-bearing trees in the orchard fields was calculated by the following formula based on the orchard area determined in the official surveys and field experimental data of nutrient uptake.

Output (t) = Orchard area (ha) x Nutrient uptake based on field experiment (kg/ha)/1000

However, it was difficult to calculate the output because no field experimental data of nutrient uptake were available for pineapples, Navel orange, Iyo tangor, Hassaku pummelo mandarins, cherries, plums and pears. The data of other similar species were used for these species to calculate the output. The data of Natsudaidai were used for Navel orange, Iyo tangor and Hassaku pummelo mandarins. The data of peaches^{8,14} were used for cherries. The data of Mume apricot were used for plums. The data of Japanese pears⁹ were used for pears. However since there were no good data for pineapples, the output was estimated to be half of that of the chemical fertilizer application. The output from fruit-bearing trees in 1995 was 39,800 t for nitrogen, 9,100 t for phosphorus and 35,300 t for potassium, respectively.

The ratio of the input to output was 1.3 for nitrogen, 4.5 for phosphorus and 1.2 for potassium. The ratio of each fruit tree species ranged from 1 to 2 for nitrogen and potassium and from 2 to 6 for phosphorus, excluding Japanese pears ([Table 5](#)). These results indicate that the balance of nitrogen and potassium was adequate in 1995 while the phosphorus balance was excessive in the Japanese orchard fields. However about 30 years ago, the rates of nitrogen and potassium were also almost twice those of the present ones. The surplus chemical fertilizer may flow to groundwater. It was reported that the NO₃-N content of groundwater is presently above the environmental upper standard (10 mg/L) in some orchard fields. Results from the surveys in orchard fields show that phosphorus tends to accumulate in soil. In these areas, the available phosphorus content exceeds 100 (mg/100 g dry soil) although the adequate level of available phosphorus is 30 (mg/100 g dry soil) based on the official guidelines adopted for orchard fields.

In Japanese pears, the ratios were higher than in the other species. Especially the ratio of phosphorus was remarkably high with a value of 8. This difference may be due to the planting density. We used the mean of chemical fertilizer application rates and the nutrient uptake in order to estimate the nutrient balance. The planting density of mature Japanese pears is the lowest among all fruit tree species, 70 per ha ([Table 4](#)). Therefore, Japanese pear trees may not be able to absorb nutrients effectively because the root distribution is not very dense.

Organic matter application and nutrient balance

We must estimate the total input of organic matter to calculate the nutrient balance exactly in orchard fields. However, we could not estimate the input because statistical data were not available. The results of the official surveys covering 2,757 farmers show the tendency of organic matter consumption. The standard nutrient contents of 12 organic materials are also listed for nitrogen (0.6~3.6%), phosphorus (0.2~5.1%) and potassium (0.3~2.7%). If the consumption of these organic materials, nutrient contents and area data are used to estimate the input of organic matter, the input to the orchard fields should amount to 11,900 t for nitrogen, 15,600 t for phosphorus and 12,400 t for potassium. This input ranged from half to one-fourth of that from chemical fertilizer. However, organic matter application is common in only some orchard fields because it is difficult to obtain a sufficient amount of organic matter in other orchard fields. Therefore these data show that nutrient input from organic matter may be the same as or higher than that from chemical fertilizer in some orchard fields. The surplus organic matter may lead to eluviation of nutrients around the fields. The results of the soil surveys in orchard fields show that the potassium content

of soils is excessive in some orchard fields to which a large amount of manure had been applied for a long time because the manure has a high potassium content. In these areas, the rate of potassium fertilizer application decreased.

Conclusion

We estimated the input of chemical fertilizer to the orchard fields based on the results of official surveys of orchard areas and the standard application rate based on the cultivation guidelines adopted in 37 prefectures in 1995. The input was 50,600 t for nitrogen, 36,400 t for phosphorus and 40,700 t for potassium for the main fruit tree species. The output of nutrients from the orchard fields was estimated from the results of field experiments for the nutrient uptake of fruit trees. The output was 39,800 t for nitrogen, 9,100 t for phosphorus and 35,300 t for potassium for mature fruit-bearing trees. Because the ratio of the input of chemical fertilizers to the output from fruit trees was 1.3 for nitrogen and 1.2 for potassium, the application of nitrogen and potassium fertilizer to the orchard fields is not considered to affect the surrounding environment presently. But about 30 years ago, the application rates were almost twice those of the present ones. The NO₃-N content of groundwater exceeds the environmental upper standard (10 mg/L) in some orchard fields. And the available phosphorus content is above 100 (mg/100 g dry soil) in some orchard fields although the adequate level is 30 (mg/100 g dry soil) based on the guidelines for orchard fields because the ratio of input to output is still 4.5.

The total nutrient balance was not calculated exactly because the total nutrient input could not be determined due to the paucity of statistical data on organic matter applications. Moreover, the total output could not be calculated due to the paucity of field experimental data. However the results of the estimation of the nutrient balance in relation to chemical fertilizer application indicate that the total nutrient balance in some orchard fields may show an excess in nitrogen, phosphorus and potassium. The surplus nutrients must lead to the increase of the available nutrient content in soil and result in a load to the surrounding environment of the orchard fields if heavy application continues.

Abstract

PCR-RFLP analysis of the ITS region in the ribosomal RNA gene cluster revealed that Japanese isolates of the southern blight pathogen consisted of 5 groups. Groups 1, 2 and 3 corresponded to *Sclerotium rolfii*, whereas groups 4 and 5 were similar to *S. delphinii*, a related species of *S. rolfii*. Most of the isolates belonging to groups 1 and 2 were detected in the central to southwestern regions of Japan, while groups 3, 4 and 5 were distributed in the central to northern regions. Although the ITS-RFLP groups also differed in the size of the sclerotia, the sclerotial size varied with the incubation temperature and became indistinguishable at high temperatures. These groups showed hyphal anastomosis with one another, indicating their conspecificity.

Discipline: Plant disease

Additional key words: *Sclerotium rolfii*, *Sclerotium delphinii*

1...19): [References](#)

(Received September 6, 1999; accepted October 28, 1999)

Introduction

Sclerotium rolfii Saccardo (teleomorph; *Atheria rolfii* (Curzi) Tu & Kimbrough) is a soil-borne plant pathogenic fungus, which infects approximately 500 species belonging to 100 plant families⁶⁾ including soybean, peanut, and other leguminous crops. Infection occurs at the level of or just below the soil surface, causing basal stem rot and blighting of the leaves, referred to as southern blight. Southern blight is characterized by the presence of white mycelium and brown sclerotia, about the size of mustard seeds on diseased plants (Fig. 1a, b). Sclerotia act as the primary inoculum, since they are the sole organ capable of withstanding adverse conditions. Asexual spores are not produced, and the sexual stage is seldom observed^{14,15)}. Hot and humid weather is conducive to sclerotial germination and mycelial growth, and consequently the disease is more serious in subtropical and tropical regions than in temperate regions¹⁹⁾.

Fig.1. Mycelia and sclerotia formed on a peanut plant (a) and potato-dextrose agar (b)

Although *S.rolfsii* does not usually prevail in the cool temperate zone, southern blight has also been reported in the central to northern regions of Japan^{9,11,16}), suggesting the existence of subgroups of *S.rolfsii*, which may be adapted to relatively low temperatures. Another possibility is that the isolates reported from cool regions belong to *S.delphinii* Welch, a related species to *S.rolfsii*. *S.delphinii* is known to infect ornamental plants grown in temperate regions in North America, e.g. Delphinium sp.¹⁸), scilla¹⁰), lilies and iris¹⁷). Differentiation of these 2 species based on morphological criteria is difficult although they may be distinguished by the size of the sclerotia^{13, 17}).

Recent advances in molecular techniques have enabled inter- and intraspecific grouping of fungi³) with few morphological differences. The analysis of restriction fragment length polymorphisms (RFLPs) of the internal transcribed spacer (ITS) region of ribosomal RNA genes (rDNA) indicated the presence of genetic variation in *S.rolfsii*^{8,12}). In this paper, we reviewed the genetic variation of the Japanese isolates of the southern blight fungus and their geographic distribution. We also evaluated the species concept in *S.rolfsii*.

ITS-RFLP analysis

ITS-RFLP analysis was first applied to *S.rolfsii* and related species by Harlton et al.⁸⁾. They tested 119 *S.rolfsii* isolates and 12 *S.delphinii* isolates from the U.S.A. and other countries, using restriction enzymes *Alu* I, *Hpa* II, *Rsa* I and *Mbo* I. *S.delphinii* was distinguished from *S.rolfsii* by the *Rsa* I pattern, and *S.rolfsii* isolates were classified into 12 groups (I to XII). They also suggested the existence of phylogenetic relationships ([Fig. 2](#)).

To determine the geographical variability in the *S.rolfsii* population, we examined 67 isolates from different hosts and various regions of Japan, and classified them into 5 ITS-RFLP groups ([Figs. 3 and 4](#))¹²⁾. Groups 1 and 2 were distributed in the southwestern region of Japan, which is located in the warm temperate zone, and groups 3, 4 and 5 were found in the central to northeastern regions of Japan, which are cool temperate regions. Groups 1 and 3 corresponded to groups II and XI, respectively, and group 4 showed the same pattern as that of *S.delphinii* from the U.S.A. Groups 2 and 5 were newly found, and group 2 was similar to group 1, whereas group 5 was close to group 4.

ITS-RFLP analysis indicated that isolates resembling *S.delphinii* were distributed in the central to northern regions in Japan, whereas *S.rolfsii* occurred in the central to southwestern regions. The boundary was not clear, and they overlapped in the Kanto and Hokuriku areas. All the groups except for group 3 were found in Tokyo, suggesting that trade of seedlings and bulbs had introduced various *Sclerotium* strains.

Growth temperature reaction of ITS-RFLP groups

The most evident morphological difference between *S.rolfsii* and *S.delphinii* lies in the sclerotial size: *S.delphinii* produces larger sclerotia than *S.rolfsii*¹⁷⁾. We observed sclerotial formation in several isolates of groups 1, 2 and 4 grown on potato dextrose agar (PDA) plates at various temperatures. Group 4 produced larger sclerotia than group 1 ([Fig. 5](#)). However, the size decreased with increasing temperature, and the difference between groups 1 and 4 became less distinct. Sclerotial size of group 2 was similar to that of group 1 (data not shown). Few sclerotia were formed by isolates of group 5, and group 3 failed to produce sclerotia.

S.delphinii and *S.rolfsii* also differed in the optimal temperature for mycelial growth. *S.rolfsii* grew better at high temperatures¹³⁾ than *S.delphinii*, which is in agreement with the fact that *S.rolfsii* is prevalent in tropical and warm temperate regions whereas *S.delphinii* occurs in cool temperate regions. In our observations of the Japanese isolates, the growth temperature response was different among the ITS-RFLP groups but did not vary as much as that between *S.delphinii* and *S.rolfsii* in foreign countries. Group 1 showed optimum growth on PDA at 30°C ([Fig. 6](#)), but the growth rate decreased at 33°C whereas *S.rolfsii* isolates from the U.S.A. and South Asia grew well even at 35°C^{5,13)}. The optimal growth temperature was 28°C for most of the isolates of group 5 and some of group 4, but other isolates of group 4 grew most rapidly at 30°C. Group 2 showed the same pattern as group 1 (data not shown), and one isolate of group 3 was not included in this test because it showed restricted growth.

Hyphal anastomosis between different RFLP groups

Conspicuity can be determined by hyphal interactions in basidiomycetous fungi. Hyphae of the same isolate often fuse (or anastomose) with one another, forming a hyphal network. Anastomosis may also occur between hyphae of different strains of the same species but usually results in the death of fused cells and in the subsequent formation of a boundary line between the mycelia. Hyphal anastomosis does not occur between different species⁷⁾ nor between genetically isolated populations within a species complex³⁾.

Hyphal anastomosis was observed between different RFLP groups, when they were paired on water agar plates ([Fig. 7](#)). Fused hyphal cells in the contact zone subsequently died in every combination except for the self-pairings, suggesting that all the groups should be considered as the same genetic entity. Some researchers proposed the term *S.rolfsii* var. *delphinii* to accommodate *S.delphinii* in the *S.rolfsii* complex²⁾.

Conclusion

ITS-RFLP analysis suggested the existence of population differentiation in the southern blight fungus in Japan. The groups from southern regions included *S.rolfsii*, and those distributed in the northern regions corresponded to *S.delphinii* in a broad sense. Before ITS-RFLP analysis was applied, *S.rolfsii* and *S.delphinii* had been distinguished by the sclerotial size and optimal growth temperature. However, sclerotial morphology was found to vary with the incubation temperature, and optimal growth temperature did not enable to distinguish ITS-RFLP groups in Japan. Lack of significant differences within the southern blight fungus may be due to the less distinct climatic differences between localities in Japan, and indicate the existence of intergrades between the 2 species. *S.rolfsii* and *S.delphinii* are considered to represent 2 extremes of continuous variation.

Information about the mating behavior of *S.rolfsii* and *S.delphinii* is limited, and the biological species concept¹⁾ is not easily applicable to these fungi. The phylogenetic tree based on ITS-RFLP analysis indicated a close relationship between these species (Fig. 2). Moreover, hyphal anastomosis also suggested their incomplete segregation as separate species. Further investigations are required to reveal the genetic background of the groups and to reassess the species concept of *S.rolfsii* and *S.delphinii*.

Abstract

Studies on the robotization of agricultural vehicles have been conducted to perform labor-saving, high-precision operations, etc. Component technologies for the robotization were described in general, along with navigation systems. As an example of robotized vehicles, we planned to develop a tilling robot. To recognize the position with an error less than 5 cm and at intervals less than 1 s, we developed 3 types of navigation systems; an off-the-wire type, a kinematic global positioning system (GPS) with inertial navigation system (INS) type and an optical type.

Discipline: Agricultural machinery

Introduction-Objectives of robotization of agricultural vehicles

Currently, whether the agricultural industry in Japan will be able to survive is a cause for concern due to the difficulty in finding successors and the rapidly expanding market for imported agricultural products. Efforts are being made to promote the industry through labor-saving, lower costs, and enhanced product quality. In addition, studies on the robotization of agricultural vehicles have been conducted in recent years²⁾ to achieve the following objectives³⁾:

- 1) Labor-saving through completely unmanned operations,
- 2) High-precision work superior to human work, and
- 3) Improvement of safety and amenity by eliminating operator intervention.

Subsequently, new working methods will be developed in response to the robotization of agricultural vehicles and the following additional benefits are anticipated³⁾:

- 1) Single operator can manage and operate many vehicles concurrently,

2)Through continuous day and night work, a small machine can cover a large area and solve problems such as soil compaction, and

3)The ability to detect vehicle positions will enable to obtain information on yield and soil conditions of each part of the field, and to execute precision farming.

This paper describes the navigation systems we studied, together with the control of vehicles with these systems and the performance of their prototypes.

Technology and conditions required for robotization of agricultural vehicles

1) Component technologies³⁾

The component technologies that support the robotization of agricultural vehicles are similar to the 5 main components for common mechatronics systems, which are listed in Fig. 1. Each component is described below.

Fig. 1. Component technologies for the robotization of agricultural vehicles

(1) The energy supply and operating functions require technical developments, in addition to conventional technology, in the following areas:

- a. While an actuator mechanism which provides excellent control is required for the steering, throttle, transmission, and brake operations in place of an operator, conventional systems for manual operation are also required for traveling to and from the field and teaching the field area.
- b. Various adjustments of the implements must be automated to enable unmanned operation.
- c. Power sources corresponding to the sensor and actuator are required.
- d. Each part must be highly reliable since prompt detection of failures cannot be expected during unmanned operation.

(2) The information transfer and signal conversion functions require a keyboard and monitor for dialogues between the robotized vehicle and the operator. In addition, stable communication functions are required among the sensor, controller and actuator, depending on the navigation system used and also between the vehicle and an external device.

(3) Judgment and decision functions determine the vehicle behavior. These are the basis of the system, which is composed of a computer, hardware including peripheral devices and software.

The know-how necessary to perform unmanned operations is incorporated into the software. A slight error in judgment and control may lead to an accident. Therefore methods such as a division of tasks are required for avoiding such malfunctions, and sufficient field tests under various conditions are also required.

(4) For the sensing and recognition functions, the robot itself must detect internal information such as the fuel level and operating conditions of each part, as well as external information such as the vehicle position, heading, and the status of the soil and peripheral conditions. Although the information about navigation is particularly important for the robotization of vehicles, since no navigation system currently in use efficiently meets the requirements of cost, performance, and ease of use, new technology must be developed.

2) Conditions for development and introduction

Each component described before is required for robotization of vehicles to function under the conditions of use required by outdoor agriculture. [Table 1](#) shows the conditions of use as compared with those in other fields. The conditions of use for agricultural vehicles, such as the operator, annual operating hours, and the capital of the managing body, differ markedly from those in other fields. Therefore, considerations for lowering the cost, enhancing the reliability, and improving the operation should be included from the beginning of development.

Navigation systems-classification and objectives

1) Classification and adaptability of navigation systems

Classification of navigation systems is shown in [Table 2^{5\)}](#). Because fields vary widely depending on the kind of crops and the stage of work, there is no universal navigation system that can adapt to every stage of agriculture. [Table 3](#) shows the general adaptability of the respective navigation systems in the case of agriculture⁶⁾. In the following, general conditions and the restricting factors are described.

- (1) In paddy fields or upland fields, since the whole field is tilled, it is almost impossible to use a fixed route with a mechanical system. Furthermore, because the running route is fixed, a fixed route may lead to the deterioration of soil penetrability due to the pressure on the soil.
- (2) When using the spot mark system, the other navigation systems must be applied between the marks.
- (3) The accuracy of the internal information system will decrease in a large field or during long continuous work. A field with a slippery surface may cause an error in the estimation of the traveling distance based on wheel rotation.
- (4) When visually observing external information from the vehicle, such as a known point, an error may occur due to the rolling and pitching of the vehicle, which requires a correction.
- (5) Since no stable map in the field, is available, it is difficult to apply the map matching method used in the case of car navigation.
- (6) The external information system may not be applied where the work boundary is unclear, such as during puddling, or in the absence of ridges or row edge.
- (7) When using the external mark system, the measurement may be hindered by obstacles, depending on the observation medium. For example, when light is used as the medium, shade from trees in an orchard may occur, or the measurement may not be correct due to reflected rays from a glasshouse.

2) Navigation systems for tilling robot

As an example of robotized agricultural vehicles, we planned to develop a tilling robot that can recognize its own position and heading, while performing unmanned tilling at almost the same work rate as manual work.

Based on the above factors, external information system and the external mark system of a free route type were considered to be suitable for the position detecting system for tilling robots. Furthermore, we estimated that the concurrent use of an internal information system with distance and heading system is adequate for detecting the vehicle heading in the turning and for temporarily continuing the unmanned operation during a malfunction of the positional detecting system.

Among the navigation systems described in this section, the systems that have been studied are outlined below.

[NEXT](#)

BACK

Navigation systems-positioning systems

1) Development of off-the wire type navigation system (LNAV) [6,7](#)

The LNAV developed by KUBOTA Co. is a navigation system characterized by a free route and external information with a relative distance. The cables for generating the magnetic fields for each modulation frequency are installed, as shown in [Fig. 2](#). Although the magnetic fields are generated in the field depending on the distance from each cable, the relation between the strength of the magnetic field and the distance is not linear, since each cable has a finite length. Therefore, as shown in [Fig. 3](#), a magnetic field sensor is mounted on the right and left front parts of the vehicle. The vehicle performs a teaching run along the field boundary by manual operation. The teaching data TD0 related to the boundary of the field are obtained from the left sensor, and the teaching data TD1 of the magnetic field distribution along the first returning path are obtained from the right sensor. Then, the magnetic field distribution data at the end of the path are also obtained. In the first returning path in an autonomous operation, while performing an autonomous straight run by referring to the TD1 from the left sensor, the vehicle automatically obtains the TD2 for the next path from the right sensor. After the 180° turn based on information on the end position, the vehicle performs the next straight run according to the TD2. In this way, the LNAV does not detect the absolute position in the field but guides the vehicle to repeat the magnetic field distribution initially obtained for performing the operation.

Based on the above description of the LNAV system, no test was performed to measure its positioning accuracy, but because it could accurately repeat the autonomous run on the taught path, it was estimated that with this system the error was 5 cm or less. Furthermore, the data sampling interval was 0.1 s or less. This system is not influenced by natural conditions like weather. However, the cost to construct the cable line and the fixed path for work are limiting factors.

2) Development of GPS type navigation system (SNAV) [6,7](#)

The SNAV developed by Japan Aviation Electronics Industries, Ltd., is a navigation system characterized by a free route and external marks with hyperbolic navigation. In the SNAV the differential GPS (DGPS), geomagnetic sensor (TMS) and the inertial measuring unit (IMU) are combined with the device configuration as shown in [Fig. 4](#). The GPS system has a data sampling interval of 1s basically. As the communication and processing times are added, the calculated DGPS position data involve a considerable delay. The SNAV supplements the positions during such delays using an IMU.

Presently, satisfactory positional detection has been achieved at intervals of 0.1 s. The positioning error amounted to several cm or less over several hours of measurement when the mobile station was fixed to a position. And the errors in autonomous operation were 10 cm or less due to the decrease of the turning velocity in taking account of the capacity of the IMU.

Several types of GPS positioning systems have been commercialized by several companies. The accuracy and the sampling rate are sufficient in the double frequency real time kinematic GPS type. However, the cost and information service of the reference station are still unsolved.

3) Development of optical type navigation system (XNAV) [4,6](#)

The XNAV is a navigation system characterized by a free route and external marks with traverse surveying. The XNAV was developed by BRAIN-IAM and the manufacture of its prototype was assigned to Sanyo Electric Co., Ltd.

(1) System configuration and principle

The principle of the XNAV measurement is shown in [Fig. 5](#). Target P, installed on the vehicle, was observed from the center O of the transit section of the reference station. The diagonal distance L between O and B, the horizontal angle H formed by the reference line and segment OP, and the vertical angle V are obtained. And then the coordinates of the target point P (x_i , y_i , z_i) are obtained through the principle of traverse surveying. Although segment OP can always be obtained by tracing and estimating the target from the reference station ([Fig. 6](#)), the steps to follow are shown in [Fig. 5](#).

Fig.6. References station of the prototype XNAV system

a. Input image 1 when the strobe light on the target is lit and image 2 when it is not lit at the shortest possible interval,

b. Compute the differential image between image 1 and image 2, and binarize it,

c. Extract the strobe image from the differential image,

d. Repeat steps a to c to calculate the traveling speed of the target,

e. Move the transit section so that the strobe image appears in the center of the image sensor, and

f. Measure distance L and calculate the position.

(2) Performance, precision, and ease of use

In the test results of the XNAV, the positions were detected during continuous operation of approximately 15 min at the velocity of 0.4 m/s in a roughly flat field 45x15 m in size. The positioning accuracy was 5 cm or less with an average data sampling interval of 0.52 s. However, sometimes the target was missed during a steep turn. Manual coordination was required on 2 occasions, and at other positions the measurements could be continued by using the self- tracking restoration function.

(3) Characteristics and problems

Although this system does not require field equipment other than one reference station in the field, there are shortcomings, including adaptation to the changes in natural lighting conditions and reliability of the self-restoration function.

(4) Total station of automatic tracking type AP-L1¹⁾

Fig.7. References station of AP-L1

Total station AP-L1, with an automatic tracking function for moving objects, was put on the market by TOPCON, Co., while the XNAV was under development. The AP-L1 is able to track and range the target automatically by a single laser beam, and is also equipped with automatic searching and retracking functions when the target is missed. In the same way as the XNAV, the AP-L1 measures the diagonal distance L and the horizontal and vertical angles, H , V while tracking the optical reflection target from the reference station (Fig.7). It also calculates the 3-dimensional coordinate positions of the target point. As a result of field tests, we found that it fully reaches the target accuracy and tracks a moving object in a very stable manner. We confirmed that it can perform automatic tracking, position measurement, and data communication at a distance of 500 m in an area with good perspective. At that point, the modification and improvement of the XNAV were discontinued and the AP-L1 was used in place of the XNAV in subsequent tests. The main specifications of the AP-L1 are shown in [Table 4](#).

Abstract

We have developed a tilling robot that can recognize its own position and heading, while performing unmanned tilling at almost the same work rate as manual work. The tilling robot is composed of navigation systems for positioning and heading, a robotized vehicle, a controller, and an operation software. A geomagnetic sensor (TMS) is utilized for the navigation system for heading. The operation software consists of teaching, path planning, vehicle controlling, self-diagnosis, and abnormality alarming sections. We found that the tilling robot can perform unmanned tilling operations over a whole field area of 50 a with almost the same efficiency and accuracy as manual work.

Discipline: Agricultural machinery

Additional key words: mobile robot, unmanned operation, operation software, tractor, navigation 1..11):[Reference](#)

(Received for publication, July 14, 1999)

Development of tilling robot

1) Tilling robot

The BRAIN-IAM has accumulated data related to technology for robotization of agricultural vehicles from several trials since 1988^{1,2,5}. The Ministry of Agriculture, Forestry and Fisheries launched an agricultural machine development project in the fiscal year 1993. A 5-year plan for the development of a tilling robot (1993 to 1997) was implemented under this project. This development was performed jointly with KUBOTA Co., Japan Aviation Electronics Industries, Ltd., Hokkaido Univ. and BRAIN-IAM.

The objective of the tilling robot is to develop a working vehicle that can recognize its own position and heading, while performing unmanned tilling, including headland treatment, at the same work rate as a manual operation. The target specifications are shown in Table 1. The fields are limited to paddy fields and upland fields that cover an almost flat and rectangular area. In our study, the robot works within sight of the operator, which enables the operator to stop the robot by remote control in case of emergency.

2) Target specifications for the navigation system

The performance required for the navigation system of tilling robots or robotized agricultural vehicles is

outlined in [Table 1](#). This table specifies the concurrent provision of positional information and the vehicle heading information. For position accuracy, we assume that the overlap width of the implement should be approx. 10 cm. The tolerance was set for half of that value to avoid untreated areas. The heading accuracy was set so that the overlap width of the implement would be maintained if the vehicle was operated autonomously, depending only on the heading information for a length of approx. 100 m of the assumed field and taking into consideration the capacity of the present heading sensor. Although the sampling interval for the position data was set at 1 s or less, it is assumed that the transitory changes of position during this interval, as required, are complemented by dead reckoning, etc.

Navigation systems

1) Navigation systems for positioning

We developed 3 types of navigation systems for positioning, namely an off-the-wire type, a kinematic GPS with inertial navigation system (INS) type, and an optical type.

The details of these navigation systems were described in "Robotization of Agricultural Vehicles (Part 1)".

2) Navigation system for heading⁶⁾

(1) System configuration and principle

Geomagnetic sensor (TMS) is a heading sensor used for the navigation system characterized by a free route and internal information with distance and heading type. A flux gate type TMS was adopted, which displays a relatively high reliability and is commonly used in the field of traffic. Principle of measurement is shown in [Fig. 1](#). Heading of the vehicle is represented by the relative angle from magnetic north by measuring the horizontal components x and y , which are detected by the intersected coils X and Y , and by calculating $\tan^{-1} (x / y)$. However, if the TMS mounted on the vehicle tilts together with the vehicle, it is impossible to detect the horizontal components of geomagnetism. Therefore, the geomagnetism must be detected as a 3-dimensional vector and the horizontal components must be calculated by measuring the pitching and rolling angles of the TMS using a clinometer. This operation is referred to as "calibration of inclination". In addition, because the vehicle itself is a magnetic substance, it is necessary to correct the error due to the influence of its magnetism. This correction is referred to as "calibration of magnetic environment". The influence of a magnetized substance is represented by the vector OO' in [Fig. 2](#). The vector OO' can be measured beforehand by running the vehicle in a loop in an area free of any magnetism from buildings, etc., and then the calibration of the magnetic environment is achieved using that value.

(2) Performance, precision, and ease of use

[Table 2](#) shows the main specifications of the TMS we used. After incorporation of the measured value into the computer and calibration of the inclination and the magnetic environment, a reproducibility of 0.3° was secured based on the trace of autonomous straight running with the TMS.

(3) Characteristics and problems

Although the cost of TMS is low and it has no driftage, TMS measures a very small magnetic field. This can cause a problem when the measured value is affected by surrounding structures, whose influences can not be corrected.

Vehicle (ROBOTRA) and control systems^{7,8)}

1) Vehicle

To test the navigation systems and autonomous operation software, the ROBOTRA (Fig. 3) was developed by trial using a stock tractor as the base vehicle. Although the new original vehicles designed for a tilling robot could have been developed in this study, commercialized tractors were eventually used due to their versatility as well as the lower development cost. The respective specifications as listed in [Table 3](#), and presently the ROBOTRA is designed for rotary tilling work. Since this base vehicle has a shuttle gear, bi-speed turning system, and automatic depth and level control functions for rotary tiller, it is possible to simplify the control parts of the vehicle.

Fig.3. Robotized vehicle “ROBOTRA”

Control of each part is achieved through an exclusive vehicle controller, as shown in [Fig. 4](#). For steering control, the steering angle is detected by the potentiometer mounted on the output shaft of the steering gear box and fed back to the servomotor driver in the vehicle controller so that the specified steering angle can be obtained. To simplify the system, shift positions are manually set prior to the test so that the velocity is controlled by switching between the part throttle previously set and full throttle. To ensure safety, the ROBOTRA has an emergency stopping mechanism that is activated by either a bumper switch or through radio control.

2) Control system

The main controller inputs information items related to navigation as well as various internal information, determines the control value for each part of the vehicle according to a path plan, and outputs them to the vehicle controller. A personal computer is presently used for the main controller. Inputs and outputs are processed through various boards that are suitable for each type of signal. A

communication modem of spectrum spread type (developed by Cralion, Co.) was used for the data transfer between the reference station of the navigation system and the controller on the ROBOTRA.

Implementation of autonomous operation

1) Autonomous operation of tilling robots using the LNAV or SNAV [8\)](#)

The operation using the LNAV is executed by detecting the position of the vehicle through comparison of a signal with the magnetic reference. In the returning operation, an original method is applied to obtain the reference value of the next path, while performing the operation on the present path. Since the SNAV uses absolute latitude and longitude as its coordinate system, it differs from the XNAV. Therefore, the operation software applied to the SNAV uses a different method of managing the coordinate system from that for the XNAV, but the method is identical in other areas.

Presently, the performance of the autonomous operation using the LNAV or SNAV is almost equivalent to that of the autonomous operation using the XNAV described in the following section. Detailed explanation will be given separately.

2) Autonomous operation of tilling robots using the XNAV

(1) Concept and strategy [9\)](#)

In the autonomous operation with the XNAV, the TMS is also used concurrently for the navigation system with the AP-L1. Detecting intervals of positional data are slightly long and heading information for the vehicle is required for turning and sideways movement. The operation of the whole field is performed by first making returning operations around the center of the field, assuming that the field has a rectangular shape, and then making a round operation around the peripheral areas of the field, including the headlands. For the tilling operation using the ROBOTRA, triple round courses are needed to perform the operation in the peripheral area, because a headland length of nearly 5 m is required for a returning operation. To generate the operation paths, one manual teaching run was performed along the field boundary, as shown in [Fig. 5](#). Information on positions P_{0s} to P_{3e} and information on directions $\mathcal{A}E_0$ to $\mathcal{A}E_3$ were obtained during the teaching run. As shown in Fig. 5, the operation paths consisted of,

- a. The transference path 1 from a corner of the field, the entrance to the field,
- b. Returning operation paths 1 to n, including the 180° turns in the headland,
- c. Transference path 2 from the end of the returning operation path to the starting point of round operation, and
- d. Round operation paths 11, 21, 31, ..., including the 90° turns in each corner of the field.

In path planning, it was assumed that the operation ended near the entrance to the field. By following the procedures of the actual operation reversely, the routes of 3 round operation paths were set so that the overlap between work areas was 10 cm, and the number of paths and routes of returning operation were set for the remaining area with proper overlap.

(2) Operation software [10,11\)](#)

Operation software to perform "teaching", path planning and autonomous operation consists of multiple software modules. [Fig. 6](#) shows the flow of general software. These software modules include "straight operation routine", " 180° turning routine", " 90° turning routine", "sideways movement routine", etc.

A returning operation consists of a straight run control and a 180° turn control. In the straight operation control routine ([Fig. 7](#)), an interval of 0.5 s was used to obtain position data and steering control. It was specified that heading data from the TMS would be applied to the straight run control for the period of time when normal position data could not be obtained. In addition, countermeasures were implemented, such as temporary retraction after an 180° turn to facilitate sideways movement for adjusting overlap at the starting point of tilling.

In the round operation module, highly precise positioning is required to avoid any extrusion beyond the border of the field area, to ascertain that there are no untreated areas and to minimize stamping of the treated area. Therefore, the following measures were incorporated:

- a. Small retraction or switchback before a 90° turn,
- b. Guidance to the target route after the turn, by sideways movements of forward and backward runs, and
- c. Providing learning function for the turning radius.

Options to change the operation method depending on the conditions of the field have been provided, such as performing round operations of the whole field or returning operations to diagonal directions of the rectangular field.

In addition, the positioning accuracy was improved at the end of the path by concurrently using dead reckoning at intervals of 0.1 s, based on the heading information and vehicle velocity.

(3) Self-diagnosis and abnormality alarming³⁾

To secure the reliability and safety of unmanned operations, this system is required with the following functions:

- a. A "self-diagnosis" function for confirming the normal operation of various sensors, actuators and control adjustment before starting the operation, and
- b. An "abnormality alarming" function for detecting the abnormalities of the system, and indicating any abnormalities to the operator (supervisor) during the operation, and/or temporarily discontinuing the operation until the abnormal state is eliminated.

These functions are incorporated into the operation software, as shown in [Tables 4 and 5](#).

(4) Work performance⁴⁾

To evaluate the performance of unmanned operation, we planned and executed 3 categories of evaluation tests as follows:

- a. Work performance tests to check the work efficiency and accuracy,
- b. Operation tests to check the ease of use and safety in the installation and setting of the robot, and
- c. Reliability tests to check the resistance to environments and the safety and reliability of work.

To evaluate the effect of labor-saving by unmanned operation, in the work performance tests, we introduced such indexes as operator efficiency which refers to the time during which the operator works in a unit area. And to evaluate the work accuracy, indexes on straight running performance were introduced, too.

Evaluation tests were executed in several fields. In some of the work performance tests, conventional manual operations were performed with the ROBOTRA by a skilled worker as well as under the conditions of unmanned operations. Examples of test results are shown in Table 6, and the trace of unmanned operation with the ROBOTRA and XNAV system in a paddy field 100 x 50 m in size is shown in [Fig. 8](#). The overlap between work areas was set at 10 cm for both returning and round operations with a 1.7 m width implement. We found that the work efficiency and the work accuracy were nearly equivalent to those of conventional manual operations. In the straight running performance, the robot was superior to a skilled operator. Throughout the evaluation tests, no trouble occurred and there was no problem in the resistance to environments and the durability of the robot.

Conclusion and prospects

The authors carried out studies on navigation systems such as LNAV, SNAV, XNAV and TMS for tilling robots. Using these navigation systems, the position of the moving vehicles can be recognized with an error less than 5 cm and at intervals less than 1 s. During these studies, we attempted to use them for field operations as far as possible and investigated the feasibility of robotizing agricultural vehicles.

The tilling robot was composed of these navigation systems, the prototype vehicle, the controller and the operation software. We observed that the tilling robot can perform unmanned tilling over a whole field area of more than 50 a with almost the same efficiency and accuracy as manual work. However, when an unmanned vehicle performs an operation such as tractor work, any abnormality or problem of hardware or software may lead to a serious accident. Therefore, the tilling robot was fitted with the self-diagnosis and abnormality alarming functions, which conferred a high reliability and provided a fail-safe system for any emergency.

Furthermore, when these technologies are introduced into actual fields, the following applications must also be studied.

- 1) A single operator supervises several tilling robots that operate simultaneously.
- 2) The operator performs other tasks while supervising the operation of the tilling robot.
- 3) The tilling robot is also used for such operations as soil puddling, ridging, etc.
- 4) New working methods are developed to maximize the use of the robot's ability.

Abstract

Experiments were conducted to control spiny amaranth (*Amaranthus spinosus* L.) and velvetleaf (*Abutilon theophrasti* Medic.) in a field of forage corn sown in early, mid-and late spring by using an Italian ryegrass (*Lolium multiflorum* Lam.) living mulch, and to control swinecress (*Coronopus didymus* (L.) J. E. Smith) in an Italian ryegrass sward by dense sowing at the Kyushu National Agricultural Experiment Station, Nishigoshi, Kumamoto. Growth of spiny amaranth in the corn field depended on weed control treatments. The living mulch adequately controlled the weed in the field of corn sown in early spring, but the weed-controlling effect was reduced with the delay in the sowing date, and the living mulch did not control the weed in the late spring sowing plot. Although the living mulch substantially reduced the fodder yield of corn in the early spring sowing plot, it only slightly reduced the corn yield in the mid-spring sowing plot. Pre-emergence application of atrazine + alachlor adequately controlled the weed irrespective of the sowing dates. Neither living mulch nor pre-emergence herbicide mixture adequately controlled velvetleaf, but the growth of velvetleaf in the field of forage corn depended on the sowing date of corn. At the time of corn harvest, growth in the late spring sowing plot was more reduced than that in the plot sown in mid-spring, which indicates that a shift of the corn sowing date to late spring could be effective for avoiding damage by velvetleaf. Sowing of Italian ryegrass at twice as much as the standard density adequately suppressed the growth of existing swinecress in the ryegrass sward, and dense sowing markedly reduced the amount of the weed both in the first and second croppings of ryegrass without reduction of the crop yield. Cropping systems of forage crops that could effectively avoid the damage caused by velvetleaf, spiny amaranth and swinecress were examined based on the experimental results.

Discipline: Weed control

Additional key words: dense sowing, living mulch, spiny amaranth, swinecress, velvetleaf

1...13): [References](#)

(Received for publication, June 16, 1999)

Introduction

In recent decades, various alien weeds have been detected in forage crop fields throughout Japan. It is considered that these species were introduced through imported concentrates¹⁰⁾, and some of them are recalcitrant. Our previous questionnaire revealed that the most serious naturalized weeds in the Kyushu district were spiny amaranth (*Amaranthus spinosus* L.) and velvetleaf (*Abutilon theophrasti* Medic.) in forage corn fields and swinecress (*Coronopus didymus* (L.) J. E. Smith) in Italian ryegrass swards³⁾.

Spiny amaranth and velvetleaf compete with corn during the growing season, and their mature lignified plants, which reach 2 m or more in height, mechanically disturb the harvest. Spiny amaranth often occurs in fields treated with the conventional pre-emergence herbicides, *i.e.*, atrazine, alachlor and their combination, and velvetleaf is considered to be resistant to the pre-emergence herbicides^{3,6,12)}. Although swinecress reaches a height of only 20 to 30 cm and has no adverse effect on Italian ryegrass growth, cows tend to produce milk with a strong odor of swinecress when the weed contaminated their feed⁹⁾. Swinecress plants are often overlooked because they slip into the ryegrass sward, and thus, chemical control of this weed is frequently unsuccessful.

For these reasons, it is important to develop cultural methods to replace chemical applications for the control of spiny amaranth, velvetleaf and swinecress.

Living mulch (cover crop) is considered to be a suitable cultural method to control weeds in row crops in the United States⁵⁾ and Sato et al.⁹⁾ reported that the growth of swinecress observed in Italian ryegrass swards was affected by the sowing density of ryegrass.

The objectives of this study were 1) to implement the cultural control of spiny amaranth and velvetleaf in forage corn fields by the use of an Italian ryegrass living mulch, 2) to control swinecress in Italian ryegrass swards by dense sowing, and 3) to analyze the cultural systems applied to control these weed species in forage crop fields.

Materials and methods

All the experiments were conducted at the Kyushu National Agricultural Experiment Station in Nishigoshi, Kumamoto. The soil type was a thick high humic Andosol (Melanudands). Plots were arranged in a randomized complete block design with 2 or 3 replications, and data were subject to an analysis of variance ($P < 0.05$).

1) Control of spiny amaranth and velvetleaf in forage corn field

Experiments were conducted to control spiny amaranth and velvetleaf in a forage corn yield using a cultural method in 1995 and 1996. The experimental design is shown in [Table 1](#). Corn (*Zea mays* L. cv. Pioneer 3352) was sown 20 cm apart in rows 0.75 m apart in 3 m long plots. Velvetleaf seeds were treated with water at 70°C for 15 min to promote their germination². After sowing of spiny amaranth or velvetleaf seeds, plots were treated with either a living mulch or a pre-emergence herbicide mixture to control the weeds. Italian ryegrass (*Lolium multiflorum* Lam. cv. Tachiwase) was sown at a density of 0.3 and/or 0.6 kg/a in the living mulch plots, and pre-emergence application of atrazine + alachlor at a rate of 10.0 + 10.8 g/a was performed in the herbicide-treated plots. For each weed, a single plot was left untreated as a check plot. In all the experiments, both the sowing of the weeds and the weed control treatments were carried out on the same day as the sowing of corn.

To monitor the growth of weeds and corn, vegetation from either a 0.4 x 0.75 or a 0.6 x 0.75 m area with 2 or 3 corn plants in the center was cut periodically, and leaf area and dry weight of weeds and corn were determined. At harvest time, 5 corn plants from a 1 m section of a central row in each plot, and vegetation in a 1 m section of interrow adjacent to the central row were cut to determine the dry weight.

2) Control of swinecress in Italian ryegrass sward

On October 18, 1995, Italian ryegrass was sown in three 3 x 6 m plots infested with swinecress seeds previously sown at a density of 50 g/a. In one of the plots, ryegrass was sown at a density of 250 g/a with post-emergence application of thifensulfuron-methyl (Harmony) at a rate of 0.375 g/a 6 weeks after sowing (herbicide-treated plot). In the 2 remaining plots, ryegrass was sown at the density of 250 g/a (check plot) and 500 g/a (dense-sowing plot) without herbicide application. Samples of crops from the first and second croppings (hereafter referred to as "first and second crops") from two 0.5 x 0.5 m quadrates in each plot were harvested on April 15 and May 2, 1996, respectively. All the samples were assorted into the ryegrass and swinecress (no other species were found), and the growth of the weed and yield of ryegrass were determined. Prior to the sowing, swinecress seeds were treated by the method of Kobayashi³ to promote their germination. Plots were fertilized at a rate of 0.5-0.5-0.5 kg/a with a 16-16-16 N-P₂O₅-K₂O compound fertilizer before sowing.

Results and discussion

1) Control of spiny amaranth and velvetleaf in forage corn field

(1) Spiny amaranth control

Changes in the weight of spiny amaranth during corn growth are shown in [Fig. 1](#). Italian ryegrass living mulch completely controlled spiny amaranth during the growing season of corn in the early spring sowing plot. Adequate weed control was achieved because Italian ryegrass grew vigorously enough to compete with the weed under cool temperatures during the growing season. The effect of the living mulch on weed control was less pronounced with the delay in corn sowing, and the mulch of the late spring sowing plot failed to control the weed because the ryegrass seedlings withered at high temperatures after emergence. The effect of the mulch on the control of spiny amaranth in the mid-spring sowing plot was intermediate between that of the early and late spring sowing plots.

Pre-emergence application of atrazine + alachlor adequately controlled spiny amaranth in every sowing. Weed seeds were present in the surface soil in the early spring sowing plot, and in soils at a depth of 0-8 cm in the mid- and late spring sowing plots. The herbicide mixture completely controlled the weed when the weed seeds were in and under the herbicide-treated layer. Since spiny amaranth is sensitive to atrazine + alachlor, these herbicides may be absorbed both through the roots and the hypocotyls exposed to the treated soil¹⁾.

Changes in the dry weight and leaf area of corn and spiny amaranth during corn growth are shown in [Table 2](#) and [Fig. 2](#), respectively. In the early spring sowing plot, the living mulch suppressed the growth of corn. The dry weight and LAI (leaf area index) of corn in the living mulch plots were found to be significantly smaller than those in the untreated and herbicide-treated plots during growth in the early spring sowing plot. In the mid-spring sowing plot, although the dry weight of corn in the living mulch plot was smaller than that in the untreated and herbicide-treated plots 6.5 weeks after sowing, and although the LAI of corn in the living mulch plot was smaller than that in the herbicide-treated plot 7.5 weeks after sowing, the living mulch suppressed the growth of corn less in the mid-spring sowing plot than in the early spring sowing plot. In the late spring sowing plot, the living mulch did not suppress the corn growth, and there was no difference in the growth parameters among the weed control treatments.

Dry weight of spiny amaranth at the corn harvest time and corn yield are shown in [Fig. 3](#). Spiny amaranth plants were not detected in the living mulch plots sown in early spring. In the mid-spring sowing plot, the dry weight of the weeds in the living mulch plots was smaller than that in the untreated plots, while in the late spring sowing plot, the dry weight of the weeds was similar. In the herbicide-treated plots, few spiny amaranth plants were observed, and the dry weight of the weeds was significantly smaller than that in the untreated plots in every sowing. In the early spring sowing plot, corn fodder yield in the living mulch plots was reduced to 60-66% of that in the untreated plot. In the mid-spring sowing plot, a slightly lower corn yield was observed in the living mulch plot. No significant difference was observed in the yield between the living mulch and the untreated plots in the late spring sowing plot. Corn fodder yield in the herbicide-treated plots was approximately similar to that in the untreated plots irrespective of the sowing dates. In the untreated and herbicide-treated plots, corn yield in the late spring sowing plot was lower than that in the early and mid-spring sowing plots, because harvest was earlier than the maturation time of corn to avoid damage by typhoons.

Meanwhile, pre-emergence application of atrazine + alachlor successfully controlled spiny amaranth irrespective of the sowing dates without any reduction in corn yield, although this herbicide mixture has often been reported to be ineffective in corn fields^{8, 11}). Failure to control the weed using pre-emergence herbicides is often observed in fields in which slurry and/or immature compost had been continuously applied. It is assumed that a change in soil adsorption resulting from continuous application of organic fertilizer might be responsible for the ineffectiveness of the pre-emergence herbicides¹³).

The results revealed that the Italian ryegrass living mulch 1) strongly suppressed corn growth in the early spring sowing although it could control the weed, 2) could not control the weed in the late spring sowing, and 3) could adequately control the weed in the mid-spring sowing without severe reduction of the corn yield. The use of the living mulch could be a suitable method of control of spiny amaranth in fields of forage corn sown in mid-spring if a slight reduction of corn yield and slight infestation with the weed were acceptable to the farmers. Moreover, it is definitely an effective method of control in the fields where application of slurry and/or immature compost as fertilizer had reduced the effectiveness of pre-emergence herbicides.

(2) Velvetleaf control

Changes in the dry weight of corn and leaf area of corn and velvetleaf during corn growth are shown in [Table 3](#) and [Figs. 4](#) and [5](#), respectively. Data on mid- and late spring sowings are presented and analyzed because velvetleaf seeds used in the early spring sowing were less vigorous and the percentage of emergence was too low to obtain the data.

Neither the Italian ryegrass living mulch nor pre-emergence herbicide mixture controlled velvetleaf during the growing season of corn irrespective of the sowing dates. There were no differences among the weed control treatments in terms of the growth of the weed for both sowing dates. Although the living mulch had no effect on weed growth because ryegrass seedlings withered at high temperatures, the dry weight of the weed in the late spring sowing plot was smaller than that in the mid-spring sowing plot for all of the investigation dates during corn growth.

In the mid-spring sowing plot, there were no significant differences in the change in the dry weight of corn between the plots treated with living mulch and untreated plots, and the dry weight of the herbicide-treated plots was largest among the weed control treatments. Although the LAI of corn in the mid-spring sowing plots was smaller in the living mulch and untreated plots than that in the herbicide-treated plots 5 and 6 weeks after sowing, no significant differences were observed among the weed control treatments subsequently.

In the late spring sowing plot, the living mulch did not suppress corn growth, and there were no differences in the growth parameters among the weed control treatments.

Dry weight of velvetleaf at corn harvest time and corn yield are shown in [Fig. 6](#). No significant differences were observed in the dry weight of velvetleaf among the weed control treatments in either the mid- or late spring sowing plot. However, the growth of the weed in the late spring sowing plot was much more reduced than that in the mid-spring sowing plot, and the difference corresponded to the weed growth during the corn growing season. The reduced growth of velvetleaf in the late spring sowing plot may have been caused, partly, by competition with vigorous corn growth during the growing season, and, partly, by the short photoperiodic response of the weed^{4,7}). There were no significant differences in the corn yield among the weed control treatments in either the mid- or late spring sowing plot.

In the current experiment, neither the Italian ryegrass living mulch nor the pre-emergence herbicide mixture could control velvetleaf in the forage corn field. However, shifting the sowing date to late spring should be recommended as a useful cultural method for avoiding damage by this weed.

2) *Control of swinecress in Italian ryegrass sward*

Growth of swinecress and yield of Italian ryegrass at harvest time are shown in [Table 4](#). At the first crop harvest, the plant density and weight of swinecress in both the dense sowing and herbicide-treated plots were smaller than those in the untreated plot. No flowering plants of the weed were observed in the first crop. At the second crop harvest, the plant density and weight of swinecress in both the dense sowing and herbicide-treated plots were much smaller than those in the untreated plot. After the first crop harvest, most of the swinecress plants in each plot resumed growth and flowered by the second crop harvest. The number of flowering plants in both the dense sowing and herbicide-treated plots was significantly smaller than that in the untreated plot.

Ryegrass yield in the dense-sowing plot was almost similar to that in the untreated plot, but was higher than that in the herbicide-treated plot at each harvest. The decrease of the ryegrass yield in the herbicide-treated plot was ascribed to injury by the herbicide during the growing season (Table 4).

It is concluded that dense sowing of Italian ryegrass should be a promising method not only for the suppression of the growth of swinecress plants present in the Italian ryegrass swards but also for the prevention of future infestation through the inhibition of seed production.

3) *Cropping systems of forage crops for weed control*

Forage corn production followed by the planting of Italian ryegrass is a major cropping system in the Kyushu district, where pre-emergence application of atrazine + alachlor is performed for weed control in forage corn field (System 1 in [Table 5](#)). Spiny amaranth and velvetleaf in the corn fields and swinecress in the ryegrass swards are the most serious weeds in this cropping system. The present study revealed that 1) ryegrass living mulch could be applied to control spiny amaranth in corn sown in mid-spring, 2) damage to corn caused by velvetleaf should be less serious in the late spring sowing than that in the mid-spring sowing, and 3) the growth of swinecress in the Italian ryegrass sward could be suppressed when the ryegrass is sown at a high density. Based on these results, Table 5 presents 5 modified cropping systems in the forage crop fields infested by these weed species.

Spiny amaranth could be controlled with the pre-emergence herbicide mixture irrespective of the sowing date. However, in the fields where fertilization with immature compost has reduced the effectiveness of the herbicide mixture owing to the changes in soil adsorption, Italian ryegrass living mulch should be applied for controlling the weed and corn must be sown in mid-spring in this case (System 2). Although neither the pre-emergence herbicides nor the living mulch could control velvetleaf, weed damage to corn was less appreciable in the late spring sowing. In the Kyushu district, when Italian ryegrass is harvested twice using a bale machine specialized for grass harvesting, the second crop is often harvested in mid-spring. Therefore, it is recommended to sow corn in late spring after the second harvest of Italian ryegrass to avoid the damage by velvetleaf and to use efficiently the bale machine (System 3).

As herbicide application is not useful to control swinecress in an Italian ryegrass sward, dense sowing may be the only effective method of weed control. In the case of the ryegrass sward already infested with swinecress, dense sowing might be combined with System 1, 2 or 3, depending on the weed species in corn, and Systems 4, 5 and 6 could be recommended.

Abstract

An ammonia treatment system for cereal straws has been recently developed in Japan. The new method is based on a contractor system and is referred to as the "HOKUNOU-S" system. Ammoniation can be used for all types of silos, including, stack, bag, tube and bunker silos as well as wrapped bales. In addition, this technique is suitable for use where a safe, economical, labor-saving treatment with ammonia can be applied. The injection system consists of a large-sized high-pressure vessel, a volume and pressure regulator, lead hose, an injection pipe and nozzle; the durability of this equipment and the safety of its handling comply with Japanese industrial standards. For one treatment, normally 8 kg of ammonia is injected into a round bale 1.2 m in diameter within 1-2 min. About 10 t or 40 round bales of cereal straw can be treated by a contractor within 1 h. By treating rice straw with ammonia, the TDN content of rice straw increased from 40 to 60%. As a result, treated rice straw was similar to good quality grass hay while treated barley and wheat straws were similar to grass hay harvested at a slightly later stage. An adequate level of breeding efficiency in yearly calving was obtained in the 3-year reproduction test using a total of 96 breeding cattle. The cost varied with the supply and demand of straw, the length of the actual working time of the wrapping machine, and field conditions (wet conditions cause an increase in time and therefore an increase in harvesting expenses).

Introduction

Feeding value, palatability, and digestibility of low-quality cereal straws can be remarkably improved by treatment of the straw with ammonia⁷⁾. Ammoniation of straw has thus contributed to a considerable increase in livestock production in many countries. A fully automated system of ammoniation is already being employed in some European countries. However, a method for ammoniating crop residues has only been partly adopted in Japan due to the difficulty in handling ammonia and farmers' collection of cereal straw. Furthermore, in Japan, the storage, transportation, handling and application of ammonia are more strictly regulated than in other countries. Use of ammonia is restricted by the following regulations: the Poisonous and Deleterious Substance Control Law, the High Pressure Gas Control Law, the Fire Service Law, the Industrial Safety and Health Law, and the Ordinance on the Prevention of Hazards due to Specified Chemical Substances. To promote widespread production and the use of cereal straw for feed, it is necessary to develop a safe, low-cost ammonia process as well as a system for supplying and using ammonia safely. Such a treatment system has been recently developed in Japan. The new method based on a contractor system is referred to as the "HOKUNOU-S" system³⁾.

Description of the contractor system "HOKUNOU-S"

The operation of this new system consists of the following 3 functions: collection of cereal straw, wrapping of the straw with plastic stretch film, and ammonia injection. A specially trained and certified contractor injects liquid ammonia into wrapped round bales through a perforated stainless steel pipe. As illustrated in [Fig. 1](#), the contractors are responsible for dealing with the treatment while the farmers are required to bale, collect, and wrap the straw to be treated.

Fig.2. Rapid and safe injection of ammonia

Ammoniation can be used for all types of silos, including stack, bag, tube and bunker silos, as well as wrapped bales. In addition, this technique is suitable for use where a safe, economical, labor-saving treatment with ammonia can be applied and where the results of its effectiveness can be confirmed (Fig. 2). For outside storage, round bales wrapped with plastic stretch film allow for better treatment and preservation. There is a minimum risk of waste compared with that of stack and bunker silos. If the moisture content is high, the quality of straw ammoniated in stack or bunker silos is often reduced soon after opening.

1) Rapid and efficient operation of ammonia injection

The injection system consists of a large-sized high pressure vessel, a volume and pressure regulator, lead hose, an injection pipe and nozzle; the durability and safety of handling of this equipment comply with the Japanese industrial standards. Ammonia is injected through a perforated stainless steel pipe, the sharpened conical head of which is easily inserted into wrapped bales of straw. The pipe is perforated with a number of holes, 2-3 mm apart, along its length for efficient and faster injection of liquid ammonia, which results in the thorough volatilization of the remaining ammonia, as indicated by structural tests. A variable orifice meter controls the flow rate of liquid ammonia to the bale. However, other factors affect the flow rate of ammonia, such as the ambient temperature and the pressure of ammonia in the vessel. For one treatment, normally 8 kg of ammonia is injected to a round bale 1.2 m in diameter within 1-2 min. About 10 t or 40 round bales of cereal straw can be treated by a contractor within 1 h.

Fig.3
Wrapping of cereal straw with plastic stretch film

2) *New plastic stretch film and air-tightness*

Cereal straw, air-dried to less than 30% of its original moisture content, is collected and wrapped with a newly introduced plastic stretch film. This film was developed to improve various physical properties including the ability to stretch, plasticity, clinging ability and durability. All of these are combined to ensure a complete airtight seal for the prevention of mold growth and better preservation over longer periods of time, even when

ammoniation is delayed (Fig. 3). A rudimentary method of ammoniation was used to inhibit further mold growth in grass hay and cereal straw, particularly when they became wet due to rain. However, such wet materials must not be injected with ammonia, due to the possible formation of toxic substances. Due to the security issues relating to the safety of livestock feed and public food supply, there is a growing awareness of the potential problems associated with ammoniation of crop residues with excessively high moisture. These issues will be discussed later in this report.

3) *Appropriate amount of ammonia injected*

Based on a number of experiments, the quality of treated straw can be improved when the amount of ammonia added increases. An amount of ammonia ranging from 2.5 to 3.5%, based on the dry matter of the straw, can be justified for the cost. Since in straw containing more than 30% moisture, a reduction in forage quality and the occurrence of toxic products are likely to occur, emphasis should be placed to determine the maximum amount of ammonia that can be safely administered. Four percent ammonia, based on the dry matter content, may be recommended as the upper limit. This amount will result in high performance in terms of cost and will also enable to avoid the risk of toxicity problems in livestock, e.g., hyperexcitability. As the concentration of ammonia is closely related to a satisfactory reaction with the straw, it is preferable to hire trained contractors than using farmers' more rudimentary methods to ensure that an accurate amount of ammonia is injected.

4) *Distribution of ammonia injected into straw*

When ammonia is injected into the straw and absorbed, it binds to the fiber. Although the concentration of ammonia during dissipation remained at about 3.9% in a bag silo and 6.1% in a wrap silo just after injection, it drastically decreased to less than 1.0% after about 20 days and 0.78 and 0.82% remained approximately 103 days later, respectively. It was also observed that treatment with 1% ammonia always resulted in a lower level of permeation of ammonia than treatment with 3%, as evidenced by the average value of 0.02% about 103 days after injection. This type of ammonia became stable until 28 days after injection and did not change appreciably in the wrapped bales and bag silos ([Table 1](#)).

The amount of straw-bound ammonia can be estimated by air-drying a sample in an oven and measuring the increase in the nitrogen content of the treated materials. The amount of absorbed and straw-bound ammonia was calculated to be about 70 and 20% of the total amount, respectively, when an amount of 3% ammonia was used. The residual amount of ammonia injected vaporized and was released during storage. In straw with a high moisture content, a considerable amount of absorbed ammonia easily vaporizes and is released into the atmosphere, especially when combined with the moisture from ponds near the upper surface of the bale or stack when opened. Wastage of ammonia and air pollution can be prevented by avoiding treating straw with a high moisture content and by mixing ammonia in the treated materials with volatile fatty acids (VFAs). Ammonia binds well to the VFAs which are present in the silage. These aspects should be carefully considered as the treatment becomes more popular in Japan.

5) Temperature for treatment

A chemical reaction between ammonia and straw normally occurs faster at higher than at lower temperatures. When liquid ammonia is injected, the temperature increases rapidly, reaching a maximum value 2-6 h after injection. The increase ranges between 40 and 60°C, depending on the following factors: temperature at the onset, amount of ammonia injected, exposure time of the reaction, and moisture content of the treated materials. Due to the combination of internal temperature with radiant heat from sunlight, temperatures above 80°C can occur in the outer layer of round bales. The decrease in temperature also depends on a number of factors causing ambient temperatures to level off at about 15°C. This temperature is normally reached within 1-2 weeks after injection. Liquid anhydrous ammonia is gradually vaporized at the bottom of a stack, leading to a drastic cooling of the surroundings. The temperature at the bottom is below 0°C for 5 days after injection and reaches a value of 15°C (ambient temperature) after an additional 6-7 days ([Fig. 4](#)). The time necessary to treat cereal straw depends on the temperature; the lower the temperature, the lower the rate of treatment. Data on the temperature of the treatments revealed that optimum improvement in the feeding value can be achieved after 8 weeks of storage at temperatures below 5°C, between 4-8 weeks at temperatures around 5-15 °C, between 1-4 weeks at temperature from 15-30°C, and at 1 week at 30°C. These findings indicate that effective treatment requires more than 1 month at high temperatures and 3 months at low temperatures. Palatability is also improved when the duration of the period of treatment increases. Colorless and transparent films were initially used, which enhanced the increase of the ambient temperature. In the new injector system, white films were developed and were recommended for use in order to avoid the drastic increase of ambient temperature and toxicity of the treated materials to livestock.

Feeding method of treated cereal straw for cattle and sheep

1) Intake of treated straw

By treating rice straw with ammonia, the TDN (total digestible nutrients) content increased from 40 to 60%. Thus, treated rice straw was found to be similar to good-quality grass hay, while treated barley and wheat straws were similar to grass hay harvested at a slightly later stage. Ammoniated cereal straw offered to ruminants provides a larger source of supplementary nitrogen than grass hay. When fed to animals in higher amounts, supplements of minerals and vitamins are required. Cereal straw contains virtually no vitamins and fewer minerals than does grass hay. According to the practical guidelines for the feeding of ammoniated cereal straw in Japan, the recommended daily allowance of treated roughage was up to 2 kg per day per cow. These guidelines were set mainly because the concentration of ammonia in roughage (dry matter basis) was barely controlled under the conventional method, and was used only as a method of inhibiting mold in damp grass hay. The "HOKUNOU-S" system has been authorized for application to cereal straw, but not to grass hay. Furthermore, since it can only be applied under strict and safe conditions, it may enable to increase the intake of treated straw as ruminant feed, thus lowering the cost of production for beef and dairy cattle operations.

2) Feeding experiment with treated straw given to breeding beef cattle

A 3-year reproduction test using a total of 96 breeding cattle was carried out at the Tokachi Farm of the National Animal Breeding Center and the Hokkaido National Agricultural Experiment Station in Japan. Cattle reared under the system of summer-grazing and winter-housing were fed treated straw during the winter. In these cattle, dry-matter intake of treated straw (6 kg per day), and palatability of treated straw as a basal ration were high ([Table 2](#)). The contents of vitamins and minerals of the treated straw are lower than those of grass hay. However, by supplementing the ration with vitamins A, D and E, phosphate, calcium, and other minerals, a satisfactory level of breeding efficiency in yearly calving was obtained ([Table 3](#)). The occurrence of white muscle disease in calves can be prevented by the addition of selenium in rations, since the selenium levels in the soils of field and cereal straw tend to be very low in Japan. If ammoniated straw is to be used as livestock feed, selenium should be added.

Treatment costs for cereal straw

The treatment costs for cereal straw include the expenses for the purchase or baling of the straw, collection and transfer, and wrapping and ammonia injection. The cost is about 32 yen per kg of wheat or barley straw in Hokkaido and if the cereal straw could be home-delivered, the price may be reduced to 20 yen. The cost varies with the supply and demand of straw, the length of the actual working time of the wrapping machine, and field conditions-wet conditions cause an increase in time leading to the increase of harvesting expenses⁸⁾.

Metabolic disorders in cattle fed treated roughages

Only in the last 2 decades has ammoniation of cereal straw and other agricultural by-products been subjected to research for use in animal feed rations. However, in 1984, the first cases of hyperexcitability in cattle and sheep fed on treated roughage were reported, due in large part to the increasing popularity of ammoniation as a method of enhancing the intake and digestion of low quality roughage in ruminants^{1,2,6)}. The hyperexcitability of ruminants, generally referred to as "Bovine bonkers", is associated with a neurological disorder. Thus, a number of leading factors have been extensively

examined, including the method of ammoniation, treatment temperature, level of intake of treated roughage, cereal species and variety, sugar and magnesium contents in the roughage. The possibility of transfer of substances to milk and other animal products should be more thoroughly investigated to ensure the safety of society's food supply.

1) Feeding test for detection of possible toxicity of roughages in Japan

Since the late the 1980s, feeding trials using treated rice, wheat, and barley straw have been extensively conducted on dairy cows and beef cattle in Japan. There have been no reports of the occurrence of metabolic disorders in ruminants fed cereal straw treated with 3% ammonia based on dry matter weight. It was also confirmed that straw treated with an amount of up to 6% ammonia did not show any adverse effect on the health and growth efficiency of steers; the feeding value was found to be as high as that of straw treated with a 3% concentration of ammonia. However, in rare cases where immature grass containing higher levels of soluble sugars was treated even with a 3% concentration of ammonia and was subsequently fed to cows, the suckling calves displayed signs of hyperexcitability⁵⁾, presumably due to the passage of toxins in cow's milk. A feeding trial using such toxic grass (treated with a 6% concentration of ammonia) showed a decrease in milk production in young dairy cows compared with previous calvings. Treatment of high-quality immature grass with high concentrations of ammonia was found to be toxic and to have an adverse effect on milk production⁴⁾.

2) Practical guidelines for ensuring feed safety

Several important factors must be considered for the ammoniation of crop residues. The feeding system, and type and age of animals are also equally important factors to be considered to determine whether treated roughage will have a toxic effect or cause hyperexcitability. By following a standardized procedure for ammoniation, the occurrence of "Bovine bonkers" can be prevented to achieve safety in animal production and in the supply of wholesome food to the public. It has been demonstrated that in the presence of moisture, ammonia and glucose react to form 4-methylimidazole. The 2- and 4-methylimidazole compounds are known to cause convulsions in mice and have been implicated in a clinical poisoning syndrome in cattle. The guidelines for ammoniation recommended in Japan are as follows:

(a) Roughage containing high levels of reduced sugars, including grass and whole crop feeds, should not be subjected to ammoniation. Moldy roughage should be excluded from treatment because it may produce toxic materials (Fig. 5).

Fig.5. Moddy roughage that should not be ammoniated

plastic stretch film and storing feed in a shaded area. It is also recommended to quickly wrap round bales to avoid heating due to respiration and aerobic fermentation.

The contractor must follow these guidelines completely, as required by the legislation concerning feeds and feed additives. The legislation has recently been amended in Japan to include the use of "HOKUNOU-S"-processed ammoniated straw as feed for ruminants.

(b) The concentration of ammonia administered is normally 3% or less, based on the dry matter of the straw; when the moisture content exceeds 30%, a concentration of up to 4% ammonia is permitted.

(c) Better diffusion of ammonia can be obtained by injecting ammonia into the lower part of round bales and turning the bales upside down.

(d) Treatment at high temperatures should be avoided by using white

Abstract

Janthinobacterium lividum was isolated from wet silk thread whose color became bluish-purple^{7,8}. This bacterium produced large amounts of bluish-purple pigment on some media containing amino acids, such as Wakimoto medium. The pigment was extracted with methanol and was identified as a mixture of violacein and deoxyviolacein. This pigment could be used to dye not only natural fibers like silk, cotton and wool, but also synthetic fibers like nylon and vinylon, and generally gave a good color tone. The shade depended on the material. Silk, cotton and wool showed a bluish-purple color, nylon a dark blue color, and acetate a purple color. Dyeing could be performed by a simple procedure consisting of either dipping in the pigment extract or boiling with the bacterial cells. By changing the dipping time and the temperature of the dye bath, shades ranging from light purple to deep bluish-purple could be selected. The color fastness of the dyed material was about the same as that of materials dyed with vegetable dyes, but the color faded easily when the material was exposed to sunlight. However, since the pigment can be mass-produced by culturing, if these shortcomings could be overcome, the dye may become promising. The pigment displayed an antimicrobial activity against phytopathogenic fungi like *Rosellinia necatrix* which causes white root rot of mulberry⁷. It could also be used as a bio-fungicide.

Discipline: Sericulture

Additional key words: *Janthinobacterium lividum*, violacein, natural pigment, bluish-purple color.

(Received for publication, May 12, 1999)

Introduction

At present, fabrics are dyed mainly with synthetic pigments. However, natural pigments are still valuable because of their natural color tones. People have had a strong liking for natural purple pigments since ancient times. Among the natural purple pigments, that obtained from shell fish belonging to the genus *Murex* is very famous. But it is very expensive because mass production is difficult. About 10 years ago, one of the present authors (Kojima) observed that parts of wet silk threads, that had been left unattended, had turned bluish-purple. Since then, this color change of silk thread waste was observed every year in winter⁷. In the course of studying this phenomenon, one of the present authors (Shirata) isolated *Janthinobacterium lividum* from such silk threads^{7,8}. The bluish-purple pigment produced by this bacterium dyes not only natural fibers like silk, wool and cotton, but also synthetic fibers like nylon and acetate fairly well. The main component of this pigment was found to be violacein, which could be obtained in large amounts by culturing the bacterium. Since the fabric dyed with this pigment has a mild feel, it can be successfully used as a fabric dye⁶.

Materials and methods

1) Culture medium

The following 6 types of culture media were used.

(1) Semi-synthetic potato agar medium (Wakimoto medium): 1,000 mL of boiled extract of 300 g potato tubers, 0.5 g of $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 2 g of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 5 g of peptone, 15 g of sucrose and 15 g of agar.

(2) Potato sucrose agar medium (PSA medium): 1,000 mL of boiled extract of 250 g potato tubers, 20 g of sucrose and 15 g of agar.

(3) King B medium: 20 g of proteose peptone No. 3, 1.5 g of K_2HPO_4 , 1.5 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 10 mL of glycerol, 15 g of agar and 1,000 mL of water.

(4) Modified King B medium: King B medium without K_2HPO_4 and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$.

(5) Peptone agar medium: 20 g of peptone, 1,000 mL of water and 15 g of agar.

(6) Silk extract agar medium: 1,000 mL of boiled extract of 20 g of silk thread waste and 15 g of agar.

Unless otherwise specified, the semi-synthetic potato agar medium(a) was used for all the experiments.

2) Isolation and identification of the bacterium

The bacterium was isolated using standard methods from the bluish-purple parts of silk thread waste. Fresh bacteria that had been cultured for one day at 25 were used for identification. The morphology of the bacterium and the colonies, the extent of multiplication at 37, motility, Gram reaction, and production of water-insoluble pigments and fluorescent pigments were examined by standard methods⁹. Other bacteriological properties were determined by identical sets of bacteria, API20E and API20NE, using *Janthinobacterium lividum* strain IAM13948 (=ATCC 12473 type) as the standard.

3) Bioassay of physiological activity

(1) Effect on cultured insect cells

A cultured cell line originating from the ovaries of *Antheraea eucalypti*, a silkworm of the family Saturniidae, has been established². We used *A. eucalypti* cells that had been successively cultured in the Silkworm Disease Laboratory of the National Institute of Sericultural and Entomological Science to study the effect of the pigment on cultured cells. These cultured cells are known to be highly sensitive to toxic components. In our experiments, the cells were cultured at 26 in a culture solution prepared by the addition of 5% each of silkworm serum and bovine embryo serum to the medium used by Grace². For examining the effects, 0.1 mL of the pigment suspension containing 0.3% of the dried methanol extract of the pigment was added to 3 mL of the culture solution and the culture was maintained for 48 h. The cells were then observed through an inverted microscope

to detect abnormalities.

(2) Toxicity to silkworms

First instar larvae of the silkworm variety Habataki were fed with mulberry leaves that had been treated with 0.1 g of the dried methanol extract of the pigment per 1.4 g of leaf, and the growth during the first instar stage was observed.

(3) Anti-microbial activity

Five bacteria and 8 fungi, all of which are plant pathogens, were used for testing the anti-microbial activity ([Table 3](#)).

In the case of bacteria, 15 mL of King B medium that had been first dissolved and then cooled to 55 and 2 mL of a bacterial suspension containing about 10^9 cells per mL were mixed and poured into a 9 cm diameter petri dish to prepare flats containing the bacteria. Separately, 1 g of dried methanol extract of the pigment was dissolved in 50 mL of acetone to prepare a stock solution. This stock solution was mixed with an equal amount of distilled water to prepare a diluted 1/2 strength solution, which was then diluted successively, to half strength each time, using 50% acetone. A 10 $\frac{1}{4}$ L of this diluted solution was dropped onto the medium containing the bacteria. After evaporation of the acetone and water in a clean bench, the bacteria were cultured for 1-2 days and the diameter of the growth inhibition zone of the bacteria, that appeared as a transparent circular area in the region where the diluted pigment solution had been added, was measured.

In the case of fungi, a small piece of fungal mass (about 0.5 x 0.5 x 0.5 mm) was inoculated onto PSA medium and 10 mL of the diluted pigment solution prepared above was dropped over the fungal mass. After culturing for 3-4 days, the diameter of the fungal colonies that had developed was measured.

(4) Color fastness

Silk and cotton fabrics that had been dyed with the methanol extract of the bacteria, and those dyed by boiling with the bacterial cells, were used to examine the color fastness, according to the JIS method⁴. The color depth of the silk fabric used in the experiment corresponded to No. 3 of the standard color depth chart.

<i>Sclerotinia sclerotiorum</i>	95	94	83	23	8	0

a): The pigment was extracted from bacterial cells with methanol and dried. 1 g of this dried extract was dissolved in 50 mL of acetone which was taken as the full strength solution. The solution prepared by the addition of an equal amount of distilled water to the full strength solution was taken as the 2 dilution solution. In the subsequent dilution steps, an equal amount of 50% acetone was used for the dilution. A 50% acetone solution was used as the control.

b): A 10 µL aliquot of the diluted solution was dropped onto King B medium that had been mixed with the bacterium. After 2 days of culture, the diameter of the area where there was no growth was measured. The ± symbol indicates that the antibacterial activity was very low.

c): Small pieces of fungal colonies were placed on PSA medium and 10 µL of the diluted solution was dropped onto them. The diameter of the fungal colonies was measured 3–5 days later and the inhibition rate of the growth of each fungal colony compared to the diameter of the fungal colonies in the control, was calculated.

BACK

Results and discussion

1) Characteristics of the bacterium and pigment

(1) Isolation of the bacterium

Considering that the blue color of the silk thread waste was due to a microbe, we attempted the isolation of the bacteria on various media⁸⁾. During the first 2 days of culture, a number of yellow and greyish white bacterial colonies appeared, but there were no bluish-purple colonies. After 4 days, however, small bluish-purple colonies appeared on the King B medium (Fig. 1-1). This culture was mixed with sterile water and subjected to pure culturing on the semi-synthetic potato agar medium. Dark bluish-purple colonies and light purple colonies developed within 3 days (Fig. 1-2). When silk thread waste was inoculated with the dark bluish-purple colonies, the thread developed a bluish-purple color within a few days.

Fig.1. *Janthinobacterium lividum* which produces a bluish-purple pigment and samples dyed with the pigment

1: Isolation of bacteria on King B medium. Bacteria that produced bluish-purple pigment could be seen in 4-days-old colonies.

2: Isolation of bacteria that produced bluish-purple pigment on semi-synthetic potato agar medium. The light and dark purple colonies all consist of *J.lividum*, the dark colored colonies being long to strains with high pigment production.

3: Multiplication of *J. lividum* and pigment production on potato sucrose agar medium (PSA, upper) and semi-synthetic potato agar medium (lower) at different temperatures (10-37). More pigment was produced on the semi-synthetic potato agar medium and the optimum temperature was 25.

4: Emergence of pigment-producing mutant bacteria. Reverse mutation from non-pigment-producing bacteria to pigment-producing bacteria could be seen.

(2) Pigment production by the isolated bacterium under different conditions

The production of the bluish-purple pigment differed considerably, depending on the medium used. The media, listed in decreasing order of pigment production, were 1. semi-synthetic potato agar medium, 2. silk extract agar medium, 3. King B medium and peptone agar medium, and 4. potato sucrose agar (PSA) medium. The bacteria multiplied fairly well in the PSA medium but pigment production was low (Fig. 1-3). The media listed under 1. to 2. above are rich in peptone or amino acids unlike medium 4.

When shake culture in a liquid semi-synthetic potato medium was compared with culture on the solid agar medium, for pigment production, culture on solid medium was found to be better. Extraction of the pigment was also easier from the bacterium on the solid medium. However, the bacterium cultured in the liquid medium also produced a fairly large amount of pigment.

As for the effect of the culture temperature, the bacterium grew well in the range of 5-30, with optimum growth at 25. No growth occurred at 37. Maximum pigment production occurred at 25, followed by 20. At temperatures lower than 10 and higher than 30, pigment production was very low (Fig. 1-3).

Bacterial cells cultured at different temperatures were extracted with methanol to determine the dyeing performance of the extracts for silk fabric. The darkest color was obtained with extracts of bacteria cultured at 25, followed by bacteria cultured at 20, 15, 10, 30 and 5°C. The order of the temperature for pigment production, was about the same as that of the growth and color of the bacteria on the medium.

When the isolated bacteria were cultured at temperatures higher than 20, particularly in the range of 27-30, a mutant of light purple or white color bacteria often appeared (Fig. 1-4).

On the basis of the above results, the semi-synthetic potato agar medium was selected as the optimum medium for pigment production. The optimum temperature for culture was 20-25. All the subsequent culture experiments were conducted using this medium and this temperature range. When the bacterium was cultured under these conditions for 5 days, 0.25 g of bacterial cells were produced per 9 cm diameter petri dish. By extracting these cells with methanol, 47 mg of dry extract was obtained which was dissolved in 16 mL of methanol to prepare a stock solution for dyeing. Thus the extract content of this stock solution was 0.3%.

(3) Identification of the bacterium

The bacterial strain that showed the highest pigment production was selected and single colony separation was performed three times to obtain a pure strain. The selected strain S-9601 was used for the identification of the isolated bacterial cells. The colonies of this strain initially showed a greyish-white color when grown on the semi-synthetic potato agar medium. After several days of culture, the colonies showed a light bluish-purple and then a dark bluish-purple color. The colonies were flat with entire margins. The bacteria were Gram negative, aerobic, bacilli, having flagella and motility. The bacteriological characteristics are shown in [Table 1](#).

The bacteriological characteristics of strain S-9601 agreed with the reported properties of *Janthinobacterium lividum*¹. When the isolated strain and the standard *Janthinobacterium lividum* were tested together, the 2 were identical in terms of the production of the bluish-purple pigment and all bacteriological characteristics. Therefore, the bacterium was identified as *Janthinobacterium lividum*.

(4) Extraction of pigment

The bacterium was inoculated onto the semi-synthetic potato agar medium and cultured for one week. The bacterial cells that had become dark bluish-purple were placed in a small beaker and extracted with various organic solvents. Tetrahydrofuran was found to be the most efficient solvent for extracting the pigment, followed by methanol. Acetone, ethyl acetate and ether did not extract the pigment well. Almost no pigment was extracted with water ([Table 2](#)).

(5) Separation of the pigment components and their structure

The bacterial cells were extracted with tetrahydrofuran for one day and the extract was filtered. Then, after concentrating the extract under reduced pressure, it was fractionated by silica gel chromatography (hexane : tetrahydrofuran: acetone = 4 : 2 : 1) and reversed phase high performance liquid chromatography (70% methanol), recrystallized, and 2 bluish-purple pigment components were separated. Component 1 (which was the main component and had a higher polarity than the other component) and Component 2 were subjected to different types of instrumental analysis, to determine their chemical structure.

Component 1 had a molecular weight of 343 when estimated by FAB-MS: $m/z344(M+H)^+$ and the presence of nitrogen was inferred. The IR spectrum suggested the presence of amide also. 1H and ^{13}C NMR spectra showed that Component 1 has a total of 4 NH or phenol OH, 11 quaternary carbons and 9 tertiary carbons, and no secondary or primary carbons. Based on these data and after detailed examination of the MS spectrum, etc., Component 1 was identified as violacein ([Fig. 2](#)).

Component 2 had a molecular weight of 327 when estimated by FAB-MS: $m/z344(M+H)^+$ and the presence of nitrogen was inferred. The IR spectrum was similar to that of Component 1. 1H and ^{13}C NMR spectra did not show any signal originating from phenol OH. The carbon signal that appeared at the base of the phenol OH was shifted to a considerably higher magnetic field. Based on these data and other changes in the spectral pattern, Component 2 was identified as deoxyviolacein (Fig. 2), the deoxy form of Component 1 without the phenol group. Various spectral data of these 2 components of the pigment agreed with reported data^{3,6}.

(6) Safety and antimicrobial activity of the pigment

a: Safety

When the effect of the extracted pigment on cultured insect cells was studied, no adverse effect could be detected. It was thus concluded that the pigment was not toxic or exhibited a negligible toxicity to insect cells. The toxicity to silkworm cells was then examined. Twenty silkworms were made to ingest a total of about 2 g of mulberry leaves on which the pigment had been applied during their 1st instar stage. All 20 of them developed normally, without any signs of abnormality.

b: Antimicrobial activity

A study of the antimicrobial activity of the pigment toward plant pathogens revealed that it had such an activity against 11 of the plant pathogenic microorganisms tested, excluding *Erwinia carotovora* and *Pseudomonas cichorii* ([Table 3](#)). The inhibitory activity was particularly strong against *Colletotrichum dematium* and *Rosellinia necatrix* which cause anthracnose and white root rot diseases of mulberry, respectively ([Fig. 3](#)).

2) Dyeing and characteristics of the pigment

(1) Method of dyeing

a: Dyeing with the extract solution

Dyeing was attempted using an organic solvent solution of the pigment. After extraction of the pigment with tetrahydrofuran and air-drying of the extract, a fixed amount of dry pigment was dissolved in a certain amount of various organic solvents. Silk and cotton fabrics were immersed in the various solutions for half a day and the extent of dyeing was compared. The cotton and silk fabrics were dyed very well both in the methanol and the ethanol solutions ([Table 4](#)).

In the next experiment, the bacterial colonies were extracted with methanol and the fabric was directly immersed in the extract. The fabric developed a bluish-purple color, indicating that methanol could extract the pigment well, and also enabled the pigment to become attached to the fabric.

The dyeing method used was very simple and consisted of 3 steps: **1.**immersion of the silk fabric in the methanol extract overnight; **2.**washing with water; and **3.**drying in the shade.

b: Boiling dye with bacterial cells

The bacterial cells were transferred to a vessel along with the medium and boiled after the addition several times of more than 10 times the amount of water. After bringing the solution to boiling, the fabric to be dyed was dipped in it and the bath was allowed to simmer for about 20 min. The fabric was then washed with water and dried in the shade. If a deep color was not required, immersion of the fabric for 3-5 min in the bath, after boiling and cooling to 80-90, was sufficient.

The characteristics of the 2 methods of dyeing used here were as follows: Athe procedure was very simple, C satisfactory dyeing could be achieved without using mordants, and E dyeing occurred uniformly. Fabric made from the silk of the silkworm variety Akebono is considered to be generally prone to uneven dyeing and to require special procedures for dyeing. However, even Akebono silk could be uniformly dyed by an unskilled person using the dyeing methods described above when the liquor ratio of the bath was sufficiently high. The shade of the dyed fabric varied depending on the amount of dye present in the bath in the range of light blue, violet, bluish-purple and dark bluish-purple. Fig.1-5, 1-7 and 1-8, respectively show the silk fabric dyed to a deep color in the extract solution, a silk scarf dyed to a comparatively light color with the extract, and a kimono dyed to a very light color by boiling with the bacterial cells.

5: Silk fabric dyed and showing a bright bluish-purple color in a concentrated methanol extract of the pigment.

6: Dyeing performance of the pigment with 9 different materials (multifiber test cloth). A: polyester, B: raw silk, C: acrylic fiber, D: rayon, E: wool, F: acetate showed a purple color. Nylon and vinylon showed a deep bluish-color, whereas acetate showed a purple color.

7: Scarf showing a light bluish-purple color in a relatively dilute methanol extract solution of the pigment.

8: Kimono dyed by boiling with the bacterial cells.

Fig.1. *Janthinobacterium lividum* which produces a bluish-purple pigment and samples dyed with the pigment

(2) Dyeing performance

α : Dyeability of different fibers

Since we had found that the pigment was capable of dyeing not only natural fibers but also synthetic fibers, we compared the dyeing performance of 9 different fibers, using a multi-fiber test cloth (Fig. 1-6). The dyeing performance differed depending on the type of fiber. Nylon was the easiest to dye, followed by vinylon, acetate, raw silk, cotton and wool. Rayon could be dyed only slightly and almost no dyeing occurred with acrylic fiber and polyester. Although Fig. 1-6 shows that polyester also had been dyed to a moderate extent, almost no dyeing occurred when the pigment concentration was low. Most of the fibers showed a color range from light purple to bluish-purple. However, the shade differed slightly depending on the fiber, for example, nylon showed a deep bluish-purple color and acetate a purple color.

Control (water)		+

a): The color depth of the silk fabric dyed at room temperature was classified into 5 grades, from colorless (–) to dark (++++).

BACK

(2) Dyeing performance

(2) Dyeability of difference

b: Duration of immersion and extent of dyeing

The extent of dyeing differed with the duration of immersion in the dye bath. At room temperature using the methanol extract, silk and cotton become dyed within 5-10 min of immersion. The color became deeper within 1-10 h and dye uptake continued even after, reaching a peak in about 2 days. On the contrary, nylon and acetate required only a very short time for dyeing. Dyeing occurred within several seconds after the start of immersion and within more than 10 h. Dyeing of acetate peaked after about 1 h. With nylon, the shade could be varied freely from pale lavender to dark bluish-purple by changing the dyeing time.

c: Temperature and dyeing rate

The dyeing rate was significantly affected by the temperature of the dye bath. For example, when silk was dyed in the methanol solution of the pigment, the immersion time required for the color depth achieved in 15 min of dyeing at 20, was 5 min at 40, 1 min at 60, and 30 s at 70. For achieving the color depth obtained after 6 h at 20, it took one day at 40 and 3 days at 60.

(3) Color fastness

Silk samples dyed by the 2 methods were tested for their color fastness⁴. The method of dyeing did not affect appreciably the color fastness ([Table 5](#)). Although the fastness of the color against light was somewhat low (Grade 1), the fastness against washing was of Grade 2-3, and 3-5 in other tests. Overall, the color fastness was about the same as that of vegetable dyes. In other words, although the color fastness was not very high, it was in the practically tolerable range, except for the fastness against light⁴. About the same results were obtained with cotton fabric in all the tests. The color fastness against light of deeply dyed nylon and vinylon was slightly higher than that of silk or cotton(Grade 1-2).

(4) Improvement of color fastness against light

In practice, when a bluish-purple dye is used to dye fabrics, the major problem is the photosensitivity of the color. The bluish-purple color fades very rapidly in the presence of sunlight, and such dyeing is therefore of limited practical use⁴. As a result, we examined various treatments for improving the resistance to light of textiles dyed with the bluish-purple pigment⁵. We had examined various treatments for improving the color fastness against light of fiber and textile products dyed with this bluish-purple pigment. It was found that if the dyed material was subjected to post-treatment with a thiourea solution, the fading of color due to light was considerably reduced⁵.

A piece of silk fabric (plain Habutae with Mezuke weight 14) was dyed in a methanol solution of the bluish-purple pigment extracted from the bacterium, at room temperature by dipping in the dye bath at a liquor ratio of about 1:100 for 2 days. The dyed material was then immersed in a 0% ~ saturated thiourea solution (liquor ratio about 1:300) for about 1 min at room temperature. It was then drained and air-dried. The color fastness of the dried material against light was determined by the direct sunlight method (JIS L 0841). The thiourea-treated fabric showed a slower rate of color fading, suggesting that the color fastness had improved ([Fig. 4](#)). The effect of suppression of fading under light became more pronounced with the increase of the thiourea concentration. When the dyed samples were treated with a 5% thiourea solution and a saturated thiourea solution, the former showed a color fastness of Grade 2 and the latter of Grade 3. The color fastness of the untreated material was lower than Grade 1. The bluish-purple dyed material which had been treated with the thiourea solution did not cause any change in shade, nor did it have any adverse effect on the feel of the material.

Next, we treated the bluish-purple dyed material once, 2 or 5 times with a saturated thiourea solution, through the steps described below.

1. Dipping in a saturated thiourea solution for 3 min at room temperature, draining and air-drying.
2. Washing with lukewarm water (deionized water at 40) for 2 min.
3. Dipping in a saturated thiourea solution for 1 min at room temperature, draining and air-drying.

Only the steps 2. and 3. were repeated when the treatment was applied several times. The fading of color under light was suppressed even more with repeated

(2) Dyeing performance
thiourea treatment ([Table 6](#)).

Conclusion

About 10 years ago, one of the present authors (Kojima) discovered that the color of some thread dust left in a bucket had become bluish-purple. We were able to isolate a bacterium which was identified as *Janthinobacterium lividum*.

The bacterial cells were extracted with tetrahydrofuran for one day and the extract was filtered. Then, after concentrating the extract under reduced pressure, it was fractionated by silica gel chromatography (hexane : tetrahydrofuran : acetone = 4 : 2 : 1) and reversed phase high performance liquid chromatography (70% methanol), recrystallized, and 2 bluish-purple pigment components were separated. The color was derived from a pigment called violacein stored by the bacteria. The bacteria are not pathogenic and violacein is not toxic.

The pigment from these bacteria can be used to dye natural fibers, providing good color tone and stability. The results of the color fastness tests against washing, hot-water, sweat and rubbing were about the same as those of vegetable dye and were in the practically tolerable range, except for the fastness against light (Grade 1). We examined various treatments for improving the resistance to light of textiles dyed with the bluish-purple pigment. It was found that when the dyed material was subjected to post-treatment with a thiourea solution, the fading of the bluish-purple color due to light was considerably reduced. When the dyed samples were treated with a 5% thiourea solution and a saturated thiourea solution, color fastness of Grade 2 and Grade 3 was obtained with the former or the latter, respectively. Also, the bluish-purple dyed material which had been treated with the thiourea solution did not show any change in shade, nor did it have any adverse effect on the feel of the material. Moreover, since mass-culture of the bacteria is possible, the pigment and dye can be produced cheaply.

Abstract

The objective of the current studies was to analyze the relation of sex steroid treatment with the pattern of uterine secretory proteins and production of tumor necrosis factor α (TNF α) and nitric oxide (NO) by murine macrophages. Specific pathogen free (SPF) CD1 mice were ovariectomized and divided into 6 groups which were treated with different sex steroids: progesterone (group 2), estradiole (group 3), progesterone plus estradiole (group 4), estradiole plus progesterone (group 5), testosterone (group 6) and placebo (group 1). The treatments were continued by subcutaneous embedding of hormone pellets for 30 days. Total white blood cell counts in groups 4 and 5 showed a statistically higher total leukocyte count ($p \leq 0.05$) than that in groups 2 and 6 ($p \leq 0.05$). Lipopolysaccharide (LPS)-stimulated peritoneal macrophages from estrogen-treated mice produced a significantly higher level of NO than those in the other groups ($p \leq 0.05$). TNF α production by the macrophages significantly increased by estrogen or testosterone treatment compared with the control ($p \leq 0.05$). LPS induced a 2 fold production of both TNF α and NO by peritoneal macrophages. It was observed that steroid treatment induced a *de novo* synthesis of products with patterns specific to uterine proteins. Our results showed that sex steroids affect the macrophage function and modulate the pattern of secretory uterine proteins. The usefulness of the mouse model with subcutaneous embedding of hormone was also demonstrated.

Discipline: Animal health/ Animal industry

Additional key words: LPS, uterus, NO

(Received for publication, June 8, 1999)

Introduction

The sex steroids exert various actions on the reproductive tract and they modulate the immune system^{18,31}). It is known that estrogen stimulates, whereas progesterone and testosterone suppress systemic¹²) and local³³) production of immunoglobulins, respectively. The natural killer cell activity was inhibited by estradiole^{1,2}) and progesterone²). Both estrogen and progesterone show an enhancing effect

while Danzol, a synthetic testosterone, an inhibitory effect on interleukin-1*b* (IL-1*b*), serum proteins and TNF*α* production in cultured human monocytes¹⁹). Macrophages of the uterus show a change in number and functional ability in the production of cytokines, reactive oxygen intermediates and bioactive lipids depending on the reproductive cycle⁹). Although data on the influence of sex steroids on macrophages have accumulated, many aspects remain to be elucidated^{3,4,9,12,15}). Characteristic pattern of uterine secretory proteins which has been analyzed in relation to the host reproductive cycle and host defense mechanisms in some animals, has not been reported in mice^{14,20,24,25}). The purpose of this study was to develop a mouse model for chronic sex steroid treatment with estradiole, progesterone, testosterone and their combination and to determine the effects on the modulation of TNF*α* and NO production by macrophages, as well as the pattern of uterine secretory proteins.

Materials and methods

1) *Animals*

Forty specific pathogen free (SPF) mice (strain CD1), nulliparous (CLEA Inc., Japan), 6-8 weeks of age and weighing 30-40 g were used. The mice were kept in micro-isolation units in a laminar flow rack housing system (ICM Inc., Tsukuba, Japan). All the mice underwent an ovariectomy operation under general anesthesia with intraperitoneal injection of 50 mg/mice of pentobarbital sodium (ABBOT Laboratories, USA). Mice were given proper postoperative care and were maintained under SPF housing system.

2) *Treatment with sex steroids*

Two weeks after the ovariectomy, the mice were divided into 6 groups and treated as shown in [Table 1](#). In the combined treatment, implants were applied at 2 different sites. The treatment continued for 30 days in the SC implants. Progesterone (C₂₁ H₃₀ O₂), estradiole (C₁₈ H₂₄ O₂) and testosterone (C₁₉ H₂₈ O₂) were purchased from NACALAI TESQUE Inc., Kyoto, Japan. The hormone pellets were prepared by mixing the sex steroid with 0.2 g cholesterol and 0.1 g sesame oil⁶). This mixture was injected subcutaneously in the hind back with a syringe with a wide gauge needle. The controls received only the vehicle.

3) *Hematology*

At the end of the treatment period, heparinized and non-heparinized blood was collected under general ether anesthesia. Serum was stored at -20°C until the assay. Differential leukocyte count was performed using May-Grunwald-Giemsa stained blood smears. White blood cell count (WBC) was performed using a Coulter counter (Coulter Electronics Inc., Florida), with LYES II (K-CN) reagent for the simultaneous quantitative determination of hemoglobin and leukocytes (Japan Scientific Instrument Co., Ltd.).

4) *Peritoneal macrophages*

Peritoneal macrophages were collected aseptically by injection with 5 mL of cold RPMI 1640 (Nissui Pharmaceutical Co., Ltd., Japan) and the back of the mice was agitated for 30 s. Thereafter, the fluid was aspirated. Peritoneal cells were harvested with 2 successive washings in RPMI 1640 medium by centrifugation at 300 xg for 5 min at 4°C. The number of macrophages was counted and the macrophages were seeded into the wells of 96 well plates (Becton Dickinson) at the rate of 10⁴ macrophages/ well. They were incubated for 2 h at 37°C in 5% CO₂ to allow them to adhere and those that did not adhere were removed by washing twice in RPMI 1640.

5) *Analysis of TNF α and NO*

The macrophages of each group were stimulated by lipopolysaccharide (LPS, *Escherichia coli* 0111: B4, Sigma, USA) for 4 h and 20 h. Supernatants were collected at 4 h for the TNF α assay and 20 h for the NO assay after the stimulation and stored at -20°C until the assay. Two sets of wells were prepared: LPS+ and 2 other sets as LPS- or controls during the assays.

The NO synthesis of the macrophages was determined by Griess assay⁷). Cell culture supernatants were assayed by the addition of 1:1 (v/v) 50 mL to each well of a 96-well plate (in triplicate), and 50 mL Griess reagent (N-1-naphthyl ethylene diamine dehydrochloride 0.1% in H₂O, sulphonil amide 1% in 5% H₃PO₄, Sigma), then immediately mixed and incubated at room temperature for 5 min. Absorbance at 550 nm was measured by using the plate reader Model 450 (Bio Rad, USA). The NO concentration was

calculated from the standard curve produced during each assay by using NaNO₂ (NACALAI TESQUE Inc., Kyoto, Japan) dissolved in 15 mM Hepes, pH 7.5 and expressed as nmol /mL as mean values \pm SD.

The level of TNF α in the supernatant of the macrophage culture was measured by the sandwich ELISA method. Rat anti-mouse TNF α monoclonal antibody (mAb) (generously provided by Dr. Nakane of Hirosaki University) was diluted to 2 mg/mL in 0.1 M NaHCO₃, pH 8.2. Wells of a 96 flat-bottomed probind assay plate (Becton Dickinson) were coated with 50 mg/well of the capture antibody and incubated overnight at 4°C. The plates were washed 2 times in 350 mL of PBS Tween-20 (Bio Rad) using an immuno-wash 450 (Bio Rad). Three hundred fifty mL of blocking agent (Snow Brand, Japan) was added per well and incubated for 2 h at room temperature and washed 2 times. Standard recombinant mouse TNF α (Genzyme) diluted serially in the blocking agent to generate a standard curve and samples were added at the rate of 100 mL/well in triplicate and incubated at 4°C overnight and washed 4 times. Biotinylated anti-mouse TNF α clone mp6-XT3 (Pharmingen, USA) diluted to 1 mL/mL in the blocking agent was added and washed 6 times. Then 4x10³/mL of the peroxidase-conjugated streptavidin (Biogenx Lab. USA) diluted 1:3 v/v in the blocking agent was added at 100 mL/well, incubated for 30 min at room temperature and washed 8 times. Finally 20 mg of a substrate, phenylene diamine (NACALAI TESQUE), in 25 mL of 0.1 M citric acid, 25 mL of 0.2 M NaHPO₄/2H₂O and 1 mL of 30% H₂O₂ was added at the rate of 100 mL/ well and the color was allowed to develop at room temperature for 90 min. The color reaction was stopped using 3N H₂SO₄ and read at OD 450 nm using a microplate reader 450 (Bio Rad). TNF α values were calculated from the standard curve as mean \pm SD. The sensitivity of the assay was 50 pg/mL.

6) Examination of uterine fluid

Uterine secretion was washed out aseptically in 200 mL of 0.9% NaCl solution. Individual and pooled samples from the same group were designated as uterine luminal proteins 1 to 6 (ULP1 to ULP6) and stored at -20°C until assay. Uterine fluid was cultured in DHL and B. H. I agar medium (Eiken Chemical Co., Ltd., Japan) for bacterial examination.

For electrophoresis, uterine fluid was adjusted to 200 mg/mL protein, and added to the 2X SDS sample buffer 2: 1 (v/v) and to 5% 2-mercaptoethanol. The sample cocktail was then denatured by incubation for 5 min at 100°C. The samples and molecular markers were loaded on Phast gel gradient 10-15 (Pharmacia Biotech, USA) using an 8/1 sample applicator and analyzed by Phast system SDS-PAGE (Pharmacia KLB). Electrophoresis was run for 65 Vh at 250 V, 10.0 mA, 3.0 W and 15°C. Gels were then stained using a silver staining kit (Pharmacia Biotech). The gels were analyzed using Phast image software (Pharmacia LKB); gels were scanned in transmittance mode. Lanes were examined slice by slice with calibration curves.

7) Statistical analysis

Data were analyzed by the Student T test ($p \leq 0.05$ indicated statistical significance).

Results

The concentration of NO was compared in the 20 h culture supernatant of resident peritoneal macrophage cell culture obtained from the *in vivo* sex steroid-treated mice and *in vitro* macrophages exposed to LPS ([Table 2](#)). The peritoneal macrophages from the group treated with estradiole alone showed a significantly higher concentration of NO than those in the other groups ($p \leq 0.05$) ([Table 2](#)). No statistical difference was observed in the production by macrophages without LPS stimulation ([Table 2](#)). NO values were always higher in the LPS+ than LPS- macrophage culture supernatants.

TNF α production in the 4 h culture supernatants with or without LPS is shown in [Table 2](#). Peritoneal macrophages from the estradiole or testosterone-treated groups showed a higher level of TNF α production without LPS stimulation ($p > 0.05$) than those in groups 1, 2 and 4. LPS treatment stimulated TNF α production by the macrophages in all the groups. However, the groups treated with estradiole or testosterone showed a significantly higher TNF α production than group 1 ($p \leq 0.05$).

Mouse uterine fluid and serum samples were subjected to SDS-PAGE. There were many similar bands in both samples, but unique bands were also detected. After the samples were scanned, the bands common to serum and uterine proteins were deleted to determine whether the treatments with each of the sex steroids had induced specific uterine protein bands. The treatments induced several proteins as shown in [Fig. 1](#). After the samples were scanned, bands common to serum and uterine proteins, as well as specific bands in the uterine fluid or serum were obtained as shown in [Table 3](#).

Fig.1. SDS-PAGE analysis of total serum proteins (A) and (B) uterine proteins in response to sex steroid treatments

Lane 1: low molecular weight marker (94,000, 67,000, 43,000, 30,000, 20,100, 144,000).

Lane 2-7: samples from treatment groups 1,2,3,4 and 5, as described in the materials and methods.

Arrows indicate bands of 70 KDa protein.

The effect of the chronic sex steroid treatment on the total and absolute number of leukocytes is shown in [Table 4](#). The total number of white blood cells (WBC) and subsets of peripheral leukocytes in the groups 4 or 5 were higher compared to the groups 2 and 6. WBC numbers and their subsets were affected by the treatment ($p \leq 0.05$) as shown in [Table 4](#). The total number of red blood cells (RBC) and mean corpuscular hemoglobin concentration (MCHC) were not different among the treated and control groups (data not presented here). Bacterial culture of uterine fluid for *E. coli* was negative.

Discussion

In the present study, the effects of chronic subcutaneous treatment with embedded sex steroid pellets in mice on the modification of the macrophage activities, hematological characteristics, and pattern of uterine secretory protein were investigated. LPS is a well-known stimulator of macrophages^{17,23,29}). Priming effects for the up- and down-regulation of TNF α and NO production by different concentrations of LPS and other substances were reported^{22,26,34}). The present results showed that there were no significant differences in the background level of NO production by peritoneal macrophages obtained from mice treated with different sex steroids. However, LPS stimulation up-regulated NO synthesis by the peritoneal macrophages. Schneemann et al. (1993) reported a 2.5-30 fold increase of NO in the supernatants from murine peritoneal macrophages after stimulation with LPS²²). Furthermore, a single estrogen treatment led to the priming

of macrophages to produce higher levels of NO than those attained with other steroids²²). This observation suggests that estrogen plays an immuno-potentiating role. In contrast to the present results, rat alveolar macrophages treated *in vitro* with estradiol or progesterone showed a down-regulation of NO production²¹). In other cells than macrophages, it was reported that estradiol up-regulated NO production in cultured human aortic endothelial cells⁸). No significant calcium-independent NO activity was reported either during the pregnancy or after administration of sex hormones³²). These data suggest that the effect of female sex steroids varies depending on the tissues, or duration of the treatments, and under *in vivo* and *in vitro* conditions. Sex steroids affect the host antimicrobial function via NO production^{13,32}).

In the present study, the level of TNF α increased by treatment with both estradiol and testosterone. It was reported that female sex steroid hormones enhance the production of colony-stimulating factor-1 (CSF-1), transforming growth factor (TGF α), granulocyte monocyte- colony stimulating factor (GM-CSF) and TNF α ⁹). Since the NO synthesis induced by LPS was mediated by IFN and not by TNF α , it is suggested that TNF α and NO had different regulatory pathways⁵). In the LPS stimulated mouse macrophage cell lines (RAW264, ANA cells) estrogen up-regulated the TNF α production and progesterone down-regulated it¹⁶). Chao et al. (1995) reported that estrogen treatment at a rate of 10⁻² and 10⁻³ g/mL significantly up-regulated TNF α expression in male rat peritoneal macrophages, but down-regulated it at a rate of 10⁻¹ or less than 10⁻⁴ mg/mL³). These results also indicate that the effects of sex steroids on the macrophage function are complex.

Characteristic pattern of uterine fluid depending on the reproduction cycle was reported and the role of the proteins in host defense mechanisms was examined^{18-20,24,25,28,30,33}). However, since no report on the pattern in mice had been reported previously, we observed the expression patterns of protein in the uterine fluid in the present study. Treatment of ovariectomized ewes with progesterone F2 α induced the production of an immuno-suppressive protein with a molecular weight of 55,000 in the uterus²⁴). Chronic estrogen exposure was reported to lead to the development of complex endometrial hyperplasia in women and was related to the over-expression of lactoferrin²⁰). Lactoferrin (LF) is a 70 KDa protein that is not induced by either progesterone or testosterone^{28,30}). However, in our study in all the treated groups, a 70 KDa protein was induced, presumably due to the longer treatment period. However, further determination using Western blotting should be carried out.

The uterus is a sex steroid-responsive organ²⁷). Treatment with steroids induced the formation of several proteins, which were identical with serum proteins, presumably due to the uterine edematous reaction, serum transudation by vasodilation^{10,27}), or secretion by uterine epithelial cells²⁷). The patterns specific to uterus protein, in the present study, corresponded to de novo synthesized products as a result of the steroid treatment.

Compared to previous reports¹¹), in our study, the number of WBC was lower, which may be due to the fact that we used SPF mice.

In conclusion, we demonstrated the modulation of macrophage function and the expression of uterine proteins by sex steroid treatment. Further studies are required to characterize fully the uterine proteins and analyze their relationship with the function of macrophages.

Abstract

To analyze the sustainability and carrying capacity of a mangrove forest, we studied the profiles of species composition and biomass from the riverside to inland. A belt transect (25?180 m) divided into 9 plots was established in compartment 46, in the Matang Mangrove Forest Reserve, Perak, Peninsular Malaysia. Five tree species were distributed in the transect. *Rhizophora apiculata* showed the highest density, followed by *Bruguiera parviflora*, *B. sexangula*, *R. mucronata* and *Avicenia alba*. From the riverside to inland, the structure changed from pure *R. apiculata* stands to mixed *Rhizophora-Bruguiera* stands. The mean aboveground biomass of all the plots was 316 Mg ha⁻¹. The largest and smallest volumes for biomass were 558 Mg ha⁻¹ on the riverside and 144 Mg ha⁻¹ inland, respectively. The values tended to be higher in *R. apiculata*-dominant stands. If a larger productive area could be set up where *R. apiculata* would predominate, i.e. an area at a lower ground level, a larger sustainable amount of biomass for firewood and charcoal use could be produced. The annual dead biomass, which is supplied to the forest floor as nutrients for aquatic life, was 5.1 Mg ha⁻¹. While stocked biomass is more valuable to a local economy than the dead biomass, the contribution of the fallen trees (dead biomass) to habitats and nutrients for aquatic life must be evaluated exactly in the future.

Discipline: Forestry and forest products

Additional key words: *Rhizophora*, *Bruguiera*, brackish water, sustainable management

1...11):[References](#)

(Received for publication, July 16, 1999)

Introduction

The Matang mangrove forest in Perak, Peninsular Malaysia covers a land area of approximately 40,711 ha^{1,3)}. The productive forest accounts for 85% of the area and has been appropriately managed under a working plan since the beginning of the 19th century. Moderate harvesting of firewood and wood for charcoal has supported the livelihood of the local people working in forestry. Meanwhile, the floor of mangrove forests and surrounding brackish water areas have supplied habitats enabling aquatic animals, i.e. crabs, shrimps and fish, to grow and breed. In other words, the people engaged in fisheries harvest the benefits of the forest.

The brackish water mangrove project has been carried out jointly by Japan International Research Center for Agricultural Sciences, Fisheries Research Institute, University of Malaya and Forest Research Institute of Malaysia for 5 years (FY 1995-1999). It aimed at obtaining new findings and information to analyze the sustainability and carrying capacity of the mangrove ecosystems. Under the project, the forest biomass stocked as living trees (wood resources), and released as litter (nutrients for aquatic life) was analyzed. The aboveground biomass had been estimated for several forests of the same species^{4,5,9)}. However, the differences among micro-sites and the total amount of litter (biomass of dead trees) are still unknown. In this study, we report the changes in species composition and aboveground bio-mass from the riverside to inland and the dead biomass in a typical natural forest dominated by *Rhizophora* and *Bruguiera* species.

Methods

The experimental site established in compartment 46, Matang, Perak, Peninsular Malaysia (4°47'52"N, 100°38'49"E), consists of a belt transect extending from the riverside to inland with a size of 25 x 180 m. The transect was divided into 9 plots (25 x 20 m each), Plots 1-9, starting from the riverside. The edge of Plot 1 was separated by a distance of about 10 m from the riverside. The arrangement of the plots was described in previous reports^{6,7)}.

For all the live trees more than 1.2 m in height, we measured the diameter of the stem at the 1.2 m height (D), as well as the height (H) and determined the location. When the position of the highest prop root was higher than 1.2 m, we measured D at 20 cm above the prop root. In this study, trees corresponded to a stem with D x 5 cm and saplings to a stem with $H \geq 1.2$ m and $D < 5$ cm. Gap was defined as the area under a canopy opening, which is equivalent to the canopy gap defined by Runkle¹⁰⁾. Location and area of the gap were also determined. The dead trees of 1 year were recorded in the following year.

The volume of each tree (D² x H) was used to calculate the biomass (dry matter weight of aboveground organs). To estimate the biomass, we used the coefficients of allometric equations of Kusmara et al.⁵⁾.

Results

Five species were recorded in the transect. *Rhizophora apiculata* showed the highest density, followed by *Bruguiera parviflora*, *B. sexangula*, *R. mucronata* and *Avicenia alba*. While the trees showed a random distribution in space, the saplings showed a contiguous distribution (Fig. 1). Gaps existed in all the plots except in Plot 1, but the larger ones were concentrated in Plots 4, 5 and 6.

Fig.1. Spatial distribution of trees (upper) and sapling (lower) in a belt transect (Compartment 46, Matang mangrove forest)

Plots numbered 1 to 9 are located on a transect extending from the riverside to inland.

Some values among the plots showed distinct differences (Fig. 2). The maximum H of trees ranged from 33.2 m (Plot 1) to 23.4 m (Plot 5). Although the mean H of trees was similar among the 7 plots, the values in Plot 1 (26.0 m) and Plot 8 (15.3 m) were considerably higher and lower than those in the other plots, respectively. The mean D values in Plots 1 and 8 were largest (27.8 cm) and smallest (14.2 cm), respectively among the plots. The smaller the values of H and D, the higher the density. The canopy rate, which is defined as the plot area (100%) minus gap area (%), ranged from 100% in Plot 1 to 83% in Plot 5. The largest and smallest values for biomass were 558 Mg ha⁻¹ in Plot 1 and 144 Mg ha⁻¹ in Plot 8, respectively. The mean biomass of all the plots was 316 Mg ha⁻¹.

The tree species showed some features in their height distribution, i.e. the structural profile along the transect (Figs. 3 and 4). For trees, there were 4 species which differed in their distribution and density. *R. apiculata* formed a canopy in all the plots, and it was the most abundant species in each plot except in Plot 8; in particular, it occurred in the canopy layer contiguously in Plot 1. *B. parviflora* was distributed in most plots, except in Plots 1 and 6, and was mainly observed in the sub- or under-canopy layer. *B. sexangula* formed the canopy in Plots 5, 8 and 9. *R. mucronata* was found only in the canopy layer of Plot 9.

There were 4 species of saplings (Figs. 3 and 4). *B. parviflora* was the most abundant species and was distributed contiguously in Plots 4 and 5, followed by *B. sexangula* which was distributed from Plots 2 to 9. *R. apiculata* was observed in the lower layer at around 1.2 to 3.0 m and was concentrated in Plots 4 and 5. No *R. mucronata* saplings were detected in the transects, and in the case of *A. alba*, there were no trees but saplings in the lower height layer.

R. apiculata accounted for 83% of the total above-ground biomass, followed by *B. sexangula*, *B. parviflora* and *R. mucronata* with 8, 6 and 3% of the total, respectively. Percentages of tree density for *R. apiculata*, *B. sexangula*, *B. parviflora* and *R. mucronata* were 65, 14, 20, 1%, respectively. *R. apiculata* accounted for a larger biomass rate than the density rate in most plots, except in Plots 8 and 9 (Fig. 4). The profiles of densities of saplings showed different patterns compared with trees (Figs. 3 and 4). The densities were extremely high in Plots 4 and 5, and the composition rate of the species was different. For *R. apiculata* the density of saplings was lower than the density of trees, and the value was lower in plots where the species was predominant in terms of tree biomass and density, e.g. Plots 1, 2 and 6. Conversely in the case of *B. parviflora* the tree biomass and density were not the highest in all the plots, but the density of the saplings was predominant in most plots.

The mean value of aboveground biomass that produces debris (large litter) on the forest floor in a year was 5.1 Mg ha⁻¹ ([Table 1](#)). The biomass corresponded to the dry weight of the trees which had died in a year. The values ranged from 0 to 15.4 Mg ha⁻¹ among the plots and the rates to the living biomass were 0 to 6.3%.

Discussion

The study plots in the transect appeared to reflect the structure of the Matang forest reserve. The forest is widely dominated by *R. apiculata* associated with *R. mucronata*, *B. parviflora* and *B. sexangula*³. *R. apiculata* was distributed and formed a canopy layer all over the transect (Figs. 3 and 4). *R. apiculata* trees were the only trees in some plots, and they tended to grow taller with a large biomass near the riverside. Nakamura et al.⁶ reported that *R. apiculata* showed a unimodal D distribution in Plot 1 in the area closest to the riverside. Moreover, the density of individuals in the understory and the sapling layer was low and the mortality of the seedlings (H < 1.2 m) was higher than in the other species. Therefore, they suggested that *B. sexangula* and *B. parviflora* that occurred as saplings and seedlings with a lower mortality might replace *R. apiculata*. Other plots also showed this tendency. The seedling density of *R. apiculata* was higher than that of *B. sexangula* and *B. parviflora* in Plot 1⁶. Moreover, the ratios of *R. apiculata* and 2 *Bruguiera* species showed an opposite trend for the values on the riverside (Plot 1) and inland (Plot 9). For *R. apiculata*, the riverside is a suitable site for seedling establishment, but not for growth and survival. In any case, in all tree species, the seedlings can not survive under closed canopy⁶. Therefore, in Plot 1 with a 100% canopy rate (see Fig. 3) light conditions are unfavorable for recruiting the seedlings to the sapling stage, suggesting that light rather than topographical factors affects the recruitment.

The profile of the species composition from the riverside to inland showed species-specific changes (Figs. 3 and 4). While the *R. apiculata* biomass largely predominated on the riverside, mixed stands with 3 to 4 species were observed inland. The fact that the density rates of *B. parviflora* and *B. sexangula* for trees, and especially for saplings, were higher inland suggests that forests change to a *Bruguiera* spp. forest with increasing distance from inland. Fujimoto et al.² also indicated a similar change in profile in Japan: *Rhizophora* species became predominant with decreasing ground level toward the seaside. A *Rhizophora-Bruguiera* mixed forest was established at higher ground level (inland). Haron Abu Hassan³ reported that *Rhizophora* and *Bruguiera* species were the major trees and shared the main habitat in the Matang mangrove forest. Therefore, it is important to analyze the dynamics and biomass of the 2 genera to determine the sustainability and carrying capacity of the forest.

The total biomass at the study site was 316 Mg ha⁻¹ ([Table 1](#)), a value lower than that in the protected stands with a mean of 409 Mg ha⁻¹ in Matang⁹ and showed comparable values to those of *R. apiculata* forests in Indonesia (356 Mg ha⁻¹)⁴. Kusmana et al.⁵ pointed out that a large biomass of more than

200 Mg ha⁻¹ is produced in an area where the annual temperature and precipitation exceed 25°C and 2,000 mm, respectively. The Malay Peninsula where the study area is located is under such climatic conditions. Moreover, the lack of wind disturbance mainly associated with typhoons contributes to the growth of taller trees⁹, and consequently higher trees produce a large biomass¹¹. In this study, pure stand of *R. apiculata* (Plot 1) had a large biomass with a value (dry matter, 558 Mg ha⁻¹) presumably higher than the biomass values reported in the literature. Sites with an extremely high or low biomass occur patchily in natural forests. Most of the pure stands of *R. apiculata* (Plots 1, 2 and 7, Figs. 2 and 3) display a larger biomass than the stands where *Rhizophora* and *Bruguiera* species grow together. Wood of *Rhizophora* species has a higher quality as fuel compared with that of *Bruguiera* species³. For the production of larger amounts of sustainable biomass for firewood and charcoal, it is important to secure a larger productive area where *R. apiculata* can predominate easily, i.e. areas at a lower ground level.

The annual dead biomass, which is supplied to the forest floor as nutrients for aquatic life, amounted to 5.1 Mg ha⁻¹. However, since this value was only recorded for 1 year and there are no other reports on dead biomass, further studies should be carried out. The balance between dead and growth mass in a year is 0 in a well-matured forest. Based on the biomass in a stand whose age was recorded exactly in Malaysia, the annual growth was 7.9 Mg ha⁻¹⁸. Although we can not simply compare the value⁸ with the dead mass in our stands, the forest under study must be still growing and preserving organic matter as live biomass. Moreover, it remains to be determined when the respective organs (leaf, branch and stem) fall to the floor after dying. It will be necessary to clarify the process whereby dead standing trees produce debris to determine the effect of fallen trees (dead biomass) on habitats and nutrients for aquatic life.

Abstract

Plant productivity is greatly affected by drought stress. We reported that a *cis*-acting promoter element, the dehydration response element (DRE), plays an important role in regulating gene expression in response to drought stress in *Arabidopsis*. The DRE is also involved in low-temperature and salt responsive gene expression. The transcription factor DREB1A specifically interacts with the DRE and induces expression of stress tolerance genes. Overexpression of the cDNA encoding DREB1A in transgenic *Arabidopsis* plants activated the expression of many of these stress tolerance genes under normal growing conditions and resulted in improved tolerance to drought, salt loading, and freezing. We prepared a cDNA microarray using full-length *Arabidopsis* cDNAs to identify the target stress tolerance genes of DREB1A. Twelve stress-inducible genes were identified as the target genes of DREB1A, and six of them were novel. However, use of the strong constitutive 35S cauliflower mosaic virus (CaMV) promoter to drive expression of DREB1A also resulted in severe growth retardation under normal growing conditions. In contrast, expression of DREB1A from the stress inducible *rd29A* promoter gave rise to minimal effects on plant growth while providing an even greater tolerance to stress conditions than did expression of the gene from the 35S CaMV promoter. As the DRE-related regulatory element is not limited to *Arabidopsis*, the DREB1A cDNA and the *rd29A* promoter may be useful to improve the stress tolerance of agriculturally important crops by gene transfer.

Keywords: abiotic stress, stress tolerance, gene expression, cis-element DRE, transcription factor DREB1A, transgenic plant

Introduction

Drought, salt loading, and freezing are environmental conditions that cause adverse effects on the growth of plants and the productivity of crops. Plants respond to these stresses at molecular and cellular levels as well as physiological level. Expression of a variety of genes has been demonstrated to be induced by these stresses.¹⁻⁴ The products of these genes are thought to function not only in stress tolerance but also in the regulation of gene expression and signal transduction in stress response (Fig.1).^{5,6}

Genetic engineering is thought to be useful for improving the stress tolerance of plants. Recently, several different approaches were attempted to improve the stress tolerance of plants by gene transfer.⁷ The genes selected for transformation were those involved in encoding enzymes required for the biosynthesis of

Fig. 1. Schematic representation of molecular responses to drought stress in plant cells. Molecular and cellular responses to drought stress include perception of dehydration signal, signal transduction to cytoplasm and nucleus, gene expression, and responses and tolerance to drought stress

various osmoprotectants.⁸⁻¹⁰ Other genes that have been selected for transformation include those that encoded enzymes for modifying membrane lipids, LEA protein, and detoxification enzyme.¹¹⁻¹⁴ In all these experiments, a single gene for a protective protein or an enzyme was overexpressed under the control of the 35S cauliflower mosaic virus (CaMV) constitutive promoter in transgenic plants, although a number of genes have been shown to function in environmental stress tolerance and response. The genes encoding protein factors that are involved in regulation of gene expression and signal transduction and function in stress response seem to be useful to improve the tolerance of plant to stresses by gene transfer as they can regulate many stress-inducible genes involved in stress tolerance.

Drought is one of the most severe environmental stresses and affects almost all the plant functions. Abscisic acid (ABA) is produced under water deficit conditions and plays important roles in tolerance against drought. Most of the drought inducible genes that have been studied to date are also induced by ABA.^{5,6} Several reports have described genes that are induced by dehydration but are not responsive to exogenous ABA treatments.^{5,6} These findings suggest the existence of ABA-independent as well as ABA-dependent signal-transduction cascades between the initial signal of drought stress and the expression of specific genes.^{5,6} To understand the molecular mechanisms of gene expression in response to drought stress, *cis*- and *trans*-acting elements that function in ABA-independent and ABA-responsive gene expression by drought stress have been precisely analyzed.^{5,6} In this article, we summarize recent progress of our research on *cis*- and *trans*-acting factors involved in ABA-independent gene expression in drought stress response. We also report stress tolerance of transgenic plants that overexpress a single gene for a stress-inducible transcription factor using *Arabidopsis* as a model.

A variety of functions of drought-inducible genes

Various genes respond to drought-stress in various species, and functions of their gene products have been predicted from sequence homology with known proteins. Many drought-inducible genes are also induced by salt stress and low temperature, which suggests the existence of similar mechanisms of stress responses. Genes induced during drought-stress conditions are thought to function not only in protecting cells from water deficit by the production of important metabolic proteins but also in the regulation of genes for signal transduction in the drought stress response.¹⁻⁶ Thus, these gene products are classified into two groups (Fig. 2). The first group includes proteins that probably function in stress tolerance; such as chaperones, LEA

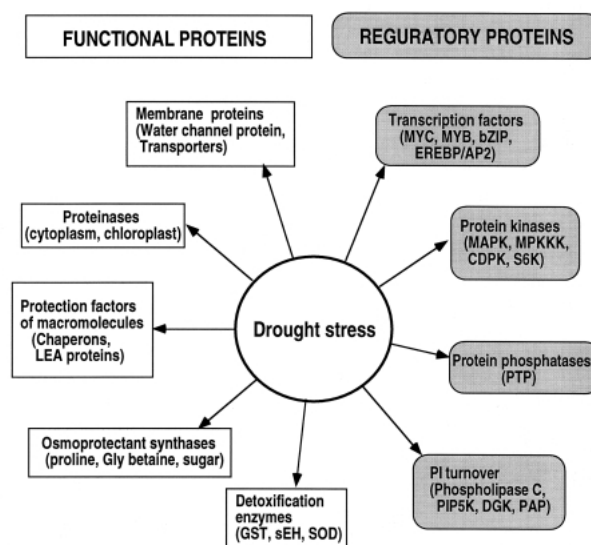

Fig. 2. Drought-stress inducible genes and their possible functions in stress tolerance and response. Gene products are classified into two groups. The first group includes proteins that probably function in stress tolerance (Functional proteins), and the second group contains protein factors involved in further regulation of signal transduction and gene expression that probably function in stress response (Regulatory proteins).

proteins, osmotin, antifreeze proteins, mRNA binding proteins, key enzymes for osmolytes biosynthesis, water channel proteins, sugar and proline transporters, detoxification enzymes and various proteases. LEA proteins, chaperones and mRNA binding proteins have been analyzed biochemically and shown to be involved in protecting macromolecules like enzymes, lipids and mRNAs from dehydration. Proline, glycine betaine and sugars function as osmolytes and protecting cells from dehydration. Key enzymes of several osmolytes have been cloned and analyzed biochemically. Water channel proteins, sugar transporters and proline transporters are thought to function in transport of water, sugars and proline through plasma membranes and tonoplast to adjust osmotic pressure under stress conditions. Detoxification enzymes, such as glutathione S-transferase, superoxide dismutase, and a soluble epoxide hydrolase are involved in protection of cells from active oxygens. Proteases including thiol proteases, Clp protease, and ubiquitin are thought to be required for protein turnover and recycle of amino acids.

The second group contains protein factors involved in further regulation of signal transduction and gene expression that probably function in stress response: protein kinases, transcription factors and enzymes in phospholipids metabolism.¹⁻⁶ Genes for a variety of transcription factors that contain typical DNA binding motifs, such as bZIP, MYB, MYC, ERF/AP2 and Zinc fingers, have been demonstrated to be stress inducible.^{4,6}

These transcription factors function in further regulation of various functional genes under stress conditions. Various protein kinases, such as MAP kinases, calcium dependent protein kinases (CDPK), SNF1 related protein kinase and ribosomal S6 kinase were demonstrated to be induced or upregulated by dehydration.^{6,15} Stress-inducible genes for protein phosphatases are reported.¹⁶ These protein kinases and phosphatases may be involved in modification of functional proteins and regulatory proteins involved in stress signal transduction pathways. Phospholipids, such as inositol 1,4,5-triphosphate, diacylglycerol and phosphatidic acid are believed to be involved in stress signaling process in plants.⁶ Enzymes involved in phospholipids metabolism of which genes are stress-inducible may play important roles in stress signaling as well. Existence of variety of drought-inducible genes suggests complex responses of plants to drought stress. Their gene products are involved in drought stress tolerance and stress responses.

Expression of dehydration-induced genes in response to environmental stresses and ABA

The expression patterns of genes induced by drought were analyzed by RNA gel-blot analysis. Results indicated broad variations in the timing of induction of these genes under drought conditions. All the drought-inducible genes are induced by high salinity stress. Most of the drought-inducible genes also respond to cold stress but some of them do not, and vice versa. Many genes respond to ABA whereas some others do not.¹⁻⁶ ABA-deficient mutants were used to analyze drought-inducible genes that respond to ABA. Several genes were induced by exogenous ABA treatment, but were also induced by cold or drought in ABA-deficient (*aba*) or ABA-insensitive (*abi*) *Arabidopsis* mutants. These observations indicate that these genes do not require an accumulation of endogenous ABA under cold or drought conditions, but do respond to ABA. There are ABA-independent as well as ABA-dependent regulatory systems of gene expression under drought stress. Analysis of the expression of ABA-inducible genes showed that several genes require protein biosynthesis for their induction by ABA, suggesting that at least two independent pathways exist between the production of endogenous ABA and gene expression under stress conditions.

As shown in Fig. 3, it is now hypothesized that at least four independent signal transduction pathways function in the activation of stress-inducible genes under dehydration conditions: two are ABA-dependent (pathways I and II) and two are ABA-independent (pathways III and IV).^{5,6} One of the ABA-dependent pathways requires protein biosynthesis (pathway I). *Cis-*

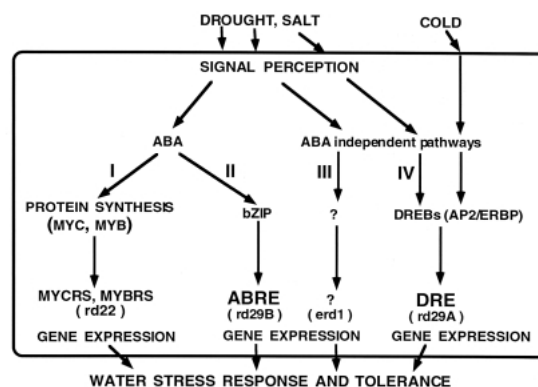

Fig. 3. Signal transduction pathways between initial dehydration stress signal and gene expression. There are at least four signal transduction pathways: two are ABA-dependent (I and II) and two are ABA-independent (III and IV). Protein synthesis is necessary for one of the ABA-dependent signal pathways (I). ABRE is involved in one of the ABA-dependent pathway (II). In one of the ABA-independent pathways, DRE is involved in the regulation of genes not only by drought and salt but also by cold stress (IV). Another ABA-independent pathway is controlled by drought and salt, but not by cold (III).

and *trans*-acting factors involved in ABA-induced gene expression have been extensively analyzed in one of the ABA-dependent pathway (pathway II). One of the ABA-independent pathways overlaps with that of the cold response (pathway IV). There are several drought-inducible genes that do not respond to either cold or ABA treatment, which suggests that there is a fourth pathway in the dehydration stress response (pathway III). Recently, based on genetic analysis of *Arabidopsis* mutants with the *rd29A* promoter::luciferase transgene, the existence of drought-, salt- and cold-specific signaling pathways in stress response was suggested, but crosstalks between these signaling pathways were also observed.

Identification of a *cis*-acting element, DRE, involved in drought-responsive expression

Numbers of genes are induced by drought, salt and cold in *aba* (ABA-deficient) or *abi* (ABA-insensitive) *Arabidopsis* mutants. This suggests that these genes do not require ABA for their expression under cold or drought condition. Among these genes, the expression of a drought-inducible gene for *rd29A/lti78/cor78* was extensively analyzed.¹⁷ At least two separate regulatory systems function in gene expression during drought and cold stress; one is ABA-independent (Fig. 3, pathway IV) and the other is ABA-dependent (pathway II).

To analyze the *cis*-acting elements involved in the ABA-independent gene expression of *rd29A*, we

constructed chimeric genes with the *rd29A* promoter fused to the b-glucuronidase (*GUS*) reporter gene and transformed *Arabidopsis* and tobacco plants with these constructs. The *GUS* reporter gene driven by the *rd29A* promoter was induced at significant levels in transgenic plants by conditions of dehydration, low-temperature, or high-salt or by treatment with ABA.¹⁸ The deletion, the gain-of-function and the base substitution analysis of the promoter region of *rd29A* gene revealed that a 9-bp conserved sequence, TACCGACAT (DRE, Dehydration Responsive Element), is essential for the regulation of the expression of *rd29A* under drought conditions. Moreover, DRE has been demonstrated to function as a *cis*-acting element involved in the induction of *rd29A* by either low-temperature or high-salt stress.¹⁷ Therefore, DRE seems to be a *cis*-acting element involved in gene induction by dehydration, high-salt, or low temperature, but does not function as an ABA-responsive element in the induction of *rd29A*.

Important roles of the DRE binding proteins during drought and cold stresses

Two cDNA clones that encode DRE binding proteins, DREB1A and DREB2A, were isolated by using the yeast one-hybrid screening technique.¹⁹ The deduced amino acid sequences of DREB1A and DREB2A showed significant sequence similarity with the conserved DNA binding domains found in the ERF and APETALA2 proteins that function in ethylene-responsive expression and floral morphogenesis, respectively.^{20, 21} Each DREB protein contained a basic region in its N-terminal region that might function as a nuclear localization signal and an acidic C-terminal region that might act as an activation domain for transcription. These data suggest that each DREB cDNA encodes a DNA binding protein that might function as a transcriptional activator in plants.

The ability of the DREB1A and DREB2A proteins expressed in *Escherichia coli* to bind the wild-type or mutated DRE sequences was examined using the gel retardation method.¹⁹ The results indicate that the binding of these two proteins to the DRE sequence is highly specific. To determine whether the DREB1A and DREB2A proteins are capable of transactivating DRE-dependent transcription in plant cells, we performed transactivation experiments using protoplasts prepared from *Arabidopsis* leaves. Coexpression of the DREB1A or DREB2A proteins transactivated the expression of the *GUS* reporter gene driven by the DRE sequence in *Arabidopsis* leaf protoplasts. These results suggest that the DREB1A and DREB2A proteins function as transcription activators involved in the cold- and dehydration-responsive expression, respectively, of the *rd29A* gene (Fig. 4).¹⁹

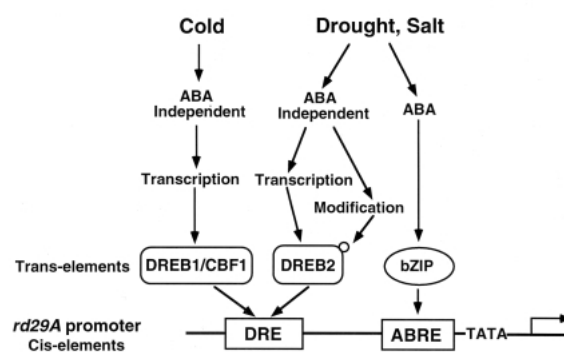

Fig. 4. A model of the induction of the *rd29A* gene and *cis*- and *trans*-acting elements involved in stress-responsive gene expression. Two *cis*-acting elements, DRE and ABRE, are involved in the ABA-independent and ABA-responsive induction of *rd29A*, respectively. Two types of different DRE binding proteins, DREB1 and DREB2, separate two different signal transduction pathways in response to cold and drought stresses, respectively. DREB1s/CBF1 are transcriptionally regulated whereas DREB2s are controlled post-translationally as well as transcriptionally. ABRE binding proteins encode bZIP transcription factors.

We isolated cDNA clones encoding two DREB1A homologs (named DREB1B and DREB1C).¹⁹ The DREB1B clone was identical to CBF1.²² We also isolated cDNA clones encoding a DREB2A homolog and named it DREB2B. Expression of the *DREB1A* gene and its two homologs was induced by low-temperature stress,²³ whereas expression of the *DREB2A* gene and its single homolog was induced by dehydration.²⁴ These results indicate that two independent families of DREB proteins, DREB1 and DREB2, function as *trans*-acting factors in two separate signal transduction pathways under low-temperature and dehydration conditions, respectively (Fig. 4).¹⁹

Analysis of the roles of DREB1A and DREB2A by using transgenic plants

We generated transgenic plants in which the DREB1A or DREB2A cDNAs were introduced to overproduce the DREB proteins to analyze the effects of overproduction of the DREB1A and DREB2A proteins on the expression of the target *rd29A* gene. *Arabidopsis* plants were transformed with vectors carrying fusions of the enhanced CaMV 35S promoter and the DREB1A (35S:DREB1A) or DREB2A (35S:DREB2A) cDNAs in the sense orientation.^{19, 25} All of the transgenic plants

carrying the 35S:DREB1A transgene (the 35S:DREB1A plants) showed growth-retardation phenotypes under normal growth conditions. The 35S:DREB1A plants showed variations in phenotypic changes in growth retardation that may have been due to the different levels of expression of the DREB1A transgenes for the position effect.¹⁹

To analyze whether overproduction of the DREB1A protein caused the expression of the target gene in unstressed plants, we compared the expression of the *rd29A* gene in control plants carrying pBI121 vector. Transcription of the *rd29A* gene was low in the unstressed wild-type plants but high in the unstressed 35S:DREB1A plants.¹⁹ The level of the *rd29A* transcripts under the unstressed control condition was found to depend on the level of the DREB1A transcripts.¹⁹ To analyze whether overproduction of the DREB1A protein caused the expression of other target genes, we evaluated the expression of its target stress-inducible genes. In the 35S:DREB1A plants the *kin1*, *cor6.6/kin2*, *cor15a*, *cor47/rd17* and *erd10* genes were expressed strongly under unstressed control conditions, as was the *rd29A* gene.^{6, 26, 27}

Recently we prepared a cDNA microarray using 1300 full-length *Arabidopsis* cDNAs to identify further target stress-inducible genes of DREB1A.²⁸ mRNA prepared from the 35S:DREB1A plants and wild-type control plants were used for the preparation of Cy3-labeled and Cy5-labeled cDNA probes, respectively. These cDNA probes regarded genes with expression levels more than two times greater in the 35S:DREB1A transgenic plants than in wild-type control plants as DREB1A target genes. In total, 12 DREB1A target genes were identified by cDNA microarray analysis. Among them, six were shown to be DREB1A target genes: *rd29A*, *kin1*, *cor6.6/kin2*, *cor15a*, *cor47/rd17* and *erd10*. Also, among the six novel DREB1A target genes that have not been shown as DREB1A target genes previously, we found cDNAs showing sequence identity with putative cold acclimation protein, DC1.2 homolog, enolase and cysteine proteinase inhibitor, and *erd4* cDNA. All these gene products probably function in stress tolerance in plant cells.

In contrast, the transgenic plants carrying the 35S:DREB2A transgene (the 35S:DREB2A plants) showed little phenotypic change. In the 35S:DREB2A transgenic plants, the *rd29A* mRNA did not accumulate significantly, although the *DREB2A* mRNA accumulated even under unstressed conditions.¹⁹ Expression of the DREB2A protein is not sufficient for the induction of the target stress-inducible gene. Modification, such as phosphorylation of the DREB2A protein, seems to be necessary for its function in response to dehydration (Fig. 4). However, DREB1 proteins can function without modification.

Drought, salt and freezing stress tolerance in transgenic plants

The tolerance to freezing and dehydration of the transgenic plant was analyzed using the 35S:DREB1A plants grown in pots at 2°C for 3 weeks. When plants were exposed to a temperature of -6°C for 2 days, returned to 22°C, and grown for 5 days, all of the wild-type plants died, whereas the 35S:DREB1A plants survived at high frequency.^{19, 27} Freezing tolerance was correlated with the level of expression of the stress-inducible genes under unstressed control conditions (Fig. 5; between 80 and 30%, survival).^{19, 27}

To test whether the introduction of the DREB1A gene enhances tolerance to dehydration stress, we did not water the plants for 2 weeks. Although all of the wild-type plants died within 2 weeks, between 70 and 20% of the 35S:DREB1A plants survived and continued to grow after rewatering. Drought tolerance was also dependent on the level of expression of the target genes in the 35S:DREB1A plants under unstressed conditions (Fig. 4).^{19, 27}

Overexpression of the DREB1A cDNA, driven by the constitutive 35S CaMV promoter in transgenic

Fig. 5. Freezing, drought and salt stress tolerance of the 35S:DREB1Ab, 35S:DREB1Ac and *rd29A*:DREB1Aa transgenic plants. The stress treatments were conducted as described in the text. control = 3-week-old plants growing under normal conditions; freezing = plants exposed to a temperature of -6°C for 2 days and returned to 22°C for 5 days; drought = water withheld for 2 weeks; high-salinity = plants soaked in 600 mM NaCl solution for 2 h and transferred to pots under normal growing conditions for 3 weeks.

plants, activated strong expression of the target stress-inducible genes under unstressed conditions, which, in turn, increased tolerance of freezing, salt and drought stresses.^{19, 27} Jaglo-Ottosen et al. reported that CBF1 overexpression also enhances freezing tolerance.²⁹ However, the overexpression of stress-inducible genes controlled by the DREB1A protein caused severe growth retardation under normal growth conditions.^{19, 27}

To resolve the problem of growth retardation, we used the stress-inducible *rd29A* promoter to cause overexpression of DREB1A in transgenic plants (*rd29A*:DREB1A plants).²⁷ Because the *rd29A* promoter was stress-inducible and contained binding sites for the DREB1A protein, it did not cause expression of the DREB1A transgene at high levels under unstressed conditions; instead, it rapidly amplified expression of the DREB1A transgene only under dehydration, salt, and low-temperature stress. The *rd29A*:DREB1A plants revealed strong stress tolerance even though their growth retardation under normal growing conditions was not significant. Moreover, the growth and the productivity of these plants were almost the same as those of the wild-type plants under normal growing conditions.²⁷

On the contrary, the *rd29A*:DREB1A transgenic plants are more tolerant to the stresses than the 35S:DREB1A plants that exhibited growth retardation under normal growing conditions (Fig. 5).²⁷ As the *rd29A* gene is one of the target genes of the DREB1A protein, the *rd29A* promoter is more suitable for the tissue specific expression of the DREB1A gene in plants than the 35S CaMV promoter. In the *rd29A*:DREB1A plants, the target gene products seem to be strongly accumulated in the same tissues that express the products under stress conditions. These results indicate that combination of the DREB1A cDNA with the *rd29A* promoter would be quite useful for improving drought, salt and freezing-stress tolerance in transgenic plants.

In previous studies, we showed that DRE also functions in gene expression in response to stress in tobacco plants^{17, 18}, which suggests the existence of similar regulatory systems in tobacco and other crop plants. DRE-related motifs have been reported in the promoter region of cold-inducible *Brassica napus* and wheat genes.^{30, 31} These observations suggest that both the DREB1A cDNA and the *rd29A* promoter can be used to improve the dehydration, salt and freezing tolerance of crops by gene transfer.

Conclusion

Molecular mechanisms of drought stress response and tolerance have been actively studied these ten years. Many genes that are regulated by drought stress have been reported in a variety of plants. Analyses of stress-inducible gene expression have revealed the presence of

multiple signal-transduction pathways between the perception of drought-stress signal and gene expression. At least four different transcription factors have been suggested to function in the regulation of dehydration-inducible genes; two are ABA-responsive and two are ABA-independent. This explains the complex stress response observed after exposure of plants to drought stress. Genetic analysis of *Arabidopsis* mutants with the *rd29A* promoter::Luciferase transgene also suggest complex signaling pathways in drought-, salt- and cold-stress responses.³² Some genes are rapidly induced by drought stress in 10 min whereas others are slowly induced in a few hours after the accumulation of endogenous ABA. Several genes for various transcription factors are induced by drought stress and ABA at transcriptional levels, which might be involved in the regulation of slowly expressed genes of which products functions in stress tolerance and adaptation. In addition, many genes for factors involved in the signal-transduction cascades, such as protein kinases and enzymes involved in PI turnover, are upregulated by drought stress signal.⁶ These signaling factors might be involved in the amplification of the stress signals and adaptation of plant cells to drought-stress conditions. Molecules that functions as osmosensors and ABA-receptors have not been identified. Based on the knowledge of osmosensors in yeast and bacteria, cloning of homologues of the two-component histidine kinase as an osmosensor is in progress in higher plants. Molecular analyses of these factors should provide a better understanding of the signal-transduction cascades during drought stress. Transgenic plants that modify the expression of these genes will give more information on the function of their gene products.

Sequence of *Arabidopsis* entire genome was completed by the end of 2000, which means that structures of all the 26,000 genes of *Arabidopsis* were determined.^{33, 34} All the stress-inducible genes will be identified by systematic analysis of gene expression. In the next decade, we think it important to develop novel methods to analyze complex networks of stress responses of higher plants. Reverse genetic approach as well as classical genetics will become more important to understand not only functions of stress-inducible genes but also complex signaling process in environmental stress responses. Efficient gene disruption methods as well as transgenic approaches using antisense or sense constructs also contribute for the precise understanding of molecular mechanisms of stress response.

Abstract

Plant growth, productivity and distribution are severely limited by environmental stresses including freezing, drought and salinity, all of which disturb the water balance of the cell. Plants have evolved different adaptive strategies to alleviate the adverse effects of these abiotic stresses. In plant cold acclimation exposure to moderate stress (such as low nonfreezing temperatures) or to other environmental cues (such as drought or changes in photoperiod) triggers stress acclimation pathways leading to an increase in freezing tolerance. We employ *Arabidopsis* as our model to explore the cold acclimation process that takes place during the growing season, typical to many temperate herbaceous species. This acclimation is associated with activation of several stress response regulons (including genes e.g. for dehydrins) and subsequent metabolic and physiological alterations required for the enhanced stress tolerance. Overexpression of some of the target genes of these regulons or metabolic engineering of biosynthesis of osmoprotectants, such as trehalose, has been shown to result in improved freezing and drought tolerance.

Elucidation of the signal pathways and components controlling the stress response regulons is one of the key areas plant stress research. A central theme in our research is to clarify how plants sense the environmental cues triggering cold acclimation and how these signals are transduced to the level of target gene expression. A number of interacting signal pathways appear to control the activation of the low temperature responsive genes, some of which are mediated through the action of the plant hormone ABA. Our recent work in *Arabidopsis* has been focused on characterization of selected candidate signal components including putative channel proteins and protein phosphatases. As one example antisense inhibition of *PP2CA* was shown to lead to accelerated cold acclimation indicating that this phosphatase is a negative regulator of the cold acclimation response. Such modulation of the key components of low temperature response pathways (regulon engineering) provides a way for improving plant stress tolerance. Another approach used for regulon engineering has been ectopic expression of the *ABI3* gene encoding a seed specific transcription factor, which also resulted in enhanced freezing tolerance. In conclusion understanding the molecular basis of plant cold acclimation response already provides several strategies to improve freezing tolerance in plants.

Keywords: stress tolerance, cold hardiness, abscisic acid, signal transduction, gene expression, Arabidopsis

Introduction

Plants are constantly exposed to, and need to survive, a changing and often unfavorable environment. This has led to the evolution of adaptive strategies that permit plant cells to sense environmental stimuli and to

activate responses that allow avoidance or survival of the environmental stresses encountered. One of the major environmental challenges to plant growth, productivity and distribution are stresses leading to cellular water deficit such as freezing, drought and high salinity (Boyer, 1982). Freezing stress is commonly

experienced by plants growing in temperate and boreal climates. Resistance or sensitivity to the stress depends on the species, the genotype, and the developmental age of the plant (Bray et al., 2000). Suboptimal temperature can cause serious damage to a number of plants. However, different plant species vary widely in their ability to tolerate low temperature stress (Levitt, 1980; Sakai and Larcher, 1987). Chilling-sensitive tropical species can be irreparably damaged when temperatures drop below 10°C while chilling tolerant but freezing sensitive species are readily damaged by subzero temperatures. Injuries are caused by impairments in cellular processes including alterations in membrane properties, interactions between macromolecules and enzymatic reactions. Freezing-sensitive tissues are damaged at subzero temperatures as a result of ice formation. In contrast, freezing-tolerant temperate plants are able to survive considerable extracellular freezing, e. g. fully acclimated herbaceous species can readily tolerate temperatures of -10 to -20°C. Freezing stress is a composite stress caused by the low temperature as such and mechanical stress due to ice formation in the tissues. On cellular level freezing stress is mainly due to freeze-induced cellular dehydration resulting in injuries in membranes (Steponkus et al., 1993) and linking freezing with other stresses (drought and high salinity) leading to cellular water deficit (Palva, 1994). However, other factors may contribute also to cellular damage during freezing stress. At low temperatures, protein denaturation may occur (Guy et al., 1998). Moreover, there is evidence that freezing stress can trigger the production of reactive oxygen species that play a role in generation of membrane damage (McKersie and Bowley, 1997). Plants can be exposed to freezing temperatures both during active growth as well as during overwintering. Overwintering woody plants as well as dormant seeds of many plant species exhibit extremes of low temperature survival, e.g. fully acclimated birch tissue can tolerate liquid nitrogen temperature.

Cold acclimation

Plants need to adjust to both daily and seasonal fluctuations in temperature. Seasonal acclimation is operational in overwintering herbs and in woody plants. In woody species, acclimation is a two-step process where the first phase of acclimation is triggered by shortening of the photoperiod and the second by low temperature. In both annual and in most overwintering herbaceous plants, freezing tolerance is not affected by the photoperiod but acclimation is mainly triggered by low nonfreezing temperatures. Cold acclimation is a rather rapid process in many herbaceous species. A substantial increase in freezing tolerance of e.g.

Arabidopsis can be achieved already after one-day exposure to low temperature although full acclimation requires more than a week. Upon return to normal growth temperatures, freezing tolerance is rapidly lost (Palva, 1994; Thomashow, 1999). In addition to low non-freezing temperatures, cold acclimation can be triggered by exposing the plants to moderate water stress or exogenously applied abscisic acid (ABA) (Lång et al., 1989; Guy et al., 1992; Mäntylä et al., 1995).

Cold acclimation is associated with several physiological and biochemical alterations in the plants. The best-characterized changes include alterations in gene expression, changes in hormone levels, increases in soluble sugars, amino acids and organic acids, accumulation of osmoprotectants and protective proteins as well as modification of membrane lipid composition (for reviews, see Palva, 1994; Hughes and Dunn, 1996; Palva and Heino, 1997; Thomashow, 1999). Although the causal relationship of many of these changes to increased freezing tolerance is still unclear, some of the genes and regulons involved in cold acclimation are being unraveled (Thomashow, 1999; Nuotio et al., 2001).

Already in 1985 it was demonstrated that cold acclimation is correlated with changes in translatable mRNA populations. Subsequently, a great number of cold-induced genes has been isolated and characterized from a variety of plant species, (for reviews see Palva, 1994; Hughes and Dunn 1996; Thomashow 1998). Some of these genes code for proteins whose biochemical function is known or at least can be predicted based on sequence homology. Among these are fatty acid desaturases, chaperones, lipid transfer proteins, proteins involved in osmoprotectant biosynthesis, antifreeze proteins and signal transduction components, such as transcription factors, kinases and phosphatases (Hughes and Dunn 1996; Thomashow 1998; Nuotio et al., 2001). However, for many of the low temperature induced/cold regulated (*LTI/COR*) gene products, there is no known function. In many cases, however, related genes have been found in different plant species, indicating that the proteins induced by low temperature are conserved.

One of the most common categories of genes induced by low temperature encode dehydrins (*dehydration induced*), also called LEA (*late embryogenesis abundant*) proteins in a wide range of higher plants. Indeed, there is evidence that they exist in all of photosynthetic organisms (Close 1997). Most dehydrin genes are induced in response to any environmental influence that has a dehydration component (such as drought, low temperature or salinity), by ABA or during the late stages of embryogenesis. The dehydrins are hydrophilic and remain soluble after boiling. They are characterised by one or more copies of a lysine rich repeat (the K

segment) EKKGIMDKIKEKLPG, which has been proposed to form an amphipathic (-helix (Dure 1993; Close 1997). Many dehydrins also contain other conserved motifs such as a run of serine residues (S-repeat) or the Y segment (Close 1997). Even though the exact function of these proteins has not been established, their biochemical properties and accumulation patterns suggest that the dehydrins could stabilize cellular structures during dehydration stress (Close 1997; Nylander et al., 2001b). There are about 10 dehydrin genes in the genome of *Arabidopsis* suggesting that dehydrins constitute a redundant family of proteins.

Although great progress has been achieved in understanding the molecular basis for plant cold acclimation during the last decade, the complexity of the systems hampers genetic engineering of plant freezing tolerance. As discussed above, little is known about the exact function of many of the proteins encoded by the low temperature induced genes. It is, therefore, essential to elucidate the function and contribution of these genes and gene products in tolerance before a general strategy for engineering plants with increased frost tolerance is available. Several transgenic plant lines overexpressing different low temperature responsive genes have been created, but only a marginal effect on freezing tolerance has been demonstrated (Artus et al., 1996; McKersie and Bowley, 1997; Puhakainen et al., unpublished). Similar results have been obtained in studies of water stress tolerance. Thus, this type of target gene engineering has not been very fruitful in engineering plant freezing tolerance. The approach is most likely hampered by the redundancy of the system, where an individual gene product has only a minor contribution to the overall tolerance. Thus this approach would require pyramiding a number of target genes providing additive effects on tolerance.

In contrast to the limited success achieved by target gene engineering, metabolic engineering of osmoprotectants appears to be of more promise in improving plant stress tolerance. Induction of osmoprotectants biosynthesis is part of the plant response to both drought and low temperature. There are now a number of examples in which increased drought tolerance was obtained by introducing simple metabolic traits from other organisms such as production of trehalose or glycine betaine (see e. g. Holmström et al., 1996; Holmström et al., 2000) to plants. In addition to their effect on drought tolerance osmoprotectants appear also to enhance freezing tolerance in plants. Recent data from our laboratory suggest that transgenic *Arabidopsis* lines producing trehalose exhibit increased tolerance to freezing temperatures both in cold acclimated and in nonacclimated plants (Tamminen et al., unpublished).

Signal transduction in cold acclimation

In order to respond to low temperature, plants have to perceive the stress, transduce the signal to the nucleus, and activate specific gene expression. The exact mechanisms by which this occurs are not clear, even though different components involved in the process have been characterized. The emerging insight is that this mechanism is complex, consisting of several distinct signal pathways that may interact with each other (Thomashow, 1999; Shinozaki and Yamaguchi-Shinozaki, 2000; Nuotio et al., 2001; Zhu, 2001). Moreover, it is likely that the low temperature signal pathways are converging and interacting with other stress-induced pathways, such as those mediating dehydration and abscisic acid responses (Ishitani et al., 1997). Our earlier work established the presence of ABA-independent and ABA-mediated pathways in low temperature signaling (Nordin et al., 1991; 1993) and also underlined the requirement for ABA in cold acclimation. Several lines of evidence indicate the role of ABA-controlled processes in cold acclimation: (i) Exogenous application of ABA at normal growth temperature leads to increased freezing tolerance (Chen et al., 1983; Lång et al., 1989). (ii) There is a transient increase in endogenous ABA at the onset of acclimation (Lång et al., 1994). (iii) Several low temperature induced genes are also responsive to ABA (Palva 1994). (iv) Both ABA-deficient and ABA-insensitive *Arabidopsis* mutants are impaired in cold acclimation (Heino et al., 1990; Mäntylä et al., 1995).

The nature of the primary sensor of low temperature is still a puzzle. Murata and Los (1997) suggested that a primary signal might be the change in membrane fluidity, which is one of the most rapid effects of temperature on the plasma membrane. The mechanisms by which reduction in membrane fluidity would lead to gene activation are not understood. Murata and Los (1997) have proposed the relationship between membrane fluidity and calcium channel activity at low temperature, but so far no such mediator has been detected. However, a clear correlation between temperature and calcium influx to the cells has been demonstrated in *Arabidopsis* (Nordin-Henriksson, personal communication) suggesting that a temperature modulated Ca^{2+} channel could indeed be involved in the temperature sensing. Mechanosensitive calcium channels exhibiting temperature dependent modulation have been identified in plants and they might be involved in low temperature sensing (Ding and Pickard, 1993). Further evidence for the role of the plasma membrane fluidity in cold sensing has come from experiments in alfalfa and Brassica (Örvar et al., 2000; Sangwan et al., 2001), where chemical agents were used to modulate membrane fluidity. Membrane fluidization during cold treatment inhibited the induction of cold

inducible genes and the development of freezing tolerance, whereas membrane rigidification at 25°C activated these genes and led to an increased freezing tolerance. The effects on gene expression were apparently mediated by reorganization of cytoskeleton and a following calcium influx.

Another type of temperature sensor has been proposed in cyanobacteria. There is recent evidence for the involvement of two-component systems in low temperature perception in *Synechocystis*. Two membrane associated histidine sensor kinases were recently identified whose inactivation was shown to result in a reduction of transcription of several low temperature inducible genes (Suzuki et al., 2000). Whether this type of sensor is operational also in plants remains to be determined.

The transduction of the signal generated by calcium influx is apparently transmitted through phosphorylation and dephosphorylation of proteins by kinases and phosphatases, respectively. Inhibitors of protein kinases can block induction of some low temperature responsive genes and development of freezing tolerance both in alfalfa and Arabidopsis (Tähtiharju et al., 1997). Moreover, freezing tolerance is induced at 25°C by a protein phosphatase inhibitor (Monroy et al., 1993). The presence of low temperature induced calcium-dependent protein kinases (CDPKs) in Arabidopsis (Tähtiharju et al., 1997) and alfalfa (Monroy and Dhindsa 1995), and the fact that their inhibition prevents cold acclimation (Monroy et al., 1993) supports the connection between changes in cytosolic calcium levels and protein phosphorylation. Specific CDPKs have also been connected to the regulation of gene expression in response to ABA, drought, cold and salinity (Sheen 1996). In addition to CDPKs, several other protein kinases have been proposed to play a role in cold signal transduction. Evidence supports the involvement of a mitogen-activated protein (MAP) kinase cascade in low temperature signal transduction.

How do these signals lead to activation of the low temperature responsive genes? We originally suggested the identity of a low temperature responsive element (LTRE) in the *LTI78* promoter (Nordin et al., 1993). The presence of this element was subsequently demonstrated by deletion analysis and it was shown that the 9-bp element, TACCGACAT, confers responsiveness to low temperature, drought and high salinity, but not to ABA (Yamaguchi-Shinozaki and Shinozaki 1994). This low-temperature and dehydration-responsive element (LTRE/DRE) occurs also in several other promoters and has also been referred to as the C-repeat (CRT) (Baker et al., 1994). A small family of proteins called CBF1, CBF2 and CBF3 (CRT binding factor) or DREB1B, DREB1C and DREB1A (DRE-binding protein), respectively, activate the expression of genes carrying the DRE/CRT/LTRE element (Stockinger et al., 1997;

Liu et al., 1998; Gilmour et al., 1998; Shinwari et al., 1998). Overexpression of *CBF1/DREB1B* or *CBF3/DREB1A* leads to the constitutive expression of genes with promoters containing the DRE/CRT/LTRE element and to improved freezing, drought and salt tolerance of non-acclimated plants (Jaglo-Ottosen et al., 1998; Kasuga et al., 1999). In addition, the overexpression of CBF3 leads to elevated levels of proline and sugars that are normally associated with cold acclimation (Gilmour et al., 2000). In conclusion, the DRE-containing CBF/DREB controlled genes constitute a low temperature responsive regulon that is ABA independent.

However, low temperature responsive genes without this *cis*-acting DRE/CRT/LTRE element in their promoters do exist, e.g. the Arabidopsis *LTI6/RCI2A* gene (Nylander et al., 2001a), indicating that also other elements confer cold responsiveness. Furthermore, most of the low temperature responsive genes are also induced by exogenous ABA. Consequently, their promoters should contain *cis*-elements mediating this response. Indeed, sequences closely resembling ABA response elements (ABREs) exist in these promoters. The ABREs have been shown to confer ABA-regulated expression of many genes when present in more than one copy (Guiltinan et al., 1990; Leung and Giraudat 1998). The consensus sequence in ABREs is the motif (C/T)ACGTGGC.

Several proteins that can specifically bind to ABREs have been reported (e.g. Guiltinan et al., 1990). They contain the basic domain/leucine zipper (bZIP) motif found in many transcription factors. Two bZIP proteins that bind specifically to the ABRE elements required in the dehydration and ABA induction of the Arabidopsis *RD29B(LTI65)* gene were recently characterized (Uno et al., 2000). These genes, encoding AREB1 and AREB2 (ABA-responsive element binding protein) are drought, salt and ABA responsive. The AREB proteins can function as transcription factors, and they need ABA for their activation. In another study a small family of ABRE binding factors (ABFs) was characterized, also from Arabidopsis (Choi et al., 2000). One of these ABF proteins corresponds to AREB2 and the others are highly homologous to AREBs. *ABFs* respond differently to various environmental stresses including low temperature, suggesting that they act in different stress-responsive pathways. Further studies of the putative role of *ABF1* in activating low temperature induced genes whose promoters contain ABREs will bring interesting knowledge about the role of ABA in cold acclimation.

The ABA-mediated signal pathway leading to expression of low temperature induced genes appears to encompass similar second messengers and signal components as described above for the ABA-independent pathway. The initial steps of temperature

sensing might be shared by both pathways, although this needs to be demonstrated. Perception of the low temperature stimulus leads to a transient increase in ABA (Lång et al., 1994), which in turn triggers downstream events leading to target gene expression. Calcium is apparently used as a second messenger also downstream of ABA through cADPR controlled release from intracellular stores (Møller and Chua 1999). Both protein kinases and phosphatases have been implicated in these events by biochemical and molecular (Møller and Chua 1999; Sheen 1996) as well as genetic studies using ABA-insensitive mutants (Nordin et al., 1993; Lång and Palva, 1992). The latter studies showed that ABA induced expression of several cold responsive target genes was blocked in dominant negative *abi1* phosphatase 2C mutants (Nordin et al., 1993; Lång and Palva, 1992). Furthermore, these mutants were impaired in their freezing tolerance development (Mäntylä et al., 1995). Our recent studies have underlined the importance of protein phosphatases in cold acclimation. Antisense inhibition of the gene for protein phosphatase 2CA (PP2CA) was shown to accelerate the cold acclimation response and sensitize the cell to ABA (Tähtiharju and Palva, 2001). This suggests that PP2CA is a repressor of the ABA-mediated low temperature-signaling pathway.

Regulon engineering of freezing tolerance

As discussed above some success in improving plant freezing tolerance has been achieved by overexpression of target genes and metabolic engineering of osmoprotectants biosynthesis. A completely different strategy to enhance plant stress tolerance involves manipulation of the signal transduction pathways leading to activation of stress responsive genes. Expression of a big cluster of genes controlled by the same regulatory pathway is expected to have greater effect on freezing tolerance than expression of an individual gene. Such regulon engineering was recently achieved (Jaglo-Ottosen et al., 1998; Kasuga et al., 1999) by overexpression of the CBF/DREB transcriptional activator. This overexpression activated several cold-responsive genes and, more importantly, increased the freezing tolerance of nonacclimated *Arabidopsis* plants. Thus, a low temperature response was obtained without low temperature stimulus. Although the approach was used to modulate freezing tolerance in a plant fully capable of cold acclimation, it might be also extended to plants normally sensitive to freezing.

Other signal components can be also used for this type of approach. As discussed above antisense inhibition of the gene for a repressor, PP2CA of the ABA-mediated low temperature-signal pathway leads to an accelerated cold acclimation response in

Arabidopsis. A similar strategy could be used to enhance cold acclimation in crop plants.

Many plants have the genetic potential for low temperature and desiccation tolerance, as indicated by the ability of seeds to survive these stresses. The genes responsible for this tolerance are normally under strict developmental control and expressed only during embryo maturation. However, ectopic expression of seed-specific genes may confer to vegetative tissues the ability to accumulate seed-specific transcripts and influence responses in vegetative tissues, as shown by ectopic expression of the *ABI3* gene in *Arabidopsis* (Parcy and Giraudat, 1997). We could recently demonstrate that such *ABI3* transgenic *Arabidopsis* plants exhibited enhanced freezing tolerance (Tamminen et al., 2001). Both the low temperature and ABA induced development of freezing tolerance was clearly improved in these plants.

Conclusions

Recent years have evidenced tremendous progress in plant cold acclimation research. Although the biological processes leading to cold acclimation and the mechanisms of freezing tolerance are only partially understood, several key components of cold acclimation have been recently identified. In particular, elucidation of the signal transduction pathways and identification of the regulators required for expression of the cold responsive genes has progressed rapidly. These studies have already opened new avenues to improve freezing and drought stress tolerance in crop plants.
